Breeding. Apparently breeds mainly during austral spring and summer, probably in all months Jul-Feb, depending on local conditions; also recorded in May, in Brazil; males with enlarged testes late Mar in Mendoza, WC Argentina; pairing may begin as early as middle to late winter. Monogamous; semi-colonial, with small groups of 5-6 nests often found in area of 1-1·5 ha, but no proof of polyandry. Simple ground nest of grasses and reed stems; situated in swamp, where often surrounded by water, or in dense vegetation in wet meadow, at edge of stream or open water, including estuaries. Usually 2 eggs, exceptionally 3; incubation and fledging periods unknown; chicks apparently cared for by both adults.

Movements. Mainly sedentary. Apparently regular seasonal movements recorded in some areas, e.g. in parts of Brazil and in Buenos Aires area, Argentina; regarded as non-breeding migrant to S Río Negro and N Chubut, C Argentina. Makes short distance movements in response to local conditions of drought or flooding, abandoning areas as soon as they become too dry. Largely solitary or in pairs, but outside breeding season may form small, dispersed flocks, of under 10 birds.

Status and Conservation. Not globally threatened. No precise information available on population levels or trends; secretive and nocturnal habits make species difficult to detect. Regarded as very local in Chile. Apparently not uncommon and even locally frequent in parts of C Argentina during 1970's. In Brazil, recorded only once prior to 1961, when discovered in state of Rio de Janeiro. In Argentina and Brazil, habitat alteration and destruction, often related to agricultural development, have caused declines in many birds of dry grasslands, and species of wet grasslands, such as present species, might be similarly affected. Species highly prized by hunters for its succulent flesh; frequently shot during breeding season, as tends to nest early, before local hunting seasons terminate.

Class AVES

Order CHARADRIIFORMES

Suborder CHARADRII

Family DROMADIDAE (CRAB PLOVER)

- Medium-sized, long-legged wading birds with thick, powerful bill and burrow-nesting habits.
- 38-41 cm.

- Indian Ocean coasts.
- Coastal sandbanks and tidal mudflats, sandflats and coral reefs.
- 1 genus, 1 species, 1 taxon.
- No species threatened; none extinct since 1600.

Systematics

The Crab Plover (*Dromas ardeola*) is a monotypic species found only on coasts of the Indian Ocean. Its relationship with other Charadriiformes is none too clear, but it is generally considered distinct enough to be awarded a family of its own, Dromadidae.

Although its evolutionary affinities are uncertain, the Crab Plover is usually classified as a wader. Frequently, because of similarities in skeletal characters and body shape, it is placed closest to the thick-knees (Burhinidae) or between the thick-knees and the pratincoles and coursers (Glareolidae); indeed, the results of studies using DNA suggest that it should actually be placed within Glareolidae, with only subfamily status. Then again, in plumage it closely resembles avocets (Recurvirostridae), although in terms of structure and behaviour it is quite different from them.

Some workers believe that the Crab Plover belongs elsewhere within the Charadriiformes. For instance, it is sometimes argued that it is most closely related to the auks (Alcidae), an idea originating from its burrow-nesting habit. Again, the Crab Plover's tarsal scutellation and also the countershaded, but unpatterned, grey down of its chicks are uncharacteristic of waders (Charadrii), and it has been suggested that the species may actually be more closely related to the gulls (Laridae).

With so many divergent opinions in vogue, it is probably most useful to stick to traditional usage for the mean time. A study of the patterns of downy chicks, published in 1968 by J. R. Jehl, proposed the division of all of the waders (Charadrii) into three groups, which may be recognized as superfamilies: the jacanas and painted-snipes (possible superfamily Jacanoidea); the Crab Plover (Dromadoidea); and all the remaining families in the suborder Charadrii (Charadrioidea). This division, which highlights the uniqueness of Dromadidae by awarding it a group or superfamily of its own, has received widespread acceptance and may be considered more or less the "standard" internal classification of the suborder Charadrii.

Morphological Aspects

The Crab Plover is a robust and highly distinctive black and white wader with a disproportionately heavy bill and head, and long legs. Its most conspicuous feature is the thick, relatively short, dagger-like bill, which is used for stabbing and breaking open crab shells. This large, black, laterally compressed bill has a pronounced gonys and an angled lower mandible, and is quite unlike that of any other wader, except perhaps those of the Great Thick-knee (*Esacus recurvirostris*) and the Beach Thick-knee (*Esacus magnirostris*). It may be no coincidence that these latter two species also feed extensively, perhaps almost exclusively, on crabs.

The plumage of the adult Crab Plover is predominantly white, with an obvious black saddle and flight-feathers, and a pale grey tail. In juveniles, the back and the lesser and median wing-coverts are grey, while the crown and hindneck are pale grey with darker streaks and spots. Some adults of both sexes also have darker streaks on the rear of the crown and the hindneck; it has been suggested that these variations are seasonal. In the field, males and females appear identical, the only known difference being that males tend to have slightly longer and heavier bills than females.

The Crab Plover's eye is large, presumably because of the species' crepuscular and nocturnal habits (see General Habits). Its size is emphasized further by black feathering immediately before and behind it. This combines with the down-turned gape of the large bill to give the Crab Plover a rather sad expression.

The legs are greyish blue, and the feet are similar in colour but a little darker. The powerful feet are partially webbed and have a well developed first toe, features which are probably connected with the species' habit of excavating nesting burrows. When walking, Crab Plovers tend to move slowly with a gait similar to that of *Charadrius* plovers. When pursuing crabs and other crustaceans, they adopt a more rapid, dashing walk, similar to that of avocets. During periods of inactivity, Crab Plovers regularly stand with their shoulders hunched, or rest squatting on their tarsi.

The Crab Plover's flight is perhaps slower than that of most other waders, and the wings are held quite stiffly, rather in the style of a thick-knee. In flight, the legs and feet extend beyond the tail, and the head and neck may be either sunk back into the shoulders or extended.

Habitat

A bird of subtropical and tropical Indian Ocean shorelines, the Crab Plover is rarely found more than a kilometre or so from the

sea. Its foraging habits restrict it at all times of year to mudflats and sandflats, sandy beaches, estuaries, lagoons and exposed coral reefs. Roosting occurs in the vicinity, for instance typically on sand spits in Aldabra.

For breeding, the species is confined to coastlines and offshore islands with relatively flat expanses of sand dunes, sand banks or sandy warrens. This restriction in breeding habitat ties in closely with the fact that, unique among waders, it nests in burrows (see Breeding).

General Habits

Crab Plovers are highly gregarious and noisy, whether breeding, on passage or at their wintering grounds. The species nests colonially in burrows (see Breeding), and this gives rise to a number of differences with other waders in terms of breeding biology and behaviour. For example, young Crab Plovers remain in the nest for several days after hatching, and food is brought to them by the adults.

When feeding, Crab Plovers can be seen in large flocks, and over 1000 have been seen together at non-breeding grounds in the Providence Group of Aldabra. Birds most often split up into small groups of 20 or more birds, although some individuals forage alone. When the tide is high, flocks concentrate from far around to roost communally, and birds within a radius of as much as 20 km may gather at traditional sites. In the Gulf of Kutch, up to 1200 birds have been recorded at a traditional roost-site on Bhaidar Island.

Both during and outside the breeding season, birds are most active at dusk and at night, but they also feed during the day. Crepuscular and nocturnal behaviour may be more accentuated during the breeding season, though it may cease on dark nights.

Voice

Crab Plovers are noisy, raucous birds. On the breeding grounds a constant chattering "tchuck-tchuck" can be heard, often well into the night. A shriller call, "tchuck-tchuck chuk-chuk-chuk", is given less frequently, but this call can carry up to 1·5 km. When a bird enters its nesting burrow at dawn, it will usually utter a rapid series of short and long notes, and, if disturbed by intruders, an incubating bird will hiss.

Outside the breeding season, Crab Plover flocks maintain a regular restless chattering, interspersed with far-carrying "ha-how" or "crow-ow-ow" notes and a musical "prooit". When alarmed, birds emit a loud sharp "kjep" or "kiep", repeated four or five times.

The calls of downy chicks resemble those of domestic hens. Half-grown young solicit food from their parents with a constant wheeze, resembling that produced by the young of *Larus* gulls. On migration and on their wintering grounds, young birds will beg for food from adults with a high, plaintive, twittering whistle, which rises in pitch.

Food and Feeding

As the bird's name suggests, crabs constitute the major component of the Crab Plover's diet. At any rate on Aldabra, and perhaps elsewhere, those crab species that burrow are particularly favoured. They are stalked and caught with a stab of the bill, and, if small, are swallowed whole. Larger crabs are shaken to dismember them of both claws and legs, and they are then broken into pieces by blows from the bird's powerful bill, before finally being consumed. Other crustaceans, small molluscs, marine worms and other intertidal invertebrates are also eaten, and

Even in flight, there are certain features that readily betray the identity of the Crab Plover, preventing confusion with any other waders of pied plumage. The massive bill, the conspicuously white head and neck and the long, pointed wings are all obvious. The white "V" on the lower back stands out against the black saddle, and the mostly black flight-feathers contrast strongly with the white wing lining. The length of the neck is not always apparent as it is often held hunched up into the shoulders. The wings are held rather stiffly and, as in avocets, the legs and toes trail well beyond the end of the short tail. Flight tends not to be as fast as in most other waders.

[*Dromas ardeola*, Malindi, Kenya. Photo: Paul Doherty/ Windrush Photos]

This sturdy, long-legged wader's most obvious peculiarity is its huge black bill, splendidly adapted for dealing with its main prey, crabs. These are either stabbed and swallowed whole, or are crushed first, all according to the size of the crab. The bird's head is also large, as are its eyes, the size of the latter being emphasized by dark smudges on both sides. In contrast, the neck is scarcely visible when the bird stands at rest with its shoulders hunched. The long, robust bluish grey legs have powerful partially webbed feet, effective tools when used in conjunction with the bill to excavate nesting burrows in sand dunes.

[*Dromas ardeola*, Barr al Hikman, Oman. Photo: Hanne & Jens Eriksen/Aquila]

the species has been seen feeding on mantis shrimps in the Andaman Islands and on mudskippers in Iraq.

Feeding is usually a restless, noisy and gregarious activity for Crab Plovers, which often gather in sizeable flocks to forage on mudflats, sandflats and exposed coral reefs, or elsewhere in shallow water. Flock members walk slowly in the same direction, often with a space of about two to five metres between individual birds. When a crab is spotted, a stalking bird advances rapidly in a short run, its partially webbed feet allowing it to move quickly even over silty mud. Prey items on the surface or in shallow water are stabbed with the bill, which may be held open during such strikes. Crab Plovers will also probe the substrate on occasion.

Young downy chicks are fed by their parents on pulped crab which has been brought back to the nest-burrow; older chicks are given whole live crabs to deal with.

Breeding

The Crab Plover is a colonial breeder, nesting at a small number of scattered coastal colonies. The largest colony for which an estimate of numbers has been made supports 1500 pairs, but most of the known colonies are considerably smaller. In and around the Arabian Peninsula, the breeding season begins in April and ends in June or July, with the first young seen in May and June. In Somalia, egg-laying does not take place until May or June.

It is assumed, but not known, that Crab Plovers are monogamous. Certainly, post-breeding behaviour is exhibited by groups of two adults and one juvenile, which arrive together on some wintering grounds and which are assumed to be family parties. However, groups of up to ten birds may attend nest-burrows; the precise implications of this are uncertain, but at the very least it would seem to indicate that pairs may nest in very close proximity to one another.

Unique among waders, the Crab Plover nests in burrows. These are excavated, probably by both male and female, in relatively flat coastal sand dunes and other sandy substrates. The bird probably loosens the substrate with its bill, and then scratches the sand out using its powerful feet. Completed burrows are about 1 to 2·5 m long, about 20 cm in diameter, and slope downwards obliquely to a depth of about 50 cm. At this deepest point, the burrow rises slightly and opens out to form a chamber, in which a shallow, unlined hollow is created for the egg. Burrows may change direction several times along their length and it is possible that they are reused and extended in successive breeding seasons.

This habit of burrow-nesting is most likely to have originated as a mechanism for reducing nest predation. It is also postulated that, since the downy young are countershaded but unpatterned, the use of burrows may be a fairly recent adaptation for avoiding intense solar radiation. Indeed, if a chick is exposed to sunlight it instantly runs for shade.

The clutch almost always consists of a single egg, though occasionally two are laid. The egg itself is very large for the size of the bird, being 60-65 mm long and 43-47 mm wide, and weighing an estimated 45 g. Unlike the eggs of other wader species, which tend to be cryptically patterned, the Crab Plover's egg is pure white, a clear consequence of its burrow-nesting habit, which obviates the need for camouflaging the egg. The roles of sexes during incubation and chick rearing are not known, but eight adults that were collected from nests were all females. The presence of what are assumed to be family parties later in the year may suggest that both parents remain together throughout the breeding cycle and beyond.

Upon hatching, the young are unable to walk, and, again unlike any other waders, they remain in their nests for several

days where they are dependent on the adults to bring them food. Older chicks may venture out to the burrow entrance to beg for food. Even when capable of leaving the burrow, young birds often remain there, and, once they have finally abandoned the nest, they still depend heavily on the adults for food. Frequent, persistent and sometimes indiscriminate begging for food by juveniles continues on the wintering grounds.

Movements

The Crab Plover is at least a partial migrant, and all individuals may well leave their breeding areas outside the breeding season. However, so little is known about the exact breeding range of the species that the full extent of its migration remains unclear.

It is thought that in August, after the breeding season, many adults and young move out of the Persian Gulf. These birds are thought to move southwards down the east coast of Africa or across the Indian Ocean. However, not all the birds move so far, and in the United Arab Emirates birds that breed in the colony on the island of Abu al Abyadh are thought to winter only about 250 km away at Khor al Beidah. The species is probably a passage migrant and winter visitor to southern Arabia. However, it has been recorded in all months of the year from Yemen, and it may breed on offshore islands in southern parts of the Red Sea, as indeed it does further north, off the Saudi Arabian coast.

In Africa, breeding has only been confirmed off Somalia, where the species is common from March to October. Nevertheless, the species is also suspected of breeding in Sudan and Eritrea. From September through until April, Crab Plovers are widespread along the coasts of Kenya and Tanzania, including Zanzibar, and also to a lesser extent those of Madagascar and the Seychelles; a few travel as far south as Natal. Small numbers remain throughout the northern summer on wintering grounds in the Indian Ocean, especially on Aldabra and down the East African coasts.

Lesser numbers of birds have been recorded moving along the coast of Pakistan after the breeding season, but a large concentration has been found to occur in winter nearby in the Gulf of Kutch. Crab Plovers also winter east to Sri Lanka and the Andaman Islands.

Little is known about how the birds migrate, but the limited evidence available suggests that they do so in flocks, flying low and fast over the water in tight formations, usually at night.

Relationship with Man

The coastal habitat requirements, especially the isolated sandy areas used for breeding, combined with the crepuscular and nocturnal habits of the Crab Plover, serve to ensure that the species has relatively little contact with man. A direct consequence of this is that the effects of human interference appear to be of minimal importance to this species (see Status and Conservation).

Crab Plovers are not shy, especially once they become more active towards dusk. One extraordinary story illustrates their boldness. When four individuals were shot by a collector from amongst a flock of 400, the remaining birds waded into the water and crowded round the corpses, pushing them along in the water and chattering loudly. Once the dead birds were retrieved, the flock followed the collector back onto dry land. Several other similar incidents have been reported.

Status and Conservation

The Crab Plover is endemic to the coastlines of the Indian Ocean region. The number of breeding colonies known is small, and they are situated in remote and isolated places. Consequently, little is known about population sizes, and even less about changes in numbers through time. Nevertheless, the Crab Plover is clearly sufficiently abundant to be at no immediate risk of global extinction. This said, if any of the large, densely packed breeding colonies were to be wiped out or severely threatened, the fortunes of the species might change dramatically.

The most comprehensive and thorough survey of sites important for the conservation of avifauna in the Middle East was carried out by BirdLife International and the Ornithological Society of the Middle East, in co-operation with the International Waterfowl and Wetlands Research Bureau between 1991 and 1994. The study highlighted the importance of the region for Crab Plovers.

In the non-breeding season the Crab Plover does occur singly on occasions, but it is essentially gregarious in all seasons. It forms large breeding colonies with the nest-burrows packed closely together; one colony is known to contain 1500 pairs, although most are much smaller. When feeding too it can be seen in large flocks which may disband into smaller groups to forage. Huge noisy gatherings are common on traditional roosting sites at high tide in winter.

[*Dromas ardeola*, Khor al Beidah, United Arab Emirates. Photo: Axel Halley]

The Crab Plover has highly unusual breeding habits. Alone among waders it excavates a nesting burrow, up to 2·5 m long with the nesting chamber at the end, where the single large pure white egg is laid. The chicks are altricial, unable to walk at hatching, and, unlike other wader young, they stay at the nest, in this case the burrow, for several days. They remain wholly dependent on their parents for food for a long time, and even in their winter quarters they may be observed begging insistently for food.

[*Dromas ardeola*, Barr al Hikman, Oman. Photo: Hanne & Jens Eriksen/Aquila]

Of the 391 sites identified as Important Bird Areas, 30 are of conservation value to Crab Plovers. These include all the known breeding colonies, apart from the one off the coast of Somalia.

Only nine breeding colonies are definitely known to exist, eight of which are in the Middle East. The largest is in Iran, with approximately 1500 pairs nesting on Ummal Karan Island, where the birds appear to be unprotected but not threatened. Also in Iran are two much smaller colonies, of 20 and two or more pairs, both of which fall within protected areas. At the southern end of the Persian Gulf, the United Arab Emirates supports two colonies: one, on Abu al Abyadh Island, supports about 280 pairs and is protected by the island's owner; the second is a smaller colony of 35-38 pairs at Umm Amin. Masirah Island, off Oman, has one colony of about 85 pairs, and may suffer low levels of exploitation. In Saudi Arabia there are two breeding colonies along the Red Sea coast at Al Wajh Bank, and in the Farasan Islands, where approximately 110 pairs nest; there may be a third colony at Qishran Bay. In Yemen, breeding is suspected at four different sites, but confirmation is still required. The species now appears to be present all year round in Kuwait and Iraq, but it is not thought to breed there. The only known breeding population outside the Middle East occurs on the islets of Zeyla Saad Din and Aibat, off Somalia, but the numbers present are not known. Breeding is also suspected on the coasts of Sudan and Eritrea.

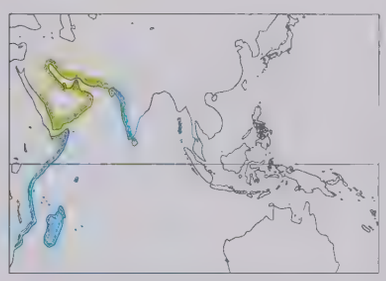
The non-breeding distribution is much wider with birds turning up sporadically as far east as Thailand and Malaysia, north to the Mediterranean coast of Turkey and south to Natal. In India, one individual was recorded 100 km inland from the sea. Mostly, however, Crab Plovers remain on the coasts between southern Arabia, Madagascar and India; they are most numerous along the Kenyan and Tanzanian coastlines.

No threats to the Crab Plover are currently known to exist. The Persian Gulf suffers chronic oil pollution, especially at its north-western end, as, to a lesser extent, does the Red Sea. This could directly affect Crab Plovers foraging on polluted coastlines, and could have an indirect and possibly more damaging long-term effect on their food supply. However, data following the 1990/91 Gulf War suggest that the consequent oil pollution had only a minimal impact upon this species. In Kuwait, for example, during studies of the effects of oil pollution on waders, out of 35 Crab Plovers observed only four were oiled, and only one of these showed heavy oiling likely to result in death. Farther south along the Saudi Arabian coastline during the 1991 spring and autumn migration periods, no evidence of oiled Crab Plovers was found, even though oil pollution was much more severe, and other species of waders were suffering considerable losses.

The most likely potential threat to Crab Plovers is the destruction of breeding colonies. Considerable exploitation of both birds and eggs was reported from the breeding colonies of Iraq at the beginning of the present century. Up-to-date information of human impact on these populations is lacking, but recent data from breeding populations in Oman, the United Arab Emirates and Saudi Arabia show little evidence of human persecution. Indeed, significant exploitation is unlikely, given that these areas are mostly uninhabited and often largely inaccessible. It has been suggested that the offshore islet colonies in Somalia are exploited, and that the suspected breeding populations in Sudan and Eritrea may suffer some human impact, but none of this has yet been proved. Away from the breeding colonies exploitation is almost non-existent, though birds are occasionally catapulted on the East African coast and in the inner Seychelles. Human exploitation of breeding colonies probably continues to a small extent in some of these areas, but for the time being the level of exploitation is unlikely to be having a significant effect on the species as a whole.

PLATE 28

inches 5
cm 13



Genus *DROMAS* Paykull, 1805

Crab Plover

Dromas ardeola

French: Drome ardéole **German**: Reiherläufer **Spanish**: Dromas

Taxonomy. *Dromas Ardeola* Paykull, 1805, India.
Relationships uncertain; perhaps closest to Burhinidae and Glareolidae, but frequently awarded separate superfamily on its own, mainly on grounds of plumage of downy chicks; sometimes considered related to Laridae, or to Alcidae because of burrow-nesting habits. Monotypic.
Distribution. Coasts of Indian Ocean. Breeds on shores of NW Indian Ocean, Persian Gulf and Red Sea. Non-breeders regularly range S to Kenya, Tanzania and Madagascar, and E to W India, N Sri Lanka and Andaman Is; also small numbers to NE South Africa, and to single site in SW Thailand.
Descriptive notes. 38-41 cm; 230-325 g; wingspan 74-78 cm. Unmistakable black and white wader, with stout black bill and long bluish grey legs. Plumage white apart from black back, flight-feathers, primaries, and primary and greater coverts; tail greyish. Large dark eye. Sexes similar. Juvenile lacks distinctive adult pattern, which is replaced by grey-brown wing-coverts, blotchy black-brown crown and hindneck, silvery grey mantle and browner tail.
Habitat. Sandy coastlines and islands, intertidal sandflats and mudflats, estuaries, lagoons and exposed coral reefs. Also recorded on rocky shorelines.
Food and Feeding. Predominantly crabs, but also other crustaceans, small molluscs, marine worms and other intertidal invertebrates. Most often feeds in flocks on mudflats at low tide or in shallow water. Most active at dusk and at night. Feeds by picking and probing and slow stalking; crabs are stabbed with open bill, then crushed and eaten.
Breeding. Season Apr-Jul. Breeds colonially in burrows set close together, forming honeycomb effect in sandy areas. Nest is unlined chamber at end of burrow 100-250 cm long, in sandy substrate. Normally 1 egg, rarely 2; no data on incubation; chicks have plain grey down; nidiculous, fed by parents in nest chamber; when older, fed at mouth of burrow; fledglings at least partially dependent on parents for several months

Movements. Partially migratory, but extent of movement obscured by uncertainty of breeding range. Winters throughout breeding range in Persian Gulf, Red Sea, southern Arabia and Somalia, but many birds move S down coast of East Africa to Tanzania and Madagascar area, others E to India; also occurs on many Indian Ocean islands. Few birds S to Natal; rare but annual winter visitor to SW Thailand, also ranging S to Malaysia.
Status and Conservation. Not globally threatened. No overall population estimate available. Of 9 known breeding colonies, over 1500 pairs breed in Iran, at least 300 pairs in United Arab Emirates, 85 pairs in Oman, at least 110 pairs in Saudi Arabia and unknown numbers in Somalia; may also breed in Kuwait, Iraq, Yemen, Sudan and Eritrea. No evidence of changes in numbers; persecution probably only occurs on local scale. No specific threats known, partly because species inhabits relatively isolated areas and is primarily nocturnal. The small number of breeding colonies known implies species vulnerable to effects of oil pollution and human exploitation; also introduction of potential predators to breeding islands, which could have devastating effects.

Class AVES

Order CHARADRIIFORMES

Suborder CHARADRII

Family HAEMATOPODIDAE (OYSTERCATCHERS)

- Medium-sized shorebirds, with black or black and white plumage, pinkish legs and a long, dagger-like orange-red bill.
- 40-51 cm.

- Cosmopolitan, but absent from polar regions and marginal in tropical parts of Africa and Asia.
- Mainly coastal, but also inland in Palearctic and New Zealand.
- 1 genus, 11 species, 16 taxa.
- 2 species threatened; 1 of these probably extinct since 1600.

Systematics

Oystercatchers have a worldwide distribution and all taxa are either black or black and white, apart from the Variable Oystercatcher (*Haematopus unicolor*) of New Zealand, which can be either. Despite the large geographical range of the genus, there has been little morphological divergence between species. As a consequence, the group has a chequered taxonomic history. In general, in the past, discrete populations of black morphs have been treated as full species, Old World pied morphs have been treated as subspecies of the Eurasian Oystercatcher (*Haematopus ostralegus*), and New World pied morphs, with the exception of the Magellanic Oystercatcher (*Haematopus leucopodus*), have been treated as subspecies of the American Oystercatcher (*Haematopus palliatus*).

One of the problems underlying the classification of oystercatchers is the co-occurrence of species. In western South America, Australia and New Zealand, two oystercatcher species occur sympatrically. In all instances, one species is a black or polymorphic rocky shore specialist, while the other is a pied bird which typically forages on soft substrates. In southern South America, three species co-occur. The rocky shore niche is filled by the Blackish Oystercatcher (*Haematopus ater*) and the soft substrate niche by the American Oystercatcher. The third species, the Magellanic Oystercatcher, typically occupies marshy and inland habitats.

It was proposed in the 1950's that oystercatchers had evolved as dark-plumaged birds in Eurasia. Emigrants from this stock would have moved south during the Pliocene to establish themselves as isolated new species in Australia, New Zealand, southern Africa and South America. Following this southward movement, a mutation occurred in the north, with pied birds having a selective advantage over black morphs. Subsequently, there was a second southerly movement, of pied forms, during the Pleistocene. These birds settled in the south as "secondary immigrants", sometimes in areas where black forms were already established. The two species, however, were able to co-exist by virtue of evolved ecological differences.

Whilst this scenario may have some merit in that it does not require an explanation as to how sympatric speciation may have occurred, it seems flawed on several grounds. For example, it implicitly assumes that the southern black forms would have undergone niche contraction in the absence of a potential competitor. The initial premise, that prototypical oystercatchers were black, may also be wrong. It seems likely that the pied Magellanic Oystercatcher, which is behaviourally unique among the oystercatchers in several respects, split off early from the main lineage. The Magellanic Oystercatcher also has a pale yellow eye-ring encircling a yellow eye, and secondaries that are virtually all white: these two features are unique among the oystercatchers. It is also the only New World oystercatcher to have black, not brown, dorsal coloration. Black dorsal coloration is common to all Old World species. Further evidence for the Magellanic Oystercatcher being a primitive species is that it shows several close affinities with the oldest known oystercatcher fossil, from Lower Pliocene deposits in North Carolina. Features of this species, in particular, call into question the validity of the "migration-mutation" explanation for oystercatcher distribution, as well as the initial assumption that the oystercatchers have a northern origin.

Chick coloration varies between species, but there are some consistent features of New and Old World taxa. The claws of New World chicks are dark at the base, whereas those of Old World taxa are pale. With the exception of the Magellanic Oystercatcher, the crown of New World chicks is unspotted or lightly spotted with black, while that of Old World taxa is prominently spotted and streaked with black. The crown patterning of Magellanic Oystercatcher resembles that of Old World taxa, further highlighting its enigmatic taxonomic status.

The majority of the world's oystercatchers occur in the Southern Hemisphere. Including the probably extinct Canarian Black Oystercatcher (*Haematopus meadewaldoi*), four species breed in the Northern Hemisphere compared with nine in the Southern Hemisphere. Two of the three surviving northern species are migratory, whereas no southern species migrates more than a few degrees of latitude between breeding and non-breeding grounds. These observations strongly suggest that the origins of the oystercatchers lie in Gondwanaland, and not in the Holarctic. Consistent differences between Old and New World forms in both dorsal plumage and eye colour suggest that these characters diverged following the separation of South America from the rest of Gondwanaland. If pied plumage is primitive, as indicated by the Magellanic Oystercatcher, then melanism arose independently in the two lineages. Recent studies have concluded that the oystercatchers and the avocets and stilts (Recurvirostridae) are closely related. If this is the case, the latter might be predicted to have a similar pattern of distribution to the oystercatchers. Although the Recurvirostridae are not as diverse as the Haematopodidae, six out of seven of the world's avocets

The Variable Oystercatcher is unique among waders in being polymorphic in plumage. A bird of the intermediate form, commonly known as a "smudgie" and in this case more black than pied, stands beside an individual of boldly pied plumage: the white shoulder patch on this second bird, together with its neatly defined breast and its slightly smaller size, show it to be a South Island Oystercatcher, an endemic race of the Eurasian Oystercatcher.

[*Haematopus unicolor*, *Haematopus ostralegus finschi*, Kaikoura, South Island, New Zealand. Photo: Doug Wechsler/ Animals Animals]

and stilts breed in the Southern Hemisphere whereas only three breed in the north. Also, 45% of the world's oystercatchers breed in Australasia, as do 57% of the world's avocets and stilts. It has been stated that the South Island Oystercatcher (*H. ostralegus finschi*) of New Zealand is a Palearctic element in the Australasian fauna. It is perhaps better to consider the three races of Eurasian Oystercatcher in the north as southern elements in the Palearctic fauna.

The internal taxonomy of the Haematopodidae still poses several problems regarding the recognition of full species. The South Island Oystercatcher, herein considered a race of the Eurasian Oystercatcher, has alternatively been treated as a full species, or a race of either the Australian Pied Oystercatcher (*Haematopus longirostris*) or the Variable Oystercatcher. However, as well as being morphologically similar to other races of the Eurasian Oystercatcher, it shares with them the inland breeding habit. Populations of both *H. o. ostralegus* and *H. o. finschi* have increased considerably this century as the inland breeding habit has become more prevalent.

The Sooty Oystercatcher (*Haematopus fuliginosus*) is usually considered to include the form *opthalmicus*, the Spectacled Oystercatcher, as a race. The two are phenetically similar, but the Spectacled differs from the Sooty in having a broader bill and a fleshy yellowish to orange orbital ring, that of the Sooty being bright orange-red. The ranges of the Sooty and the Spectacled do not overlap in the east of Australia, but there is a putative area of intergrading between Point Cloates and Shark Bay in the west. However, the specimen evidence for this intergrading is very slim, much of the literature in support of it is confused, and there is no field evidence for hybridization between the two; indeed, most authors give the range of the Spectacled as being limited merely to the Gulf of Carpentaria and the Cape York Peninsula, which would situate the putative zone of hybridization 2700 km west of the supposed western limit of this form! Unquestionably, further investigation is required, both in the field and in the laboratory, but the marked differences, especially in the bare parts, suggest that they may well prove to be separate species.

The pied form *galapagensis* of the Galapagos Islands is normally treated as a subspecies of the American Oystercatcher. It is geographically isolated from all other populations of this species, and differs in having markedly hypertrophied feet and often an irregular lower border to the black breast. The same foot character is found in the Chatham Oystercatcher (*Haematopus chathamensis*), and is one of the only features distinguishing this species from the pied morph of the Variable Oystercatcher; it also has an irregular lower breast border. The case for separating the Galapagos form from the American Oystercatcher may, in fact, be just as strong as that for separating the Chatham Oystercatcher from the Variable. However, in the absence of any other *a priori* compelling evidence for separating the two, *galapagensis* is for the time being probably best retained as a subspecies of the American Oystercatcher.

Morphological Aspects

The lack of morphological divergence among the oystercatchers is one of the main reasons why their systematics are so poorly understood. This statement holds true not only for body dimensions, but also for plumage. Apart from differences in eye and dorsal coloration between the New and Old Worlds (see Systematics), all pied taxa have dark upperparts, a black head, neck and upper breast, a white lower breast and belly, a black tail with white uppertail-coverts and a white bar in the upperwing. The Magellanic Oystercatcher is an exception in having white secondaries, and, on the underwing, showing wholly dark primaries and primary coverts. All black taxa have completely dark plumage. The Variable Oystercatcher is unique among oystercatchers, indeed among waders, in being strikingly polymorphic. The

Oystercatchers show a notable lack of divergence in both size and plumage. All the black species, for example, have entirely dark plumage. The Sooty Oystercatcher, seen here in flight, is very similar to the other black species but can be distinguished by its relatively longer tail, as well as its range. All oystercatchers have sturdy bodies with strong, thick necks, short, square tails and long, pointed wings that allow for direct flight. The legs, feet, bills and eyes are all of colourful shades of red, pink, yellow or orange.

[*Haematopus fuliginosus fuliginosus*, Australia. Photo: R. Seitre/Bios]

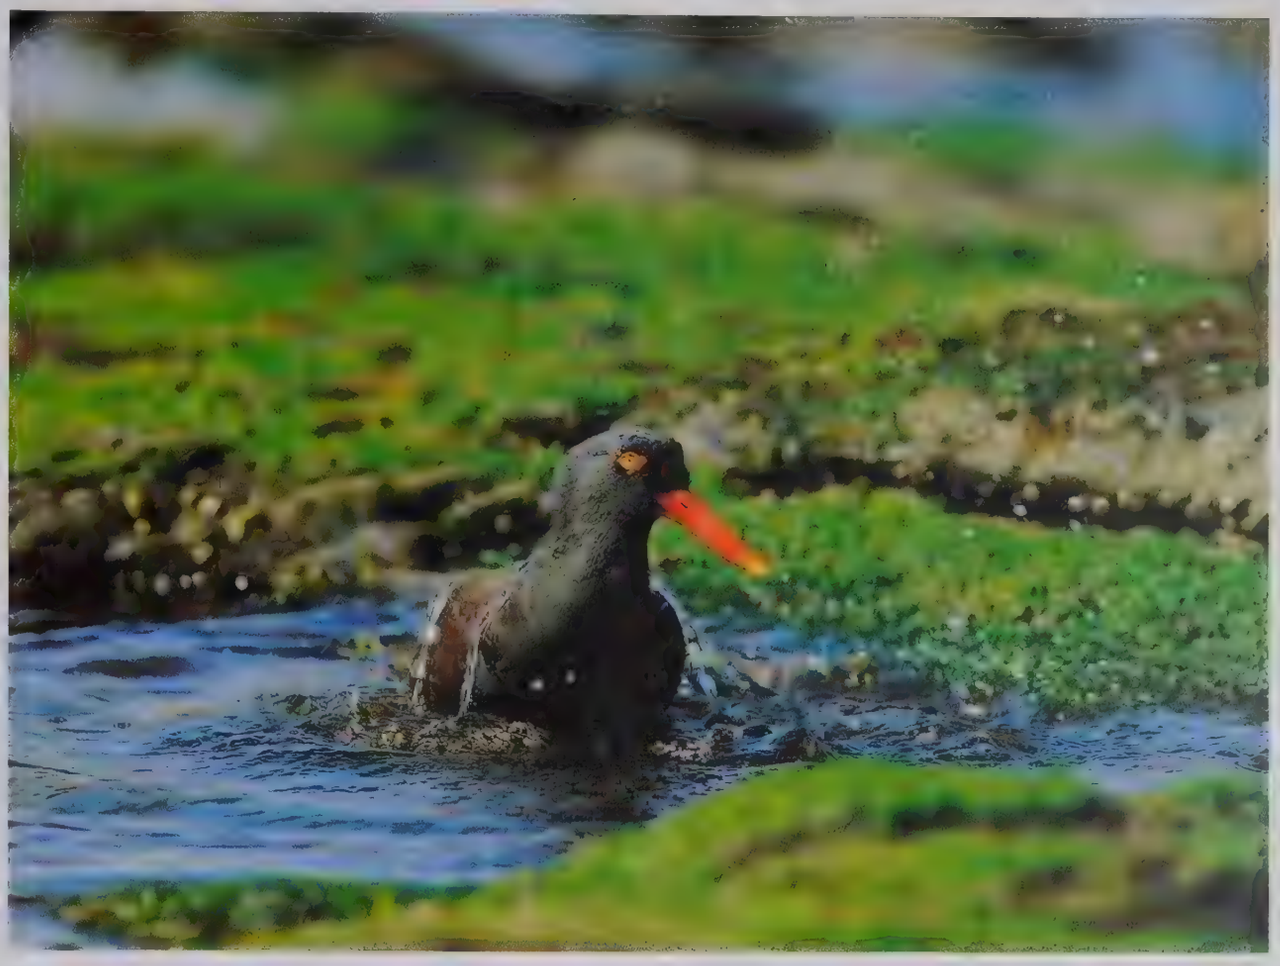
Most oystercatchers are coastal breeders, favouring habitats ranging from rocky or stony shores to sandy, shingly beaches, and even salt-marshes. The African Black Oystercatcher, a scarce species with an estimated population of only about 5000 birds, breeds on both rocky shores and sandy beaches, often in dense colonies on offshore islands. Outside the breeding season it can occur in flocks in estuaries and lagoons. The sand dunes of the Namib-Naukluft Park provide a dramatic backdrop to this small flock taking off from the shoreline.

[*Haematopus moquini*, Namib-Naukluft Park, Namibia. Photo: Thomas Dressler/ Planet Earth]

majority of the population (70%) is black, about 20% are pied, and the remainder are intermediate between the two extremes and are known colloquially as "smudgies". The black morph is most frequent in the south of the range.

Immature oystercatchers are characterized by having buffy margins to the dark feathering, giving them a slightly scaled appearance. They also have a much reduced, and dull-coloured, eye-ring. With the exception of the Blackish Oystercatcher, the legs of immatures are dusky grey and the bills are heavily suffused with brown: the adult bill colour develops from the base towards the tip. The bill and legs of the immature Blackish Oystercatcher are more of a horn colour.

In general, black morphs and the polymorphic Variable Oystercatcher are heavier than pied morphs. Of the taxa for which mensural data exist, the smallest birds are South Island Oystercatchers, in which males average 538 g and females 559 g, and Eurasian Oystercatchers, with males 594 g and females 608 g. The largest taxa are the African Black Oystercatcher (*Haematopus moquini*), with males 666 g and females 722 g, and the Variable Oystercatcher, which in the black morph has males of 678 g and females of 724 g, but in the pied morph males of 717 g and females of 779 g.



There is consistent sexual dimorphism in both body weight and bill length in all species: females are heavier and longer-billed than males. On average, the shortest bills belong to male African Black Oystercatchers, at 63 mm, and the longest to female Variable Oystercatchers of the intermediate morph, at 95 mm. Bill lengths of individual Eurasian Oystercatchers, and probably of other species too, vary seasonally depending on the choice of foraging habitat: bills tend to be longer when birds are foraging in soft substrates, such as fields, than when foraging on rocky shores, where the bill tip becomes abraded. Considering all oystercatcher species together, there are consistent differences in bill length between species that typically forage on soft substrates and those that forage on rocky shores, with means of 82±8 mm for males and 89±6 mm for females in the former, and 72±6 mm for males and 78±4 mm for females in the latter.

Within species, there is an overlap in bill length between the sexes. However, within pairs of African Black Oystercatchers, the female's bill is invariably longer than the male's. This consistent difference, which is linked to a difference in diet, may be related to minimizing territory size and thus the costs of territory defence.

The long bill of oystercatchers comprises an outer protective layer which is keratinized (the rhamphotheca) and an inner bony core which contains nerves and blood vessels. The rhamphotheca is thickest close to the bill tip, and is joined to the core by connective tissue containing many nerves and few blood vessels. The nerves of the core branch towards the bill tip, and the distal 15 mm of the bill, contain many Herbst's Corpuscles. These corpuscles are believed to act as mechano-receptors, which would come into play when the bird is foraging by touch rather than by sight, for instance in soft mud. Oystercatcher species which forage in soft sediments have more pointed, and presumably more sensitive, bills than those that feed on rocky shores. The blade-like bill, coupled with the bony core, is an excellent tool for capturing and handling shellfish. However, the highly sensory nature of the bill tip suggests that oystercatchers evolved from a tactile-foraging ancestor. This, in turn, suggests that use of rocky shores, and its link to black plumage, are derived rather than primitive features of oystercatchers, providing further support for a pied ancestor (see Systematics).

Being coastal birds that forage extensively along the seashore and feed mainly on marine creatures, oystercatchers have well developed salt glands, which are situated in the supra-orbital area. These enable the birds to drain off excess salt from the blood stream, if there is a build-up caused by their prey or imbibed sea water.

In keeping with other morphological characters, wing length is highly conservative within the group. Wing length averages 252-289 mm in males, and 252-285 mm in females. Despite these figures, females generally have longer wings than males, in keeping with their larger body size, but this is not a strict rule. For instance, the average wing lengths of male and female African Black Oystercatchers are identical, and the wings of male Sooty

Washing or bathing, along with preening, forms part of the comfort behaviour of oystercatchers, particularly of non-breeding birds at high tide roosts. It most frequently involves dipping the head in shallow water and jerking it rapidly up, thereby sending a tonifying cascade down the back, as demonstrated by this Blackish Oystercatcher. Preening activities may interrupt the bathing routine from time to time, but the latter formally ends with a drying-off flight when the bird hovers low, with legs dangling.

[*Haematopus ater*, Falkland Islands. Photo: Barbara Gerlach/ DRK]

Oystercatchers are longer than those of the females. There is no difference in the ratio of wing length to body weight in migratory and sedentary oystercatchers. The flight of oystercatchers is powerful, fast and direct, but they lack the manoeuvrability typically seen in members of Charadriidae and Scolopacidae.

They move freely about on land, and can run quite fast, although again they are probably somewhat less graceful than members of some of the other wader families. Relative to most other waders, the legs and feet are sturdy. Even so, African Black Oystercatchers foraging on rocky shores are regularly found to be missing one or more toes, or have toes that have been partially amputated. Such damage presumably occurs on sharp rocks or mussels. The unusually hypertrophied feet of the Galapagos race of the American Oystercatcher (see Systematics) are presumably an adaptation to minimize such damage: this species forages on shores of solidified lava, which are particularly sharp and jagged.

Oystercatchers normally have a complete post-breeding moult. Primary moult is descendant and, at least in the Eurasian Oystercatcher, secondary moult starts six to eight weeks after the beginning of primary moult. Post-breeding moult in some species, such as the Eurasian and African Black, usually starts while adults are still feeding young, and, in the case of the migratory Eurasian, often while they are still on the breeding grounds. The post-breeding moult of this species takes place mostly between June and November, with a tendency for more northerly breeders to start their moult later than southerly breeders. Post-breeding moult in the partially migratory South Island Oystercatcher starts in January, and is mostly completed by April, whereas in the more sedentary Australian Pied Oystercatcher it extends from January to May. In sedentary species, this moult tends to be more protracted than in migratory and partially migratory species. Thus in the Sooty Oystercatcher it lasts from January or February to June, in the Variable from December to July, and in the African Black from March to November. Eurasian Oystercatchers undergo a short, partial pre-breeding moult, mainly affecting the head and neck feathers, but whether all oystercatcher species do so is not known.

Habitat

Most oystercatchers are coastal breeders, nesting in a range of habitats from rocky shores to shingle and sand beaches, and saltmarshes. Some species, however, also breed inland. The central Palearctic race *longipes* of the Eurasian Oystercatcher has an entirely inland breeding distribution from the Black and Caspian Seas northwards, while portions of the populations of nominate *ostralegus* and the race *osculans*, respectively of the Western and Eastern Palearctic, also breed inland. In the south, Magellanic and South Island Oystercatchers breed inland, as do a few Australian Pied Oystercatchers. Extensive inland breeding by Western Palearctic Eurasian Oystercatchers and South Island Oystercatchers has evolved only during this century, concomitant with major population increases of both species. All of the species that breed away from the coast are species which habitually forage on soft substrates. This foraging behaviour is carried across to the inland breeding areas, where earth-dwelling arthropods dominate the diet. Most inland-breeding birds move to the coast outside the breeding season, including birds of central Palearctic *longipes*, which move south to the coasts of the Arabian Gulf and north-east Africa.

None of the rocky shore specialists, including all of the black taxa, breeds inland. Some of them do, however, undergo seasonal shifts in habitat choice. Those Eurasian Oystercatchers which forage on rocky shores during the breeding season move onto soft substrates, especially estuaries, during the winter. American Black Oystercatchers (*Haematopus bachmani*) and Sooty Oystercatchers also increase their use of soft substrates during the non-breeding season. In the case of American Black Oystercatchers, this seasonal shift is linked with avoidance of winter storms. The classification of oystercatchers as hard or soft substrate foragers is a useful one for ecological comparisons of the different species, but all species exhibit some plasticity in their habitat choice, indicating that they are not highly specialized at the species level. The lack of specialization at this level is presumably linked to the morphological conservatism of oystercatchers worldwide.

Oystercatchers have a highly developed system of displays used in various behavioural contexts, such as territory-holding, courtship and attention-distraction, most of them accompanied by varyied piping calls. The Magellanic Oystercatcher is remarkable for its cocked-tail display in the breeding season: as the bird bends forward, it raises its tail vertically, so as to reveal in startling fashion the pure white undertail-coverts. Notable features of this species are the yellow eye-ring and the almost completely white secondaries.

[*Haematopus leucopodus*, New Island, Falkland Islands. Photo: Kenneth W. Fink]

African Black Oystercatchers can be found on both sandy and rocky shores throughout the year, but during the breeding season part of the population moves away from mainland rocky shores onto sandy beaches and rocky offshore islands. This change in habitat use is probably not linked to either food supply or weather conditions, but is mediated by predation. Birds breeding on islands which are predator-free have much higher breeding success than mainland birds. Breeding success on the mainland may be higher on sandy beaches than on rocky shores, because predators are more easily detected on beaches. Incubating adults themselves are at considerable risk from nocturnal mammalian predators.

General Habits

All oystercatchers are territorial during the breeding season, and a proportion of the population of some species, including the Australian Pied, African Black and Chatham Oystercatchers, defend territories throughout the year. Many species form foraging flocks during the non-breeding season. In most cases these flocks are small, numbering less than 50 birds. There is a tendency for species which breed inland to form larger non-breeding flocks than coastal breeders. The Magellanic, Australian Pied and Eurasian Oystercatchers, the latter especially in its races *ostralegus* and *finschi*, all tend to gather in flocks which exceed 100 birds, and sometimes even 1000 birds. Black forms seldom form flocks of more than 10 birds, with the exception of the American Black Oystercatcher, which forms flocks of up to 50 birds in estuaries.

Several species form high tide roosts; these gatherings are usually larger than foraging flocks. Even in areas where African Black Oystercatchers are territorial throughout the non-breeding season, they still form such aggregations, both by day and by night. The function of high tide roosts probably varies between species. For African Black Oystercatchers, the primary function of roosts is predator avoidance, and roosts are usually sited on offshore rocks or on promontories with good all-round visibility. These roosts tend to contain more birds at night than during the day, as it is at night that the birds are at greatest risk from predators. African Black Oystercatchers suffer their highest mortalities from predators during the breeding season, when adults are tied to the nest or chicks, and can not join such roosts. In the case of the Eurasian Oystercatcher, which mostly spends the non-breeding season in much colder climes, roosts probably also serve a thermoregulatory function: their roosts are much more tightly packed than are those of African Black Oystercatchers.

Both migratory and sedentary oystercatcher species are highly site-faithful. Migratory Eurasian Oystercatchers use the same breeding territories year after year, and also tend to return to the same area of the same estuary in each non-breeding season. Migration patterns have a very strong heritable component, and most oystercatchers exhibit long-term mate fidelity. Assortative mating should therefore produce offspring which exhibit very much the same patterns of site fidelity as their parents, and such fidelity has been clearly demonstrated for African Black and Eurasian Oystercatchers, young birds returning to breed at their natal sites, usually when three to five years old. They may have spent much of the intervening time several hundred kilometres away from the natal site.

Voice

Oystercatchers have loud, piercing, piping calls, most closely resembling those of the thick-knees (Burhinidae). Indeed, the call of the African Black Oystercatcher can be confused with that of the Water Dikkop (*Burhinus vermiculatus*) by the inexperienced ear.

At least nine different calls have been identified for Eurasian Oystercatchers in different behavioural contexts, ranging from contact calls to calls associated with "Butterfly Displays" and mobbing. The best known call is undoubtedly the piping call, which is the most complex and far-carrying call of the repertoire. It typically starts with an accelerating trill, evens out in pace and then gradually slows down. This call probably has similar functions in all oystercatcher species. Piping is primarily used in aggressive behaviour between pairs with adjacent breeding territories, and even among species which defend territories throughout the year, piping is most frequent during the breeding season. It is also given when mates meet one another on the territory, especially if one mate has just returned from elsewhere.

The type of diet enjoyed by oystercatchers logically depends on the habitat frequented. Those foraging on the coast and in estuaries can vary their diet more than those feeding inland. On rocky shores molluscs, especially mussels and limpets, are the dominant items for the Blackish Oystercatcher, the only black oystercatcher in South America. The technique used in feeding necessarily varies with the kind of prey attacked. In its strong dagger-like bill the oystercatcher possesses a supremely versatile tool capable of dealing with all sorts of complicated problems.

[*Haematopus ater*, Valdés Peninsula, Argentina. Photo: Günter Ziesler]

Among Eurasian Oystercatchers, the piping display is important in establishing and maintaining dominance hierarchies during the non-breeding season, but whether it plays this role in other oystercatchers is unknown. Piping calls are very similar to alarm calls, suggesting that they are a highly ritualized form of alarm calling.

Piping may also play a role in species recognition where two or three oystercatcher species occur sympatrically. In southern South America, the piping calls of American and Blackish Oystercatchers are very similar, and these two species hybridize where their ranges overlap, as do American Black and American Oystercatchers in their zone of overlap. The piping call of the Magellanic Oystercatcher, however, is markedly different: it has an extremely narrow band width, which is thought to be an adaptation for long distance sound propagation. There is only one putative instance of hybridization involving a Magellanic Oystercatcher.

Food and Feeding

Oystercatchers foraging inland eat mostly arthropods, especially earthworms and insect larvae. On the open coast and in estuaries they have a more varied diet. Bivalves, gastropods and polychaetes figure prominently, but they also eat amphipods, crabs, ascidians, echinoderms and, occasionally, fish. On rocky shores, the diet is usually dominated by molluscs, especially mussels, limpets, snails and chitons, whereas on soft substrates, bivalves and polychaetes are the dominant prey. In Panama, American Oystercatchers have been found to eat at least 30 different prey species. Elsewhere, 24 species have been recorded as prey for South Island and Variable Oystercatchers in New Zealand, and the Sooty Oystercatcher of Australia eats at least 24 species. Altogether 52 species have been recorded in the diet of African Black Oystercatcher.

Migratory oystercatchers are forced to change their diets seasonally as they move from one habitat to another. Seasonal changes in the diets of sedentary species have not been studied, but are probably far less pronounced. They may, however, occur in response to changing body condition of prey animals. For example, at Schiermonnikoog in the Netherlands, the importance of the clam *Macoma balthica* in the diet of Eurasian Oystercatchers decreases towards late summer, as the meat content of the clams decreases. Prey behaviour is also important in diet choice. Eurasian Oystercatchers at Schiermonnikoog have a particularly high intake of *Nereis* worms during mid-summer, at the time when the burrowing depth of these worms is at a minimum.

Changes in prey selection can take place over much shorter time periods than seasons. The diet of the African Black Oystercatcher varies between day and night. Two important prey items for this species are mussels and the limpet *Patella granularis*; the proportion of mussels in the diet is maximal during the day but the proportion of limpets increases at night.

Although they breed also in coastal areas, several oystercatchers, among them the Eurasian species, are found nesting inland along rivers and other water courses and on grass and cereal cropland, perhaps some way from water. The main food items there typically include earthworms, cranefly larvae and caterpillars. Diet, to some extent, conditions bill shape: those oystercatchers with more pointed bills will be adept at probing for worms, those with blade-like tips more expert in opening cockles and mussels.

[*Haematopus ostralegus*. Photo: Danny Ellinger/ Foto Natura]

The American Black Oystercatcher frequents exposed shores and islands along the Pacific coast. It often feeds on rocks uncovered only at low tide where it finds a variety of food items, such as mussels and other bivalves, limpets and whelks, which it tackles with the appropriate technique of hammering, prising, probing or stabbing. Note the yellow eye, typical of the New World species and contrasting with the red iris of Old World taxa.

[*Haematopus bachmani*. Photo: Arthur Morris]

This difference can be explained by the foraging behaviour of the limpets themselves. During the day, they remain firmly attached to the rock because if they move about to forage they run the risk of desiccation. At night, however, the limpets forage at low tide, moving about over the rocks. When mobile they are much more easy to dislodge and become targets for hunting oystercatchers.

In addition to temporal and spatial influences on diet, the sex of the bird also plays a role. Although differences between the diets of males and females have been described for few species, the phenomenon is probably widespread because of consistent differences in bill structure between males and females of all species. The bill of the male is blunter and more robust than that of the female, and is usually shorter. Male Eurasian Oystercatchers in the Dutch Wadden Sea eat more large and thick-shelled molluscs than do females. In western England, mussels are the main prey of males, while the females select more of the smaller cockles. Both sexes of the African Black Oystercatcher eat mussels in approximately equal proportions, but the balance of the male's diet comprises mostly whelks and limpets, whereas that of the female is made up of polychaetes and small unshelled prey.

Worldwide, there is limited morphological variation among the different classes of prey taken, and there is also very limited morphological variation in the feeding apparatus of oystercatchers. For example, limpets and chitons are tightly attached to the rock and have to be knocked or levered off; bivalves must be prised or hammered open, and the flesh must either be pulled out of coiled gastropods or the shell must be broken. Whether an attack technique is effective will, in the main, be determined by prey size and shell strength. There are some small differences between oystercatchers in attack strategies. The African Black Oystercatcher almost invariably attacks only mussels that are themselves feeding. At this time the valves are gaping, and the oystercatchers stab between the valve margins to sever the posterior adductor muscle, which holds the valves together. Both Eurasian and Variable Oystercatchers use this technique, but also sometimes smash open mussel shells to reach the flesh. The African Black Oystercatcher preferentially attacks the posterior shell margins of limpets, whereas the Eurasian Oystercatcher directs most of its attacks at the anterior margins. At least among Eurasian Oystercatchers, there is cultural transmission of foraging techniques from adults to newly-independent young, but maturing birds may subsequently change their foraging techniques.

Considering any one prey species, the upper size limit eaten by oystercatchers is normally determined by the bird's ability either to dislodge the animal or to handle it. The lower size limit may be set either by dexterity or, probably more often, by profitability, in other words the amount of energy the bird will derive relative to the time and effort it must expend in obtaining that energy.

For oystercatchers that live on the coast, available foraging time is limited by two factors, the duration of tidal exposure and the digestive capacity of the bird. Even during the low tide period, oystercatchers rarely forage continuously. They are regularly forced to pause because the rate at which they capture prey is faster than the rate at which they can digest it.

Many intertidal molluscs and crustaceans are intermediate hosts to parasites, especially trematodes and cestodes, which use birds as their final host. It is in the interest of the parasite to try to ensure that the intermediate host is eaten by the definitive host, the bird, but it is in the interest of the birds not to eat parasitized prey. Birds carrying high parasite loads may be at a disadvantage, for example during periods of bad weather when prey is difficult to find. There is evidence from Western Europe and New Zealand that Eurasian Oystercatchers are partially successful in avoiding parasitized bivalves. This is not always the case, however. In England, the dogwhelk (*Nucella lapillus*) is the intermediate host to the castrating trematode parasite *Parorchis acanthus*. This parasite has a dual effect on the whelk. First, it produces gigantism, which makes the infected whelk attractive as prey. Second, it changes the whelk's behaviour: uninfected whelks form winter aggregations where they are free from predation by Eurasian Oystercatchers; although infected whelks do join these aggregations, they do so later than healthy individuals, and are thus at risk from being eaten by oystercatchers for a longer period. The oystercatchers appear unable to detect parasitized whelks and the parasite's "strategy" is thus successful.

In the Eurasian Oystercatcher pre-copulatory displays may occur early on in the season, while the birds are still in their flocks, and it may or may not lead to mounting. Later, the female may initiate formal mating by soliciting, adopting a stationary "passive" attitude. Alternatively the male may display first, adopting a "stealthy" posture; he will then either circle her or stand behind her, prior to mounting, when he calls and pecks at her head. Copulation takes a brief 1-2 seconds, after which the male flies off over his mate's head.

[*Haematopus ostralegus ostralegus*, near Hermitage Castle, Scotland. Photo: R. Kunz]

Breeding

All oystercatchers are exclusively or predominantly monogamous: extra-pair copulations probably occur regularly in most or all species, but bigamy has been reported only for the Eurasian Oystercatcher. They are all territorial during the breeding season. Fidelity to mate and breeding site tend to be strong, and the same pair of Eurasian Oystercatchers may defend the same breeding territory for as long as 20 years. The only taxon studied for which this may not be true is the South Island Oystercatcher.

Breeding takes place during the summer months. There is a tendency for species which breed at high latitudes to have a shorter laying period than lower latitude breeders. In Eurasian Oystercatchers, the timing of egg-laying strongly influences reproductive success: birds that lay early in the season fledge more chicks than those that lay later. Whilst it is tempting to suggest that the latter are inexperienced birds, in at least three oystercatcher species the timing of egg-laying by individual females is correlated between years. This suggests that some factor other than experience influences laying date.

All oystercatchers are single-brooded, although replacement clutches are readily laid if nest contents are lost. Eggs are laid in a scrape made on the ground which may be lined or unlined. Nests are frequently placed adjacent to disruptive objects, and are often sited to provide good all-round visibility. Several scrapes are made before one is chosen: typically the male plays the dominant role in nest building, although the final choice of nest-site probably rests with the female.

As for waders in general, clutch size ranges between one and four eggs, rarely five in the Eurasian Oystercatcher. Among other charadriiforms, notably plovers, sandpipers and gulls, there is a marked pattern of clutch size decreasing towards the tropics, but this pattern is not evident in oystercatchers. All species which breed predominantly or exclusively in the Northern Hemisphere have a modal clutch of three eggs. In the south, the only taxa that normally lay three-egg clutches are the Variable and South Island Oystercatchers. All other southern species have a modal clutch of two. When oystercatchers are breeding at high densities, there is a tendency for the clutch to be smaller than when pairs are well spaced. This may be because resource availability, particularly food availability, for each pair and its offspring is reduced in high-density breeding areas.

The background colour of the eggs is usually grey-blue or grey-buff, with some variation. The eggs of all species are unevenly spotted and scrolled, and are very cryptic on a grainy background such as mussel shells or rock chips. The background colour of the eggs of the Magellanic Oystercatcher is darker and greener than those of other species, which provides a suitably cryptic colour for this species against the grassy background of its nest-site.

Incubation patterns have been studied in few species. The first-laid egg of Eurasian Oystercatchers is incubated discontinuously, which places it at high risk from predators. At Schiermonnikoog, 40% of first-laid eggs are lost before the second egg is laid. The American Oystercatcher, in turn, does not incubate the first egg at all before the second is laid. In this species, which normally lays three eggs, the second-laid egg is the largest. If the first-laid egg is at high risk, and the second and third eggs do not hatch synchronously, the second egg has the greatest chance of producing a fledged chick, so the female therefore places greatest investment in the egg with the highest chance of survival. The African Black Oystercatcher is highly susceptible to egg predation and starts incubation when the first egg is laid; there is no difference in the size of first- and second-laid eggs, or in their probability of being taken by predators. In all species, incubation is continuous once the clutch is completed.

The incubation period ranges from a minimum of 24 days, in the Eurasian, Chatham and American Black Oystercatchers, to 39 days in the African Black; for most species, the modal incubation period is 27-30 days. The chicks hatch with a covering of rather dull speckled greyish brown down, with belly colour pale or dark depending on the species. This pattern helps the chicks to blend into their habitat, so that a crouched chick may look like a small stone or a cluster of pebbles, a pattern closely similar to that found in the thick-knees.

During the breeding cycle there is some role differentiation between the sexes. In the pre-laying period, females spend more time foraging than males. Early in the breeding cycle, males generally commit more time to territorial defence than females, and

females take a proportionally greater share of the incubation. The male's contribution to incubation increases gradually during the incubation period, as the investment value of the eggs increases and the opportunities for extra-pair copulations with other females decrease. In the American Oystercatcher, males provide more food to the chicks than females. Over the breeding cycle as a whole, however, energetic investment by both sexes is similar (as determined for American Oystercatchers), and there are no sex-linked differences in survival rates of adults.

In terms of chick-rearing, all birds fall somewhere along a gradient from fully precocial to fully altricial; that is from mobile, self-feeding young to defenceless young fed entirely by their parents until after fledging. Between these extremes, the oystercatchers occupy a unique position. They are the only birds with young that have full precocial mobility, most chicks leaving the nest within 24 hours of hatching, and yet receive all their food from their parents until well after fledging. A fully precocial strategy minimizes the risk of predation, because chicks can hide or run away, but at the cost of slow growth, because inexperienced young have to find their own food. A fully altricial strategy maximizes growth rate, because the young rely on experienced adults to provide food but at the cost of high predation risk because the young are confined to a nest and frequent visits by parents may attract predators to the nest. Oystercatchers have achieved the best of both worlds in a strategy known as "precocial 5", which maximizes benefits while minimizing risks.

Despite this apparent "super strategy", and the fact that both males and females feed the growing chicks, there is evidence that adult birds are energetically stressed during the chick-rearing period. Chicks of Eurasian, American, American Black and African Black Oystercatchers sometimes die due to starvation. In the case of the American Black Oystercatcher, a sibling hierarchy is established within broods, so that, if food shortage arises, it is the subordinate chick that dies first. In such cases of food becoming scarce, if the food supply is supplemented, either experimentally or due to change in invertebrate populations, breeding success increases.

The average breeding success of all oystercatchers is less than one fledged young per pair per year. Only among Eurasian and American Black Oystercatchers have average fledging successes of more than 0·5 chicks per pair per year been reported. Most mortality occurs during incubation, rather than chick-rearing. Of 229 nests of American Oystercatchers monitored in Virginia, USA, eggs hatched in only 14%. Most chick mortality occurs when chicks are small: mortality rates of more than 60% for Eurasian Oystercatchers and more than 85% for African Black Oystercatchers have been reported in the first week after hatching. The main causes of egg and chick mortality are storms and predators. Generally, the former is the more important factor during the egg stage, and the latter during the chick stage.

The fledging period ranges from 33 days, the minimum for the Eurasian, to 49 days, the maximum for the Australian Pied, the Chatham and the Variable; reported fledging periods of 56 days for the Australian Pied are questionable. There is a tendency for the fledging period of migratory species to be longer than those of sedentary species.

After fledging, young oystercatchers are fed by their parents for varying lengths of time, and young may remain with their parents for up to six months. They are long-lived birds, and deferred maturity is the norm. Some female Eurasian and African Black Oystercatchers breed for the first time at three years old, and some males breed in their fourth year. Most, however, probably do not breed until they are older than this, and one male Eurasian Oystercatcher only bred for the first time at the age of 14! Young oystercatchers almost invariably breed close to where they themselves hatched, certainly within tens of kilometres. In one bay in South Africa, where African Black Oystercatchers breed at very high densities on three rocky islands, most young birds return to their natal islands to breed.

Movements

The only oystercatchers that are truly migratory are the four races of the Eurasian Oystercatcher. The three Palearctic races all move south during the boreal winter, and inland breeders move to the coast (see Habitat). The South Island Oystercatcher, an inland breeder on the South Island of New Zealand, moves to the coasts of both North and South Islands during the austral winter and it is thought that these birds fly directly between their breeding and non-breeding grounds, travelling in small flocks of 25-70 birds.

All oystercatchers rear a single brood, though replacement clutches may be laid when required. The nest is a simple scrape in the ground, in sand or gravel in the case of the American Oystercatcher, which may decorate its nest with a few shell fragments. On average the clutch consists of 3 eggs, and in all species the eggs are unevenly spotted or blotched, which helps to camouflage them. Incubation normally lasts up to 29 days and is carried out mainly by the female.

[*Haematopus palliatus palliatus*, Long Island, New York. Photo: Tom Vezo]

The Blackish Oystercatcher of South America sites its nest on the beach, just beyond the reach of the swell, among stones and pebbles. A shallow depression in the ground, it is lined on occasion with fragments of shell or rock. The clutch size is small, only 2 eggs, and this, together with the factor of heavy predation by gulls and skuas, results in a dismal rate of breeding success, well below the already low average for oystercatchers.

[*Haematopus ater*, Falkland Islands. Photo: David Hosking/ FLPA]

Migration occurs both by day and by night. Eurasian Oystercatchers breeding in Iceland fly 800 km non-stop across the North Atlantic to reach British non-breeding grounds, and these birds start their primary moult only once their migration is complete. The longest movements undertaken by this species are by the races *ostralegus* and *longipes*. The mid-points of the breeding and non-breeding ranges of these subspecies are separated by approximately 32° of latitude, about twice the distance moved by the eastern race *osculans*. Many long distance migrant waders lay down pre-migratory fuel reserves, which, in small species, may approach 100% of their lean body mass. There is no pronounced pre-migratory fattening of Eurasian Oystercatchers; indeed, birds in the Netherlands attain peak mass in mid-winter. This suggests that distances travelled between stop-overs are not great, and most flights probably cover less than 1000 km.

Eurasian Oystercatchers are strongly site-faithful to their non-breeding grounds, and spatial segregation of sub-populations occurs. Icelandic birds, for example, spend the non-breeding season on the coasts of Ireland and western Britain, while Norwegian birds are concentrated along the coasts of the North Sea.

The American Black and American Oystercatchers are migratory in the north of their ranges, moving south in the winter. There is also a slight northerly movement of Magellanic Oystercatchers during winter, but most of the population is non-migratory. None of the other species is migratory, although several undertake small-scale seasonal movements between different habitats (see Habitat). In winter, movements of Eurasian Oystercatchers also occur in response to severe weather conditions.

Relationship with Man

The genus *Haematopus* was erected by Linnaeus in 1758 for the Eurasian Oystercatcher. There is, however, earlier reference to at least one other species. In 1648, Étienne de Flacourt, the then Governor-general of Madagascar, visited the south-west coast of Africa and provided the first description of the African Black Oystercatcher: "There are birds like Blackbirds, with a very shrill and clear cry, as large as partridges, with a long sharp beak and red legs: they are very good to eat and when they are young they taste like Woodcock".

Other writers have been less impressed by the gastronomic potential of oystercatchers than by their appearance. In his *Birds of the West Coast*, of 1976, J. F. Lansdowne wrote of the American Black Oystercatcher: "Anyone seeing a Black Oystercatcher for the first time might be inclined to laugh at its grotesque and rather comic appearance. Its outsize red bill is impossibly bright, the eyes are red-ringed, and the pallid fleshy feet bring to mind a seaside bather who has taken off his shoes and socks. When the bird nods and utters a piercingly loud whinny, the observer is convinced that it is simple as well as strange looking"!

Being specialist predators of shellfish, oystercatchers have the potential to come into conflict with man at commercial shellfish farms. In western Europe, Eurasian Oystercatchers were thought for many years to be a major economic pest of commercial cockle fisheries. Recently, however, shore crabs (*Carcinus maenas*) were shown to eat twice the biomass and 25 times as many cockles as those eaten by the birds: the relative impact of oystercatchers had therefore probably been overestimated. In North America, American Oystercatchers prey on commercial oyster beds, especially during winter, but it is not known whether they have any economic impact, concentrating as they do on the smaller oysters.

Status and Conservation

Many oystercatcher species with predominantly mainland distributions are common, and there is no good evidence for population changes in either direction. There is a suggestion that the

In coastal areas, the feeding activity of Eurasian Oystercatchers is heavily dictated by tides, and birds typically roost or loaf around the period of high tide, when conditions are not ideal for foraging. Birds tend to roost communally, but off-duty breeders will remain on the territory, resting on elevated perches with good all-round visibility, such as rocky outcrops. This species is resilient in the face of inclement climatic conditions and it winters as far north as Iceland, so summer showers, which are not uncommon within its breeding range, need pose no great problem.

[*Haematopus ostralegus ostralegus*, Foula, Shetland, Scotland. Photo: Günter Ziesler]

American Oystercatcher is decreasing in abundance, as a breeding species, in the north of its range, but it has an extensive distribution in North, Central and South America and is not threatened.

The populations of two subspecies of Eurasian Oystercatcher, nominate *ostralegus* and *finschi*, have increased this century in parallel with an increased frequency of inland breeding. There has been a southerly extension of the breeding range of *ostralegus* over the past 60 years. The race *finschi* decreased in numbers from the late nineteenth century until the middle of the twentieth century, but it has undergone a spectacular irruption since 1940.

The world populations of five taxa number less than 5000 birds. These five include three species, the Chatham, the Variable and the African Black Oystercatchers; and two well marked subspecies, the Spectacled Oystercatcher and the Galapagos race of the American Oystercatcher, both of which may actually be good species.

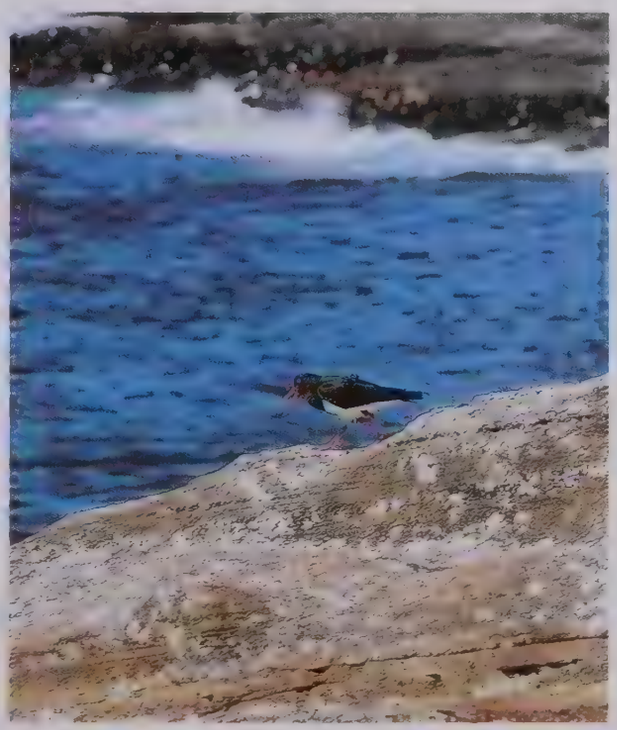
The Chatham Oystercatcher is classified as Endangered, with a world population of only about 100-110 birds on the islands of Chatham, Pitt, Mangere and Rangatira (formerly South-east Island). Breeding is largely restricted to offshore islands and cliffs, because of predation by feral cats and Wekas (*Gallirallus australis*). The two most secure breeding islands of Mangere and Rangatira are protected reserves, and are free from introduced predators. There is some evidence for a slight recent increase in overall numbers, but, simply from the extremely low numbers, this species' status is precarious. Several conservation measures have been put into practice in recent years, including artificial incubation, with the aim of reducing egg loss due to predation or storm damage.

The Variable Oystercatcher is widely distributed in New Zealand, but has a total population of only about 3900 birds. Whilst this species was not legally protected from shooting in the early part of the present century, it would appear that the effects of introduced predators combined with disturbance by humans may have been more serious. In recent years, some populations appear to be increasing, and conservation work appears to have achieved some successes, but, with its relatively low numbers, the species still may warrant monitoring.

The African Black Oystercatcher has a total population of about 4800 birds, of which 25% is supported on only ten islands, all of which are protected, with landing regulated by permit. The principal threat to the island populations is the introduction of mammalian predators. The connection of Marcus Island, in Western Cape Province, to the mainland by a causeway allowed access for several predators: in the space of four years, 25% of the island's adult oystercatchers were killed, and in three breeding seasons combined, the breeding population of about 60 pairs fledged only five chicks. On mainland coasts, however, the greatest threats to African Black Oystercatchers are development and associated disturbance, including an escalating use of off-road vehicles on beaches. The total population has probably decreased in the past 10 years and populations in the south-western Cape and Algoa Bay require monitoring.

The status and biology of the Spectacled Oystercatcher of northern Australia are very poorly known, but the total population probably numbers under 1000 individuals, and no major concentrations are known. This is one of the least known of all oystercatchers, together with the Chatham Oystercatcher and the Galapagos race of the American Oystercatcher, both of which are very rare too, and all three are amongst the priorities for conservation-related research within the family. All three taxa also constitute taxonomic enigmas (see Systematics), and further study in this field would be highly desirable, especially

American Oystercatcher chicks hatch with a rather drab coat of speckled greyish brown down, a cryptic pattern that helps them to escape detection. Oystercatcher young are fully precocial, but, strangely, they rely on their parents for food until after fledging, an advantageous strategy termed "precocial 5". Accordingly, the risk of predation is relatively small since the mobile chicks are able to run quickly for cover, while the growth rate is fast as the experienced adults provide all the food, thereby economizing on time. Despite all this, average breeding success in oystercatchers is less than one fledged young per pair per year.



[*Haematopus palliatus palliatus*, Long Island, New York. Photo: Tom Vezo]

with the use of molecular techniques. Like the Spectacled Oystercatcher, the Galapagos race *galapagensis* of the American Oystercatcher may warrant specific status. In view of this, the taxon requires urgent biological research and an accurate assessment of its distribution and abundance within the islands. The total population is estimated to be less than 100 pairs, with the introduction of predators considered to pose the biggest threat.

The presence of a black oystercatcher in the Canary Islands was first reported in the 1840's, although a specimen was not collected and described until 1888, while the last specimen was taken in 1913. This species probably became extinct early in the twentieth century. However, subsequent to 1960 there are two unsubstantiated sight records from Tenerife, outside the species' known range. Complete surveys of the west coasts of Fuerteventura and Lanzarote in June and July 1985 failed to find any sign of the bird. The only hope that a small, as yet undiscovered, population survives are two sightings, involving three birds, from the coast of Senegal in 1970 and 1975. These sightings were never ascribed to species, but it is highly unlikely that they refer to African Black Oystercatchers, which are sedentary and have never been reported north of Lobito, Angola.

Such a short time elapsed between the discovery and apparent extinction of the Canarian Black Oystercatcher that almost nothing is known of its biology, beyond the fact that it favoured rocky shores. The physical nature of the coastline in the eastern Canary Islands indicates that the population would always have been small. Its extinction was probably precipitated by increasing disturbance and competition with man for food. In the past few centuries there has been a progressive desertification of the eastern Canary Islands, accelerated recently by changing land-use practices. This has led in turn to an increasing dependence by the islanders on marine food resources, resulting in severe impacts on intertidal invertebrate populations over most of the species' historical range.

Only one wader species, the White-winged Sandpiper (*Prosobonia leucoptera*) of Tahiti and Moorea, has definitely become extinct in the past 200 years (see page 484). However, it seems very likely that the Canarian Black Oystercatcher and the Javanese Wattled Lapwing (*Vanellus macropterus*), which has not been seen since 1939 (see page 408), are now also extinct.

When last counted in the late 1980's, the Chatham Oystercatcher's total population numbered only 100-110 birds. This species is found on five or so of the Chatham Islands, where the main threat it faces is in the form of predation by cats, rats and Wekas (Gallirallus australis)*, while grazing cattle and human disturbance are other negative factors. Conservation measures are currently being taken to safeguard the species and to encourage breeding. In the meanwhile it is classified as Endangered.*

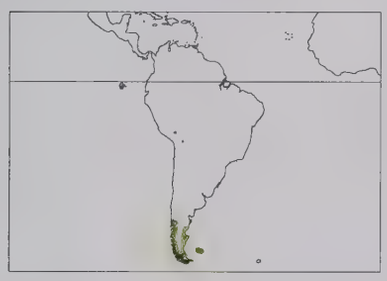
PLATE 29

inches 9
cm 23



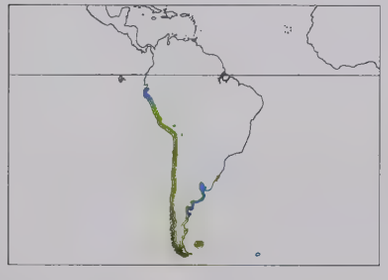
Genus *HAEMATOPUS* Linnaeus, 1758

1. Magellanic Oystercatcher

Haematopus leucopodus

French: Huîtrier de Garnot **German**: Magellanausternfischer **Spanish**: Ostrero Magallánico

Taxonomy. *Haematopus leucopodus* Garnot, 1826, Falkland Islands.
Distinctive species with taxonomic affiliations uncertain, as both adults and chicks show mixture of features which otherwise characterize taxa of Old World, rather than those of New World (see page 308). Monotypic.
Distribution. SC Chile (Chiloé I) and SC Argentina (Chubut) S to Cape Horn; Falkland Is.



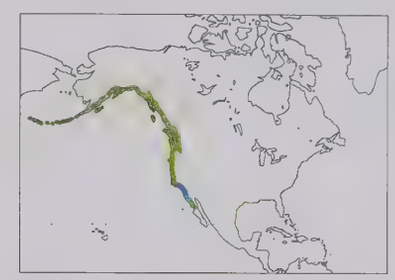
Descriptive notes. 42-46 cm; male 585-610 g, female 585-700 g. Unique amongst oystercatchers in having almost entirely white secondaries from above and below, and a yellow eye-ring. Eye yellow, as in all other New World oystercatchers; the only pied oystercatcher of New World with black dorsal coloration. Female very similar to male, but bill tends to be longer and shallower. Juvenile has browner upperparts with buff feather fringes, and duller bare part colours.
Habitat. Occurs on beaches, inland and upland grasslands and the margins of freshwater pools. Most birds move to the coast in winter, where large flocks may form, on rocky shores or soft substrates.
Food and Feeding. Feeds on mussels, limpets and crabs on rocky shores, marine polychaetes on coastal soft substrates. At inland sites eats mainly earthworms and insect larvae. All oystercatchers attack different prey types using variety of techniques, e.g. hammering, prising, probing, stabbing (see page 314).
Breeding. Laying starts in Oct-Nov in Tierra del Fuego. Cocked-tail display, with tail held vertically to display undertail pattern, is unique among oystercatchers. Nest often sited on a slightly raised grassy hillock. Clutch 1-2, usually 2; eggs have darker, greener background than those of other oystercatchers, providing cryptic aspect against a grassy background. Chick differs from those of other New World oystercatchers in having crown prominently marked with black; similar to chick of *H. ostralegus*, but differs in having dark bases to claws and dark upper breast. Incubation and fledging periods unknown.
Movements. Seasonal movement from inland breeding grounds to the coast. Breeders from extreme S of range move N in winter, but distances and destinations unknown.
Status and Conservation. Not globally threatened. Generally reckoned to be common to abundant, especially in southern parts of range. Fairly restricted range, but much of this supports very sparse human populations, with relatively limited human impact on natural environment. Extensive promotion of "adventure" tourism in recent years; and possible impact of increased human presence, recreational activities and general disturbance should be examined; nevertheless, species appears secure at present.
Bibliography. Blake (1977), Canevari *et al.* (1991), Clark (1986), Cobb (1910), Crawshay (1907), Fjeldså & Krabbe (1990), Hellmayr & Conover (1948), Humphrey *et al.* (1970), Jehl (1978), Jehl & Rumboll (1976), Jehl *et al.* (1973), Johnson (1965b), Maclean (1972a), Miller & Baker (1980), Olrog (1984), de la Peña (1981b, 1992), Scott & Carbonell (1986), Siegel-Causey (1991), Woods (1988).

2. Blackish Oystercatcher

Haematopus ater

French: Huîtrier noir **Spanish**: Ostrero Negro Suramericano
German: Südamerikanischer-Austernfischer
Other common names: Black Oystercatcher(!), South American Black Oystercatcher

Taxonomy. *Haematopus ater* Vieillot and Oudart, 1825, Straits of Magellan.
Some hybridization recorded with *H. palliatus* in zone of overlap. Monotypic.
Distribution. N Peru (Lambayeque) S through Chile to Tierra del Fuego and N up Atlantic coast to SC Argentina (Chubut); Falkland Is. Outside breeding season some birds move N to extreme N Peru, NE Argentina and probably Uruguay.



Descriptive notes. 43-45·5 cm; 585-708 g. Heavily built, all dark oystercatcher with dorsal plumage blackish brown; red eye-ring, yellow eye; deep, heavy bill orange-red, paler towards tip; legs pinkish horn. Almost identical to *H. bachmani*, but legs slightly paler, body slightly heavier and wings slightly longer; bill rather deeper, especially at gonys. Female very similar to male, but averages larger with larger bill; some white fringes to belly feathers in non-breeding plumage. Juvenile has plumage scaled with buff; bill dull, but may be yellowish at tip, whereas most juvenile oystercatchers have brown-tipped bill; legs pale.
Habitat. Breeds on pebble and shell beaches. Outside breeding season occurs on shingle and rocky shores.
Food and Feeding. Feeds mainly on mussels and limpets on rocky shores. All oystercatchers attack different prey types using variety of techniques, e.g. hammering, prising, probing, stabbing (see page 314).
Breeding. Laying mostly starts in Nov, in Tierra del Fuego; late Oct to Jan, in Falkland Is. Nest is scrape in ground placed as close to the high water mark as swells permit, sometimes on bare rock; nest depression is lined with shell fragments and rock chips. Clutch 1-2, usually 2. White ventral coloration of chick more extensive than in *H. bachmani*, but does not cover entire belly and flanks as in *H. palliatus*; buff tipping to down restricted to narrow strips on margins of dorsal and femoral stripes, resulting in greyish, rather than buffy, upperparts. Incubation and fledging periods unknown. Breeding success low due to predation by gulls and skuas; in one study only 1 chicks has reared from total of 20 nests.
Movements. Mainly sedentary. Birds breeding in extreme S (Tierra del Fuego) move an unknown distance N after breeding. Some birds occur N to extreme N Peru and also to NE Argentina and probably Uruguay, but origins of such birds unknown, and patterns of such movements unclear. Recorded in Juan Fernández Is, 800 km off Chilean coast.
Status and Conservation. Not globally threatened. Occurs at fairly low density throughout range, but range extensive and in many parts sparsely populated by humans. Densities may be depressed in areas where there is intensive exploitation of intertidal invertebrates by local people, e.g. in C Chile.
Bibliography. Baker & Miller (1978), Blake (1977), Canevari *et al.* (1991), Clark (1986), Cobb (1910), Crawshay (1907), Gewalt (1992), Hellmayr & Conover (1948), Humphrey *et al.* (1970), Jehl (1978), Jehl *et al.* (1973), Johnson (1965b), Koepcke (1970), Low (1923a), Miller & Baker (1980), Nol (1984), Olrog (1984), de la Peña (1981b, 1992), Scott & Carbonell (1986), Stresemann (1927), Woods (1988).

3. American Black Oystercatcher

Haematopus bachmani

French: Huîtrier de Bachman **Spanish**: Ostrero Negro Norteamericano
German: Klippenausternfischer
Other common names: Black Oystercatcher(!)

Taxonomy. *Haematopus Bachmani* Audubon, 1838, mouth of the Columbia River.
Occasionally included in expanded *H. ostralegus*. Name *H. frazari* may be invalid, referring to a hybrid swarm formed between present species and *H. palliatus* in Gulf of California and W Mexico; the hybridization in this overlap zone is limited. Monotypic.

Distribution. W Aleutian Is (Kiska I) through S Alaska (including Round I), W Canada and W USA to NW Mexico (Los Coronados Is and Baja California). Outside breeding season, mostly concentrated between S British Columbia and Baja California.
Descriptive notes. 43-45 cm; male 555-648 g, female 618-750 g. All dark oystercatcher with yellow eye, orange-red eye-ring and pale pink legs; as in all other New World oystercatchers, except *H. leucopodus*, dorsal coloration is blackish brown. Very similar to *H. ater*, but wings slightly shorter, not extending to tail tip at rest; slightly less stcky, with slightly darker legs; bill roughly same length as that of *H. ater*, but not as deep, especially at the gonys. Female averages slightly larger, with longer, thinner bill. Juvenile has dull orange-brown eye-ring and bill, pinkish grey legs and buff-fringed feathers.
Habitat. Breeds on rocky shores and islands. Outside breeding season frequents mudflats and rocky shores.
Food and Feeding. Diet includes mussels, limpets, chitons, echinoderms, crustaceans, polychaetes, goose barnacles and, occasionally, fish. During breeding season on rocky shores around Vancouver I, W Canada, prey includes mussels (*Mytilus californianus*), gastropods (*Acmaea*, *Lottia*, *Tectura*, *Crepidula mummaria*), chitons (*Katharina truncata*, *Mopalia*), crabs (*Petrolisthes cinctipes*, *Oedignathous inermis*), isopods (*Idothea*, *Ligia*), nemertines and echinoderms. In winter these birds move to mudflats where they prey almost exclusively on the mussel *Mytilus edulis*. Approximately 600 km to S, birds foraging in winter on boulder field along coast ate large numbers of limpets, especially *Tectura scutum*, *Lottia pelta* and *L. digitalis*; less frequently taken were *T. persona* and *L. strigatella*. On rocky shores of coastal California, *L. digitalis* and *L. pelta* are frequent prey, while on sandstone shores *Collisella scabra* is rather commonly eaten. All oystercatchers attack different prey types using variety of techniques, e.g. hammering, prising, probing, stabbing (see page 314).
Breeding. Laying in May-Jun; breeding starts c. 2 weeks earlier in S than in N of range. Nest is a shallow scrape on ground, usually lined with rock chips and shell fragments; placed on gravel or turf, or in a rocky depression. Lays 1-4 eggs, but modal clutch 2 or 3, varying regionally; incubation 24-33 days. Chick has less extensive buffy tipping to down than that of sympatric *H. palliatus*, and sides and back of neck are blackish, not buffy. Fledging 40 days. Fledging success variable 0·19-1·10 young per pair per year. Age of first breeding 3 years.
Movements. Local movement away from rocky shores to estuaries during winter, probably due to avoidance of storms. Vagrant to Pribilof Is.
Status and Conservation. Not globally threatened. Fairly widely distributed, and much of range supports relatively sparse human populations, especially in N; very little precise information available regarding abundance and trends. Numbers have decreased steadily in parts of S California during present century. Population on San Nicolas I (off Los Angeles) started to increase rapidly in early 1980's for unknown reasons.
Bibliography. 4. American Oystercatcher

Haematopus palliatus

French: Huîtrier d'Amérique **Spanish**: Ostrero Pío Americano
German: Braunmantel-Austernfischer
Other common names: American Pied Oystercatcher

Taxonomy. *Haematopus palliatus* Temminck, 1820, Venezuela.
Sometimes considered conspecific with *H. ostralegus*. Name *H. frazari* may be invalid, referring to a hybrid swarm formed between present species and *H. bachmani* in Gulf of California and W Mexico; the hybridization in this overlap zone is limited, and some authorities retain *frazari* as race of present species. Present species also known to hybridize with *H. ater* in S South America. Some differences in adult morphology and plumage between nominate *palliatus* and race *galapagensis*, coupled with extreme isolation of latter and differences in chick coloration suggest that *galapagensis* may warrant separate species status (see page 309). Several proposed races probably insufficiently distinct to warrant recognition: *pitanay* of W South America, from Ecuador to SC Chile; *durnfordi* of E South America, from S Brazil to SC Argentina; and *prattii* of Bahamas. Two subspecies currently recognized.
Subspecies and Distribution.
H. p. palliatus Temminck, 1820 - coasts of North and South America, from Gulf of California to C Chile, and from Massachusetts to SC Argentina, including West Indies.
H. p. galapagensis Ridgway, 1886 - Galapagos Is.

Descriptive notes. 40-44 cm; male averages 567 g, female 638 g. Head, neck, upper breast, flight-feathers and tail black; lower breast and belly white; the only "pied" oystercatcher species with blackish brown dorsal plumage; in flight, shows white greater secondary coverts and uppertail-coverts; eye yellow, eye-ring and bill orange-red, legs pinkish. Female averages slightly larger and longer-billed. Juvenile has buff edges to dark feathers; eye-ring, bill and legs dull. Race *galapagensis* slightly smaller, with shorter wings and bill, especially in female; black breast often has irregular lower border; legs shorter and heavier than in nominate race, and feet noticeably hypertrophied.
Habitat. Breeds in salt-marshes and on sandy and pebble beaches; many birds move to mudflats in winter. Regularly forages on rocky shores in Panama.
Food and Feeding. Feeds mainly on snails, limpets, crabs, oysters, mussels and clams. On soft substrates in Virginia, prey includes razor-clams (*Ensis directus*, *Solen viridis*), ribbed mussels (*Guekensia demissa*) and stout tagelus (*Tagelus plebeius*). On sandy beaches, birds take mole crabs (*Emerita*) and sand mussel (*Mesodesma donacium*), as well as other prey; also forage on commercial beds of the oyster *Crassostrea virginica*. In Panama, on rocky shores, molluscs (*Nerita scabricosta*, *N. funiculata*, *Siphonaria gigas*, *Fissurella*, *Thais melones*) make up more than 97% of diet. All oystercatchers attack different prey types using variety of techniques, e.g. hammering, prising, probing, stabbing (see page 314).
Breeding. Laying Apr-May in Virginia, Feb-Mar in Panama, Oct-Dec in Chile. Nest is shallow scrape on ground, usually placed on sand or gravel; depression usually unlined, but shell fragments sometimes placed around rim of nest. Clutch 1-4, usually 3; replacement clutches smaller, typically 2 eggs; incubation 24-29 days. Chick has drab upperparts with dark stripes down back and sides, and white underparts; that of race *galapagensis* has darker throat than nominate, and lacks buffy tipping on and near rectrices, having entire tail dense black. Fledging 35+ days. Fledging success (nominate *palliatus*) 0·24-0·39 young per pair per year; breeding failure most often due to predation and nest flooding during high tides or storms.
Movements. Resident throughout most of range, but most northerly breeders, especially in NE, move S in winter. Forms foraging flocks in winter. Race *galapagensis* is sedentary.
Status and Conservation. Not globally threatened. Beach development in North America has reduced nest-site availability and led to local changes in distribution, as well as a probable overall population decrease; however, distribution is extending northwards in NE of range. Race *galapagensis* is rare, with total population probably less than 100 pairs; numbers may be limited by availability of suitable feeding areas; potentially threatened by introduced predators, but distribution, biology and behaviour too poorly known to assess real conservation status.

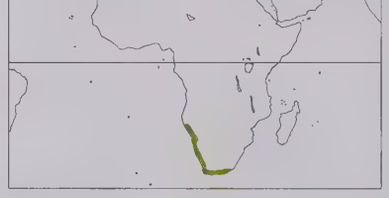
5. Canarian Black Oystercatcher

Haematopus meadewaldoi

French: Huîtrier des Canaries **Spanish**: Ostrero Negro Canario
German: Kanarischer Austernfischer
Other common names: Meade-Waldo's (Black)/Canarian Oystercatcher

Taxonomy. *Haematopus niger meade-waldoi* Bannerman, 1913, Jandía, Fuerteventura, eastern Canary Islands.
Validity of species has repeatedly been questioned, and scarcity of material limits scope of possible analyses; has been considered conspecific with *H. moquini* or *H. ostralegus*, or both. Monotypic.
Distribution. E Canary Is, especially Fuerteventura, Lanzarote and Graciosa, but also outlying islands including Montaña Clara and Roque del Este. Probably extinct.
Descriptive notes. c. 43 cm. All dark oystercatcher with red eye, orange-red eye-ring and bill, and pale pinkish red legs; in flight, when seen from below, primaries have pale bases, but this feature may be linked to feather wear. Differs from *H. moquini* in having shorter wings and longer bill; from New World black oystercatchers in having black, not blackish brown, dorsal coloration and a red, not yellow, eye; wing and tail shorter than in *H. fuliginosus*, and both bill and wing measurements average shorter than in black morph of *H. unicolor*. Juvenile unknown.



Habitat. Rocky and sandy shores. Probably predominantly a rocky shore species.
Food and Feeding. Unknown; probably mostly mussels and limpets. Likely prey species include limpets (*Patella candei*, *P. pipperata*, *P.* cf. *aspera*) and the mussel *Perna picta*; all of these species have been heavily exploited by man in E Canary Is. All oystercatchers attack different prey types using variety of techniques, e.g. hammering, prising, probing, stabbing (see page 314).
Breeding. Nest and eggs undescribed. A female "soon to lay" was collected in S Fuerteventura in early Apr 1888, and a pair in breeding condition collected on Graciosa in early Apr 1890. Clutch size probably 1-3.
Movements. Unknown, but very probably resident.
Status and Conservation. Almost certainly EXTINCT. Described as "not frequent" in mid-19th century. Last definite record was in 1913, although local fishermen and lighthouse keepers in 1970 estimated date of extinction as around 1940. Since 1965 there have been two unsubstantiated sight records from Tenerife. It is not known to which taxon 3 black oystercatchers seen on Senegal coast in 1970 and 1975 belonged: although movement from Canary Is to African mainland has been suggested in past, there is no evidence to support this; equally unlikely, however, that these birds were *H. moquini*, a species not recorded N of 12° S in Angola. Expeditions to Canary Is in 1956/57, 1970, 1985 and 1986 failed to find any trace of the bird.
Bibliography. Bannerman (1914, 1919-1920, 1922, 1963, 1969), Beaman (1994), Bolle (1854-1855, 1857), Collar & Andrew (1988), Collar *et al.* (1994), Collar & Stuart (1985), Cramp & Simmons (1983), Étchécopar & Hüe (1964), Godman (1872), Hockey (1982a, 1986a, 1986b, 1987), King (1978/79), Lovegrove (1971), Meade-Waldo (1889a, 1889b, 1890, 1893), Piersma (1986a), Stresemann (1927), von Thanner (1908).

6. African Black Oystercatcher

Haematopus moquini

French: Huîtrier de Moquin **Spanish**: Ostrero Negro Africano
German: Schwarzer Austernfischer
Other common names: African Oystercatcher, Black Oystercatcher(!)

Taxonomy. *Haematopus moquini* Bonaparte, 1856, Cape of Good Hope.
Has been considered conspecific with *H. meadewaldoi* or with *H. ostralegus*, or both. Monotypic.
Distribution. N Namibia S to Cape of Good Hope and E to E Cape Province, South Africa. Species recorded NE to KwaZulu-Natal and N to 12° S in Angola (Lobito), but only as vagrant.

Descriptive notes. 42-45 cm; male 582-757 g, female 646-800 g. All dark oystercatcher with red eye, orange-red eye-ring and bill, and deep pinkish red legs. Has longer wings and shorter bill than *H. meadewaldoi*, but field separation of the two would be difficult; black dorsal coloration and red eye separate present species from New World black oystercatchers; bill is substantially shorter than that of any black oystercatcher in Australasia. Within pairs, males have blunter and shorter bills than females. Occasional plumage variants include birds with a small number of white feathers among flight-feathers, on breast or in axillaries; leucistic individuals rare, and no records of extensive albinism. Juvenile has dull eye, eye-ring, bill and legs; feathers fringed buffy-grey.
Habitat. Typically occurs on rocky and sandy shores, less frequent in estuaries and coastal lagoons. Offshore islands and sandy beaches favoured as breeding sites.
Food and Feeding. Diet includes limpets, mussels and other bivalves, polychaetes, whelks and crustaceans. On rocky shores important prey are polychaetes (*Pseudonereis variegata*, *Marphysa depressa*), mussels (*Choromytilus meridionalis*, *Perna perna*, *Aulacomya ater*, and introduced *Mytilus galloprovincialis*), limpets (*Patella cochlear*, *P. granularis*, *P. barbara*, *P. concolor*, *P. longicosta*, *P. granatina*, *P. oculus*) and whelks (*Burnupena catarrhacta*, *B. lagenaria*). On sandy shores diet dominated by sand mussels (*Donax serra*, *D. sordidus*). In estuaries the bivalves *Macoma* and *Solen* are eaten. All oystercatchers attack different prey types using variety of techniques, e.g. hammering, prising, probing, stabbing (see page 314).
Breeding. Laying Oct-Apr, mostly Dec-Feb; breeds slightly later in Namibia than in South Africa. Nest is scrape in sand or among shells; less often eggs laid on bare rock. Extent of nest lining variable, probably dependent on availability, and lining may include shell fragments and stone chips; nests on islands usually well lined, less so on mainland, perhaps influenced by abundance of Kelp Gulls (*Larus dominicanus*) on islands. Clutch 1-2, usually 2, rarely 3; incubation 27-39 days. Chick predominantly grey above, with black dorsal and femoral stripes; highly cryptic on granitic shores. Fledging 35-40 days. Fledging success 0·3-0·6 young per pair per year on predator-free offshore islands, lower on mainland: eggs and young vulnerable to terrestrial predators. Age of first breeding 3 years in females, probably 4 years in males. Longevity over 18 years.
Movements. Adults sedentary, although some undertake small-scale seasonal movements and habitat shifts. Most immatures do not disperse more than 150 km from their natal site, although maximum recorded of 600 km. Species is vagrant to KwaZulu-Natal and Angola.
Status and Conservation. Not globally threatened. Currently considered near-threatened. Uncommon, with total population of c. 5000 birds. Greatest concentrations: on mainland coasts of W Cape Province, with 1600 birds; islands off coast of Namibia, with 575 birds; and islands off W Cape, with 790 birds. Outside these areas, the key sites are: mainland shores around Lüderitz, Namibia, with 160 birds; St Francis Bay, E Cape Province, with 70; and Algoa Bay, E Cape with 125. Coastal development has undoubtedly caused population decreases in some areas, and off-road vehicles cause disturbance on sandy beaches. Most productive sector of population is on islands, amounting to c. 30% of total population; the major threat to these populations is introduction of terrestrial mammalian predators. There is evidence that breeding productivity has increased on W coast since 1980, following invasion of rocky shores by the alien Mediterranean mussel *Mytilus galloprovincialis*.

Bibliography. 7. Eurasian Oystercatcher

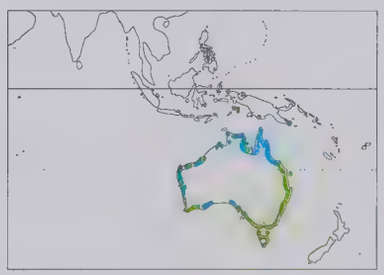
Haematopus ostralegus

French: Huîtrier pie **German**: Austernfischer **Spanish**: Ostrero Euroasiático
Other common names: Common/European/Northern Pied Oystercatcher, Sea Pie; South Island (Pied) Oystercatcher (*finschi*)

Taxonomy. *Haematopus Ostralegus* Linnaeus, 1758, Öland Island, Sweden.
At various times has been considered to include any or all of *H. palliatus*, *H. longirostris*, *H. chathamensis*, *H. unicolor*, *H. bachmani*, *H. moquini* and *H. meadewaldoi*. Taxonomic status of race *finschi* uncertain, and may be distinct species: frequently referred to *H. longirostris*, or occasionally to *H. unicolor* or even linked with *H. chathamensis*. Race *osculans* may also deserve treatment as separate species. Proposed races *malacophaga* of Iceland and Faeroes, *occidentalis* of British Is and *buturlini* of Turkmeniya and S Kazakhstan are probably insufficiently distinct to warrant recognition. Four subspecies normally recognized.
Subspecies and Distribution.
H. o. ostralegus Linnaeus, 1758 - Iceland and Scandinavia E to R Pechora, S through British Is to NW France, with isolated populations in Mediterranean from NE Spain and S France to Turkey; winters S to W Africa.
H. o. longipes Buturlin, 1910 - W & NC Russia (mouth of R Ob') S to Black, Caspian and Aral Seas and L Balkhash, and E to W Siberia; winters on coast from E Africa through Arabia to India.
H. o. osculans Swinhoe, 1871 - Kamchatka and W North Korea, and also suspected to breed from Amurland and Ussuriland through Manchuria to Hebei (NE China), and possibly in Kuril Is; winters in E China S to Guangdong.
H. o. finschi Martens, 1897 - South I, New Zealand; winters on coasts of South I and North I.



Descriptive notes. Nominate *ostralegus* 40-47·5 cm, male 425-805 g, female 445-820 g; race *finschi* c. 46 cm; male 518-615 g, female 538-622 g. Bill length of Palearctic races increases W to E: *ostralegus* male 76 mm, female 81 mm; *longipes* male 78 mm, female 89 mm; *osculans* (few data) male 99 mm, female 96 mm. Breeding adult has head, neck and upper breast all black; scapulars, upperwing-coverts and tail also black; broad white wingbar from inner secondaries to middle primaries, becoming narrower and more broken distally; middle and lower back, rump, uppertail-coverts, lower breast and belly white; eye and eye-ring red, bill orange-red, legs pink. The three Palearctic races develop a white collar on foreneck in non-breeding plumage, the only oystercatchers to do so; bill slightly duller in winter. Most similar in overall appearance to *H. longirostris* of Australia, but white wingbar of latter narrower and does not extent onto primaries; all races distinguished from *H. palliatus* by red, not yellow, eye and by black, not blackish brown, dorsal coloration; noticeably different from *H. leucopodus*, which has yellow eye and almost, wholly white secondaries. Female similar to male, but averages slightly larger with longer, thinner bill. Juvenile resembles adult with drably coloured eye, eye-ring, bill and legs, and pale margins to upperpart feathers; white neck collar develops in the first winter. Races differ mainly on bill length; also on extent of white wingbar, which in *finschi* is of variable length, not always extending onto inner primaries; *longipes* has slightly browner upperparts.
Habitat. Breeds on salt-marshes, sand and shingle beaches, less often on rocky coasts; also, especially in NW of range, breeds inland alongside water bodies and in agricultural land. In non-breeding season, mostly found on estuarine mudflats, but also salt-marshes and sandy and rocky shores. Race *finschi* breeds mostly inland on riverine shingle banks or in fields; outside breeding season, large flocks gather at major bays and estuaries.
Food and Feeding. Feeds on mussels and other bivalves, limpets, whelks, marine polychaetes, crabs, earthworms and insect larvae, rarely fish. When foraging on soft coastal substrates, important prey include bivalves (*Mytilus edulis*, *Cerastoderma edule*, *Macoma balthica*, *Mya arenaria*, *Scrobicularia plana*) and gastropods (*Littorina*). On coastal flats of W Africa, bloody cockle (*Anadara senilis*) taken. Polychaetes (*Nereis diversicolor*, *Arenicola marina*) eaten at estuaries, and crustaceans, including crabs (*Carcinus maenas*, *Uca tangeri*), also taken. Molluscs dominate diet on rocky shores, including mussels, limpets (*Patella*) and dogwhelk (*Nucella lapillus*). Inland prey includes earthworms, larvae of craneflies (*Tipula*) and caterpillars. All oystercatchers attack different prey types using variety of techniques, e.g. hammering, prising, probing, stabbing (see page 314).
Breeding. Laying (*ostralegus*) mostly Apr-May, with chicks mostly fledged by mid-Sept; *finschi* egg-laying mostly Sept-Nov. Nest is shallow scrape in ground, sometimes lined with shell and rock fragments, and, at inland sites, with small mammal droppings. Clutch size: *ostralegus* 2-5 (3), *longipes* and *osculans* 2-4 (3), *finschi* 2-3 (2). Incubation: *ostralegus* and *longipes* 24-35 days, *finschi* 24-28 days. Apart from striping common to oystercatcher chicks, upperparts and face of downy young are drab with sparse buffy tipping; crown heavily spotted black, as in *H. leucopodus*, but sooty brown throat markings do not extend onto breast, as in that species. Fledging: *ostralegus* c. 33 days, *finschi* c. 35 days. In *ostralegus*, age of first breeding 3 years in females, 4 years in males; longevity more than 40 years.
Movements. All races undertake seasonal movements and habitat shifts. Longest distance movements made by *ostralegus* and *longipes*. In nominate *ostralegus*, all inland breeders move to coast in winter; coastal populations between Norway, Gulf of Bothnia and White Sea move S; most birds spend winter in Europe, especially around the Wadden Sea and Irish Sea, with combined total of 500,000 birds; with exception of passage between Norway and Britain, North Sea acts as barrier to E-W migration; S limit to winter range of nominate *ostralegus* is normally Guinea. In races *longipes* and *osculans*, breeding and non-breeding ranges wholly disjunct. Race *longipes* winters on coast mainly from E Africa to India, but a few birds rarely penetrate as far S as South Africa. Race *osculans* occasionally winters on Anadyr estuary, Bering Is, Kuril Is and Sakhalin; also recorded in Myanmar and even Bangladesh. Birds are faithful to their non-breeding areas, but many do not return to breeding grounds for first time until their fourth year. Race *finschi* is short distance migrant, moving from inland breeding grounds to coasts of both North I and South I; several sightings of pied oystercatchers on Norfolk I and Lord Howe I, which have tentatively been attributed to *finschi* by some authors, could equally well refer to any of the other Australasian pied forms.
Status and Conservation. Not globally threatened. Both nominate *ostralegus* and *finschi* have increased during present century following on from decreases in 19th century; concomitantly, both taxa have increasingly spread to inland breeding habitats. Total breeding population of Europe reckoned at minimum of 200,000 pairs. Total population of *finschi* in early 1970's was estimated at 49,000 birds; in June 1984, 79,900 birds were counted. Numbers of race *longipes* have decreased this century, and this form is now rare in areas of Siberia where was once fairly common; reason for this decrease not known. Numbers of *osculans* have decreased since 1880's, when was described as locally abundant in parts of Japan, where is now a rare non-breeding visitor; may have bred in Japan during last century; breeding range of *osculans* poorly defined.

8. Australian Pied Oystercatcher

Haematopus longirostris

French: Huîtrier à long bec **Spanish**: Ostrero Pío Australiano
German: Australischer Austernfischer
Other common names: Pied Oystercatcher

Taxonomy. *Haematopus longirostris* Vieillot, 1817, New South Wales.
Sometimes considered conspecific with *H. ostralegus*. Occasional hybridization recorded with *H. fuliginosus*. Form *H. ostralegus finschi* frequently considered to be race of present species. Monotypic.
Distribution. Coasts of Australia and Tasmania; Aru Is and Kai Is (SE Moluccas); also occurs locally on S coast of New Guinea, where probably only non-breeding visitor.

Descriptive notes. 48-51 cm; male averages 602-675 g (410-776), female 626-710 g (500-782). White of rump extends only onto lower back and ends rather squarely; white wingbar reduced; flight-feathers wholly blackish from below. Superficially resembles *H. ostralegus*, but markedly larger; latter has back extensively white, ending in sharp "V" between scapulars; no seasonal plumage change, unlike *H. ostralegus*. Separated from pied morph of *H. unicolor* and from *H. chathamensis* by crisp lower border to black breast; from *H. palliatus* by red, not yellow, eye and black, not blackish brown, dorsal coloration; *H. leucopodus* has yellow eye and mostly white secondaries. Female as male but averages somewhat larger with longer bill. Juvenile has brownish plumage and dull bare part colours.
Habitat. Breeds on salt-marshes, sandy and shingle beaches, dunes and pastures. Outside breeding season, typically occurs on estuarine mudflats and sandy beaches.
Food and Feeding. Prey includes marine and terrestrial polychaetes, gastropods (*Paphes striata*, *Anapella cycladea*) and bivalves (*Mytilus edulis*, *Codakia*, *Chione*), as well as crustaceans, insects and fish. All oystercatchers attack different prey types using variety of techniques, e.g. hammering, prising, probing, stabbing (see page 314).
Breeding. Breeding May-Sept in N, Aug-Jan in S. Nest is shallow scrape in ground, usually close to the high water mark. Usually 2 eggs (1-3), rarely 4; incubation 28-32 days. Downy chick pale speckled grey-brown with dark brown dorsal and femoral stripes; lower breast and belly white. Fledging 42-49 days, reportedly sometimes up to 56 days. Fledging success 0·27-0·89 young per pair per year. Young remain in parental territory for 1-6 months. Age of first breeding 4-6 years. Long-term mate and nest-site fidelity.
Movements. Forms non-breeding flocks, but no major movements recorded; may breed throughout range. Status in S New Guinea uncertain; may be only non-breeding visitor, but, if so, origin of such birds unknown.
Status and Conservation. Not globally threatened, although subject to disturbance from recreation, including use of off-road vehicles. By far the commonest oystercatcher in Australia; minimum population 10,000 birds. The most important 20 sites each support more than 100 birds, with a combined total of 5680 birds. Most abundant in large bays in Victoria, Tasmania and South Australia, but especially in stretch from Eyre Peninsula to Bass Strait.

Bibliography. Ashby (1991), Baker, A. J. 9. Chatham Oystercatcher

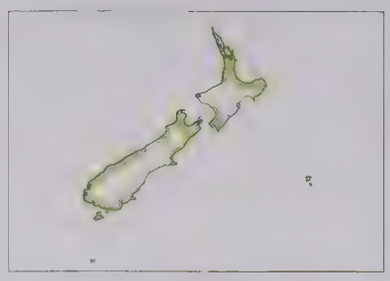
Haematopus chathamensis

French: Huîtrier des Chatham **German**: Chathamaustemfischer **Spanish**: Ostrero de las Chatham

Taxonomy. *Haematopus ostralegus chathamensis* Hartert, 1927, Chatham Islands.
Has frequently been considered a race of *H. unicolor* or *H. ostralegus*; differentiation relatively weak, and species status questionable. Form *H. ostralegus finschi* has on occasion been associated with present species. Monotypic.
Distribution. Chatham Is, E of New Zealand, where restricted to coasts of Chatham, Mangere, Rangatira (formerly South-east I) and Pitt.



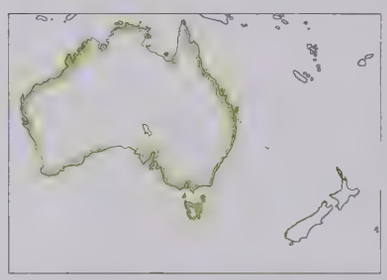
Descriptive notes. 47-49 cm; male averages 540 g, female 640 g. Black frontal coloration extends well down breast, and transition to the white lower breast is mottled, both features also found in pied morph of *H. unicolor*, but in no other Old World pied oystercatcher. Most closely resembles pied morph of *H. unicolor*, but averages slightly smaller with much shorter bill; legs and feet stockier; in flight, white uppertail-coverts less conspicuous. Distinguished from *H. palliatus* by red, not yellow, eye and black, not blackish brown, dorsal coloration; from *H. leucopodus* by red, not yellow, eye and mostly black secondaries. Female similar to male, but averages larger and longer-billed. Juvenile has brown fringes to feathers of upperparts, and dull bare part colours.
Habitat. Mostly found on rocky shores, less often on sandy or gravel beaches; sometimes nest in sites with some short vegetation.
Food and Feeding. Prey includes the anemone *Isactina tenebrosa*, an unusual prey type for oystercatchers; also polyplacophorans (*Chiton pelliserpentis*, *C. glaucus*), gastropods (*Haliotis australis*, *H. iris*, *Cellana chathamensis*, *Patelloidea corticata*, *Zelidoma digna* and several others), bivalves (*Aulacomya maoriana*, *Mytilus edulis*, *Xenostrobus pulex*), barnacles, isopods, echinoderms and ascidians. Rocky shores favoured for foraging. All oystercatchers attack different prey types using variety of techniques, e.g. hammering, prising, probing, stabbing (see page 314).
Breeding. Breeds Oct-Mar, with most laying Oct-Dec. Nest is scrape in ground, lined or unlined; often in sheltered site under overhanging rock or vegetation, sometimes in small cave or on cliff ledge. Clutch size 2-3; 3-egg clutches commonest early in breeding season; incubation c. 25 days. Chick has heavily speckled grey upperparts; tail with a conspicuous white subterminal band. Fledging period 46-49 days. Fledging success 0·20-0·85 (0·47) young per pair per year.
Movements. Mostly sedentary and territorial throughout the year; juvenile dispersal up to 40 km between islands.
Status and Conservation. ENDANGERED. Population increased from c. 50 birds in early 1970's to 100-110 birds in breeding season of 1987/88, including 44 pairs. Largest numbers on Chatham I, with 25 pairs, where population probably increasing; 9 pairs on Pitt, 8 on Rangatira, 2 on Mangere; possibly 1 pair on nearby Star Keys. Main threat is predation by introduced cats, rats and Wekas (*Gallirallus australis*); within range, only Rangatira I and Mangere I are predator-free, and both are nature reserves; in parts of range browsing mammals also have negative effects on species, while predation by Brown Skuas (*Catharacta antarctica*) may be another significant factor. Human disturbance is also a problem; access has been prohibited to a section of coast of Rangatira, in order to reduce level of disturbance. On Chatham I, some pairs nesting on sandy beaches are forced down towards seashore by introduced maram grass (*Ammophila arenaria*), where nest is more vulnerable to flooding during storms or high tides; since 1992, conservation efforts to avert this by moving nest further in from sea: artificial incubation of eggs, for return immediately prior to hatching, is probably contributing to reduce risk of predation.
Bibliography. Baker, A. J. (1972, 1973a, 1974a, 1974b, 1974d, 1975a, 1975d, 1977), Bell (1986), Collar & Andrew (1988), Falla (1939), Fleming (1939a), King (1978/79), Lindsay *et al.* (1959), Marchant & Higgins (1993), McKean (1978), Robertson (1985), Sibson (1982), Williams & Given (1981).

10. Variable Oystercatcher

Haematopus unicolor

French: Huîtrier variable **Spanish**: Ostrero Variable
German: Neuseeländischer Austernfischer
Other common names: New Zealand Black/Sooty Oystercatcher; Northern Oystercatcher ("*reischeki*")

Taxonomy. *Haematopus unicolor* J. R. Forster, 1844, New Zealand.
Has been considered conspecific with *H. chathamensis* and sometimes also with *H. ostralegus*. The various different morphs have been considered separate races, or even distinct species, e.g. pied morph formerly labelled "*H. reischeki*"; in past, *H. ostralegus finschi* too was considered to be a pied morph of present species. Monotypic.
Distribution. New Zealand, on coasts of North I and South I and adjacent islands.
Descriptive notes. 47-49 cm. Polymorphic in plumage and size: in black morph, male averages 678 g, female 724 g; in pied morph male 717 g, female 750 g; in intermediate morph male 710 g, female 779 g. Culmen shortest in black morph, male 79 mm, female 89 mm; longest in intermediate morph, male 84 mm, female 95 mm. Black morph entirely black with red eye, eye-ring and bill; coloration almost identical to that of *H. fuliginosus*, but bill longer and tail does not project beyond wingtips at rest. Pied morph differs from other Old World pied oystercatchers, except *H. chathamensis*, in black frontal coloration extending further down breast, and ending with untidy lower border; lower breast and belly predominantly white, with a few dark feathers; lacks white shoulder patch of other pied species; in flight, white wingbar reduced, back and rump blackish, with white only on uppertail-coverts. Intermediate morphs range between black and pied extremes, generally being closer to former; they are also larger, longer-billed and longer-winged than other morphs. All morphs distinguished from *H. bachmani*, *H. ater* and *H. palliatus* by red, not yellow,



eye and black, not blackish brown, dorsal plumage; separated from *H. leucopodus* on eye colour and mostly black secondaries. Female similar to male, but averages larger and longer-billed. Juvenile has black areas browner, with some pale buff tips to scapulars and upperwing-coverts; bare parts duller.
Habitat. Breeds on sandy beaches and adjacent dunes. Outside breeding season, occupies sandy and rocky shores. On Stewart I, some pairs nest in small rocky bays with overhanging trees: chicks are hidden in caves if danger threatens.
Food and Feeding. Prey includes polychaetes (*Glycera americana*, *Perinereis nuntia*), polyplacophorans (*Chiton pelliserpentis*, *C. glaucus*), gastropods (*Haliotis iris*, *Cellana*), mussels (*Mytilus edulis*, *Aulacomya maoriana*, *Modiolus neozelandicus*), several other bivalve species, as well as isopods, amphipods and crabs. All oystercatchers attack different prey types using variety of techniques, e.g. hammering, prising, probing, stabbing (see page 314).
Breeding. Eggs usually laid Dec-Jan, sometimes as early as Sept. Nest is shallow scrape in sand or shingle, with minimal lining. Clutch size 2-3, usually 3; incubation 25-32 days (28). Chick patterning variable, depending on colour morph: that of black morph resembles that of *H. fuliginosus* in having dark underparts; pied morph chick has breast white, upperparts greyish brown, but less distinctly patterned than in *H. ostralegus finschi*. Fledging 42-49 days. Fledging success variable, 0·5 young per pair per year in protected sites, lower elsewhere. Longevity record 19 years 10 months.
Movements. Forms non-breeding flocks, but no major movements.
Status and Conservation. Not globally threatened. Generally uncommon, and less frequent on E coasts than elsewhere; total population estimated at 3900 birds, of which roughly 70% black morph, 20% pied morph and 10% intermediate morph; estimated c. 2600 birds on North I, c. 1150 birds on South I. Low breeding success has been linked to possible effects of human disturbance, in the form of off-road vehicles, dogs, etc.; introduced mammals have also caused many losses through predation of eggs and chicks. In recent years, several populations apparently increasing, especially on North I; conservation activity includes protection of nests from predators and disturbance.
Bibliography. Baker, A. J. (1972, 1973a, 1973b, 1974a, 1974b, 1974c, 1974d, 1975a, 1975d), Baker, A. J. *et al.* (1981), Blackburn (1968), Braithwaite (1950), Chambers (1989), Falla (1939), Falla *et al.* (1981), Fleming, C.A. & Falconer (1974), Fleming, P. M. (1984), Watt (1955).

11. Sooty Oystercatcher

Haematopus fuliginosus

French: Huîtrier fuligineux **German**: Rußaustemfischer **Spanish**: Ostrero Negro Australiano
Other common names: Spectacled Oystercatcher (*opthalmicus*)

Taxonomy. *Haematopus fuliginosus* Gould, 1845, Tasmania.
Occasional hybridization recorded with *H. longirostris*. Form *opthalmicus* generally considered to be a race of present species, based on a putative region of intergrading with nominate *fuliginosus* in W Australia, where both taxa are rare, but no good evidence of interbreeding; also, some confusion regarding range limits of both forms, with *opthalmicus* usually said to be restricted to Gulf of Carpentaria and Cape York Peninsula; striking differences in eye-ring colour suggest that *opthalmicus* may well be a distinct species; field and laboratory research required, in order to clarify this case (see page 309); emendation of name to *ophthalmicus* is not justified. Two subspecies currently recognized.
Subspecies and Distribution.
H. f. opthalmicus Castelnau & Ramsay, 1877 - coast and islands of N Australia from Shark Bay (CW Western Australia) to Lady Elliot I (SE Queensland).
H. f. fuliginosus Gould, 1845 - coast and islands of Australia, from Houtman Abrolhos Is (CW Western Australia) round S coast and up E coast to about Brisbane (SE Queensland); Tasmania.

Descriptive notes. 46-49 cm; 550-774 g. Entirely sooty black oystercatcher with red eye, eye-ring and bill, and pink legs. Longer-tailed than other black oystercatchers; folded wings do not reach tail tip in present species, as they do in shorter-tailed, but otherwise very similar, black morph of *H. unicolor*. Differs from all New World black oystercatchers in having black dorsal coloration and red eye; wings and bill longer than in *H. moquini*, and eye-ring and bill redder. Female averages very slightly larger, with shorter wings and broader bill. Juvenile duller and browner, with pale buff or white tips to most of feathers; bare parts duller. Race *opthalmicus* differs from nominate race in having slightly shorter wings, a shorter, heavier bill, and a prominent fleshy yellowish to orange eye-ring; bill markedly shorter than in black morph of *H. unicolor*.
Habitat. Nominate *fuliginosus* breeds on sand and shingle beaches, and also on rocky shores, especially on islands; outside breeding season typically occurs on estuarine mudflats and sandy beaches. Race *opthalmicus* occurs more commonly on offshore islands with fringing coral reefs than on mainland shores.
Food and Feeding. Diet includes limpets, whelks, bivalves, chitons, crustaceans, echinoderms and ascidians, and also stranded fish. Commonly taken prey items include gastropods (*Cellana tramoserica*, *Clypidina rugosa*, *Patella peroni*, *Dicathais orbita*, *Nerita atramentosa*, *Turbo undulatus*); bivalves eaten include *Trichomya hirsuta*, *Xenostrobus pulex* and *Austromytilus rostratus*. Several species of polyplacophorans also eaten, most commonly *Ischnochiton australis*. Feeding habits of race *opthalmicus* undocumented. All oystercatchers attack different prey types using variety of techniques, e.g. hammering, prising, probing, stabbing (see page 314).
Breeding. Season Aug-Jan. Nest is scrape in ground, often among boulders, lined to varying extents with shell fragments. Usually 2 eggs (2-4); incubation and fledging periods unknown. As in other Old World oystercatchers, crown of chick is well marked with black; unusual among oystercatchers, however, the chick is an even, rusty colour and lacks white down on belly. No information available on breeding of race *opthalmicus*; chick undescribed.

Movements. Mostly sedentary. In area of Hobart (Tasmania), birds move very short distance from breeding islands to estuary of R Derwent in winter. Single record on Christmas I (Indian Ocean).
Status and Conservation. Not globally threatened. Total population probably under 4500 birds. Nominate *fuliginosus* is generally uncommon, and probably numbers less than 3500 birds; most abundant in SC & SE Australia, and also on Tasmania. The most important 20 localities together support a maximum of 2180 birds, including 1660 birds at only 7 localities; conservation action is considered necessary at these 7 main sites, in order to minimize habitat loss. Numbers in Hobart area decreased by c. 40% between early 1960's and early 1980's, but reasons for decrease unknown; over the same period, numbers of *H. longirostris* in the same area remained unchanged. Total population of race *opthalmicus* probably less than 1000 birds; precise distribution poorly known, but appears patchy; this and low abundance may be linked to apparent requirement of co-occurring islands and coral reefs, the latter being favoured feeding areas; no major concentrations of this form are known. Much scope for research.
Bibliography. Amiet (1957), Anderson, M. (1993), Ashby (1991), Baker, A. J. (1975a, 1977), Blakers *et al.* (1984), Chafer (1992a, 1992b), Considine (1979, 1982), Ford (1987), Hewish (1990), Lane & Davies (1987), Marchant & Higgins (1993), Mathews (1913-1914), McKean (1978), Newman (1982c), Newman & Fletcher (1982), Pringle (1987), Schulz (1989), Serventy & Whittel (1976), Slater (1987), Storr (1985), Thomas (1968), Wakefield & Robertson (1988).

Class AVES

Order CHARADRIIFORMES

Suborder CHARADRII

Family IBIDORHYNCHIDAE (IBISBILL)

- Distinctive medium-sized wader, strongly built but elegant, with contrasting plumage, decurved bill and long legs.
- 39-41 cm.

- Mountain systems of Central Asia.
- Shingle-bed rivers.
- 1 genus, 1 species, 1 taxon.
- No species threatened; none extinct since 1600.

Systematics

The treatment most appropriate for the Ibisbill (*Ibidorhyncha struthersii*) has long been a matter of discussion amongst taxonomists. Whereas in early classifications it was often associated with the Scolopacidae and their allies, nowadays there is reasonable consensus that it is most closely related to three groups, the oystercatchers (Haematopodidae), the avocets and stilts (Recurvirostridae) and the lapwings and plovers (Charadriidae), although there is still considerable disagreement as to which of these groups contains its closest relatives.

Perhaps equally controversial is the question of precisely what level of taxonomic separation it requires from these other groups. On frequent occasions it has been argued that the peculiarities of the Ibisbill do not warrant its separation in its own monotypic family, and authors have frequently placed it within Recurvirostridae, while it has also been linked with Haematopodidae. It shows marked similarities with the oystercatchers in terms of general breeding behaviour and calls. On the other hand, there are many reasons for linking it with the avocets and stilts, not the least of which is DNA evidence, which suggests that these birds and the Ibisbill are very close relatives, sharing a single tribe in a subfamily that includes the oystercatchers as the only other tribe; the lapwings and plovers would make up the other subfamily in this expanded version of Charadriidae.

In contrast with these various points of proximity are the Ibisbill's distinctive morphology, also visible in young birds, together with its unique territorial behaviour. As the balance of the evidence rests at present, there is probably sufficient reason to justify classifying the Ibisbill in a family of its own, perhaps forming some sort of a link between Haematopodidae and Recurvirostridae. However, the debate will undoubtedly continue.

The origins of this highly specialized wader possibly date back to the early Tertiary, when the Charadriiformes were at their early stages of development. Study of morphological and anatomical features has, in fact, led to the conclusion that at present this species does not appear to have close relatives in any of the groups with which it is often associated. Very possibly, Recurvirostridae, Haematopodidae and Ibidorhynchidae separated from the main branch of Charadriiformes at different times and developed independently from each other.

On the other hand, a number of similarities in morphology and ecology between Ibidorhynchidae and Haematopodidae led to the theory that they had a common ancestor which developed on the shores of the ancient sea of Tethys in the heart of what is now Eurasia. Tethys started to disappear in the Tertiary, as the mountain systems of Central Asia began to form. Ibidorhynchidae may have developed ecological links with the newly forming habitats, whereas Haematopodidae continued to associate itself with the remains of the ancient sea. Earlier hypotheses argued that the ancestral form of the Ibisbill was an Arctic dweller, and that during recent glaciations it was pushed into Central Asian mountain refuges where it continued its development, but these hardly seem feasible, for it would surely have taken much longer for such a highly specialized form to develop.

Morphological Aspects

In appearance, the Ibisbill is one of the most distinctive of all the waders, or shorebirds. It is medium-sized and strongly built, normally weighing in the region of 270-320 g, with females slightly larger than males. Its very long, decurved bill and its rather strikingly contrasted plumage combine to make it unmistakable.

The bird's most notable feature is its crimson bill, which measures 68-82 mm, with a tendency to be slightly longer in the female than in the male. The bill would appear to have developed to enable the Ibisbill to forage in rocky mountain streams, by means of a number of specialized methods of feeding (see Food and Feeding).

For a bird that spends a good deal of time wading in a fair depth of water the tarsus is relatively short; it is reticulated throughout. There are three toes, with the outer and middle toes connected by a small, but deeply indented, web, but no webbing between the middle and inner toes. The legs are greyish purple in colour, quite different from that of the bill, although in museum collections they turn crimson after a short while and so look much the same colour as the bill. During the breeding season, Ibisbills run short distances, very much in the mode of *Charadrius* plovers, holding the head and bill down and standing upright only to look around and evaluate a given situation. They are good swimmers and will cross river channels by this means rather than by flying.

The Ibisbill's plumage is striking. The crown and forepart of the face are black or dark brownish black, with a white margin towards the rear. The nape, neck, mantle and upper back are bluish grey, while the lower back is brownish grey. The rump shows some faint greyish black bars, which become more pronounced closer to the tail, and on it, where they can be as much as 4 mm wide. The

The Ibisbill is usually seen feeding alone on slow-moving rivers in high mountain regions of Central Asia. Wholly dependent on aquatic invertebrates, it will often stand in quite deep water for long periods, plucking insects from the surface as they float by. Alternatively, as water temperatures influence insect activity, it may use its long, decurved bill to probe under stones or rake sideways through the water in order to find food. The white facial feathering shows that this bird is in non-breeding plumage.

[*Ibidorhyncha struthersii*, India. Photo: Markku Huhta-Koivisto]

belly is white with a broad, circular black breast band, above which is a narrow white band separating it from the grey upper breast. The bold grey, dark brown and white plumage provides remarkably effective camouflage in the surroundings, an asset which is particularly advantageous when a bird is incubating eggs or brooding chicks. Winter plumage is similar, except that there is a fair amount of scattered white feathering on the face.

The wings appear generally brownish grey, but the outer primaries and coverts are blackish. A dull white band across the inner primaries and outer secondaries is visible only in flight, when it appears rather conspicuous. The overall aspect of an Ibisbill in flight recalls that of an oystercatcher, although its wings are generally very square, and the plumage is, of course, totally dissimilar. Its flight is strong, with sharp but comparatively slow wingbeats.

The juvenile is distinctly browner than the adult, lacking the intense black markings on the head and breast, which are grey-brown. The mantle and wings are brown to brownish grey, with buff-orange fringes giving a scalloped effect. Bare parts too are duller, with the bill dark pinkish grey and the legs pink or greenish grey; the iris is pale yellowish red, as opposed to dark red in adults.

The moult pattern of the Ibisbill is little known, although it is thought to follow those of other Charadrii. Full moult usually starts at the end of June, whereas spring moult into breeding plumage reportedly occurs in March.

Unlike the cases of the oystercatchers, avocets and stilts, salt glands are nearly absent in the Ibisbill. This can, of course, be explained by the fact that water in the Ibisbill's habitat is almost totally devoid of salt, as it comes from snow melting in the mountains. Conversely, the other groups occur commonly in environments where water is high in salinity, whether on coasts or inland on saline lakes.

Habitat

The Ibisbill is closely associated with the bleak mountain environment, in particular shingle-bed rivers at 2000-4000 m. However, it has also been reported breeding at altitudes as high as 4400 m and as low as 500 m.

Even though the Ibisbill is widely distributed within the mountain systems of Central Asia, its habitat is very much the same throughout its range: a shingle-bed river valley varying from 100 m to 1500 m wide, covered with pebbles, cobbles and small boulders of varying sizes, usually interspersed with patches of sand and silt. Some of the longer valleys may accommodate several pairs of Ibisbills. Such areas normally contain more than one river channel and often hold a complicated network of small, shallow channels, islets and peninsulas which provide the main feeding areas for the Ibisbill. These river valleys are usually treeless and indeed are generally fairly free of vegetation; they tend to have a slope of 5-15° or less, which ensures a relatively slow flow of water.

Ibisbills exhibit a very clear ecological preference for this particular type of habitat, since only here can they find suitable food supplies. Unlike other river specialists of the zone, such as the Brown Dipper (*Cinclus pallasii*), the White-capped Redstart (*Chaimarrornis leucocephalus*) and the Plumbeous Redstart (*Rhyacornis fuliginosus*), which are adapted to both the turbulent, boulder-strewn channels and slower-flowing waters of mountain rivers, the Ibisbill is restricted to areas of slow water flow. Hence, despite a comparatively expansive range, the high degree of specialization in the Ibisbill's feeding habits strictly limits it to the much more reduced areas of suitable habitat that are available.

General Habits

Ibisbills are solitary breeders, but the limited availability of suitable breeding sites sometimes creates the impression of loose colonies, despite individual territoriality. In autumn and winter, they are also generally solitary but are sometimes seen in pairs or in small groups of up to eight birds; flocks of up to 25 birds have also been reported. Outside the breeding season they sometimes roost together, for instance a group of seven birds was observed in early October in the Trans Ili Mountains of Kazakhstan, roosting together on a tiny islet. During winter months, birds tend to be fairly restful, but with the breeding season approaching they become much more active and vocal; at this time they become susceptible to disturbance.

Ibisbills feed during the day, most actively in the morning hours, when they are typically to be seen in short riverside grass, running a few steps and then stopping abruptly. They also have a characteristic habit of wading breast deep in the water, placing the whole head and neck under water in search of food. Birds will often spend long periods of time sitting motionless on the bank of a river or lake, when they may become virtually invisible against the surrounding landscape.

During the breeding season, Ibisbills tend to take flight more often, but otherwise they rarely fly unless disturbed, even apparently preferring to cross rivers by swimming. When disturbed, a bird usually moves its head up and down, sometimes as much as 18 times in one minute, in an apparent display of nervousness. Occasionally, an Ibisbill will run with its head turned to one side, giving the peculiar impression that the head is being carried loose, while the bird moves forward.

There is no mistaking the identity of an Ibisbill: the long decurved deep crimson bill is the give-away feature. The black facial mask, crown and breast band add distinctive notes to the largely pale plumage. As the bird flies, with its head slightly raised and its neck stretched out, the white wing-flash and dark markings around the rump and tail also become conspicuous. The legs are rather short and do not protrude beyond the tail.

[*Ibidorhyncha struthersii*, Uttar Pradesh, India. Photo: Tim Loseby]

Voice

Outside the breeding season, Ibisbills generally tend to be silent, and it is only with the onset of breeding activity in spring that they start to become much more vocal.

Calls can be made in three main situations: when a bird is disturbed, in territorial displays with a neighbouring pair, or in courtship display. The call typically made during courtship display resembles that of the Eurasian Oystercatcher (*Haematopus ostralegus*), but it is louder, more melodious and silvery, consisting of up to 40 rather penetrating notes. The species also gives three or four loud "kleep" notes, the first two of which come close together, whereas the third and fourth are given after short pauses. Both types of call are reported to occur during territorial and agonistic behaviour, as well as during courtship displays.

Food and Feeding

The Ibisbill is a highly specialized species, entirely dependent upon a very harsh habitat for its food. Its diet consists of a variety of insects and their larvae, crustaceans and small fish. During the breeding season at higher altitudes, small fish are only taken occasionally, but their capture is much more frequent during the winter months at lower altitudes, where fish may comprise an important part of the diet.

A study of feeding behaviour during mid-April in Langtang Khola, Nepal, revealed that the food taken consisted mainly of aquatic insects. Faecal analyses revealed a diet of stonefly larvae (40%), mayfly larvae (34%) caddisfly larvae (8%), caddisfly adults (9%) and small fish (3%).

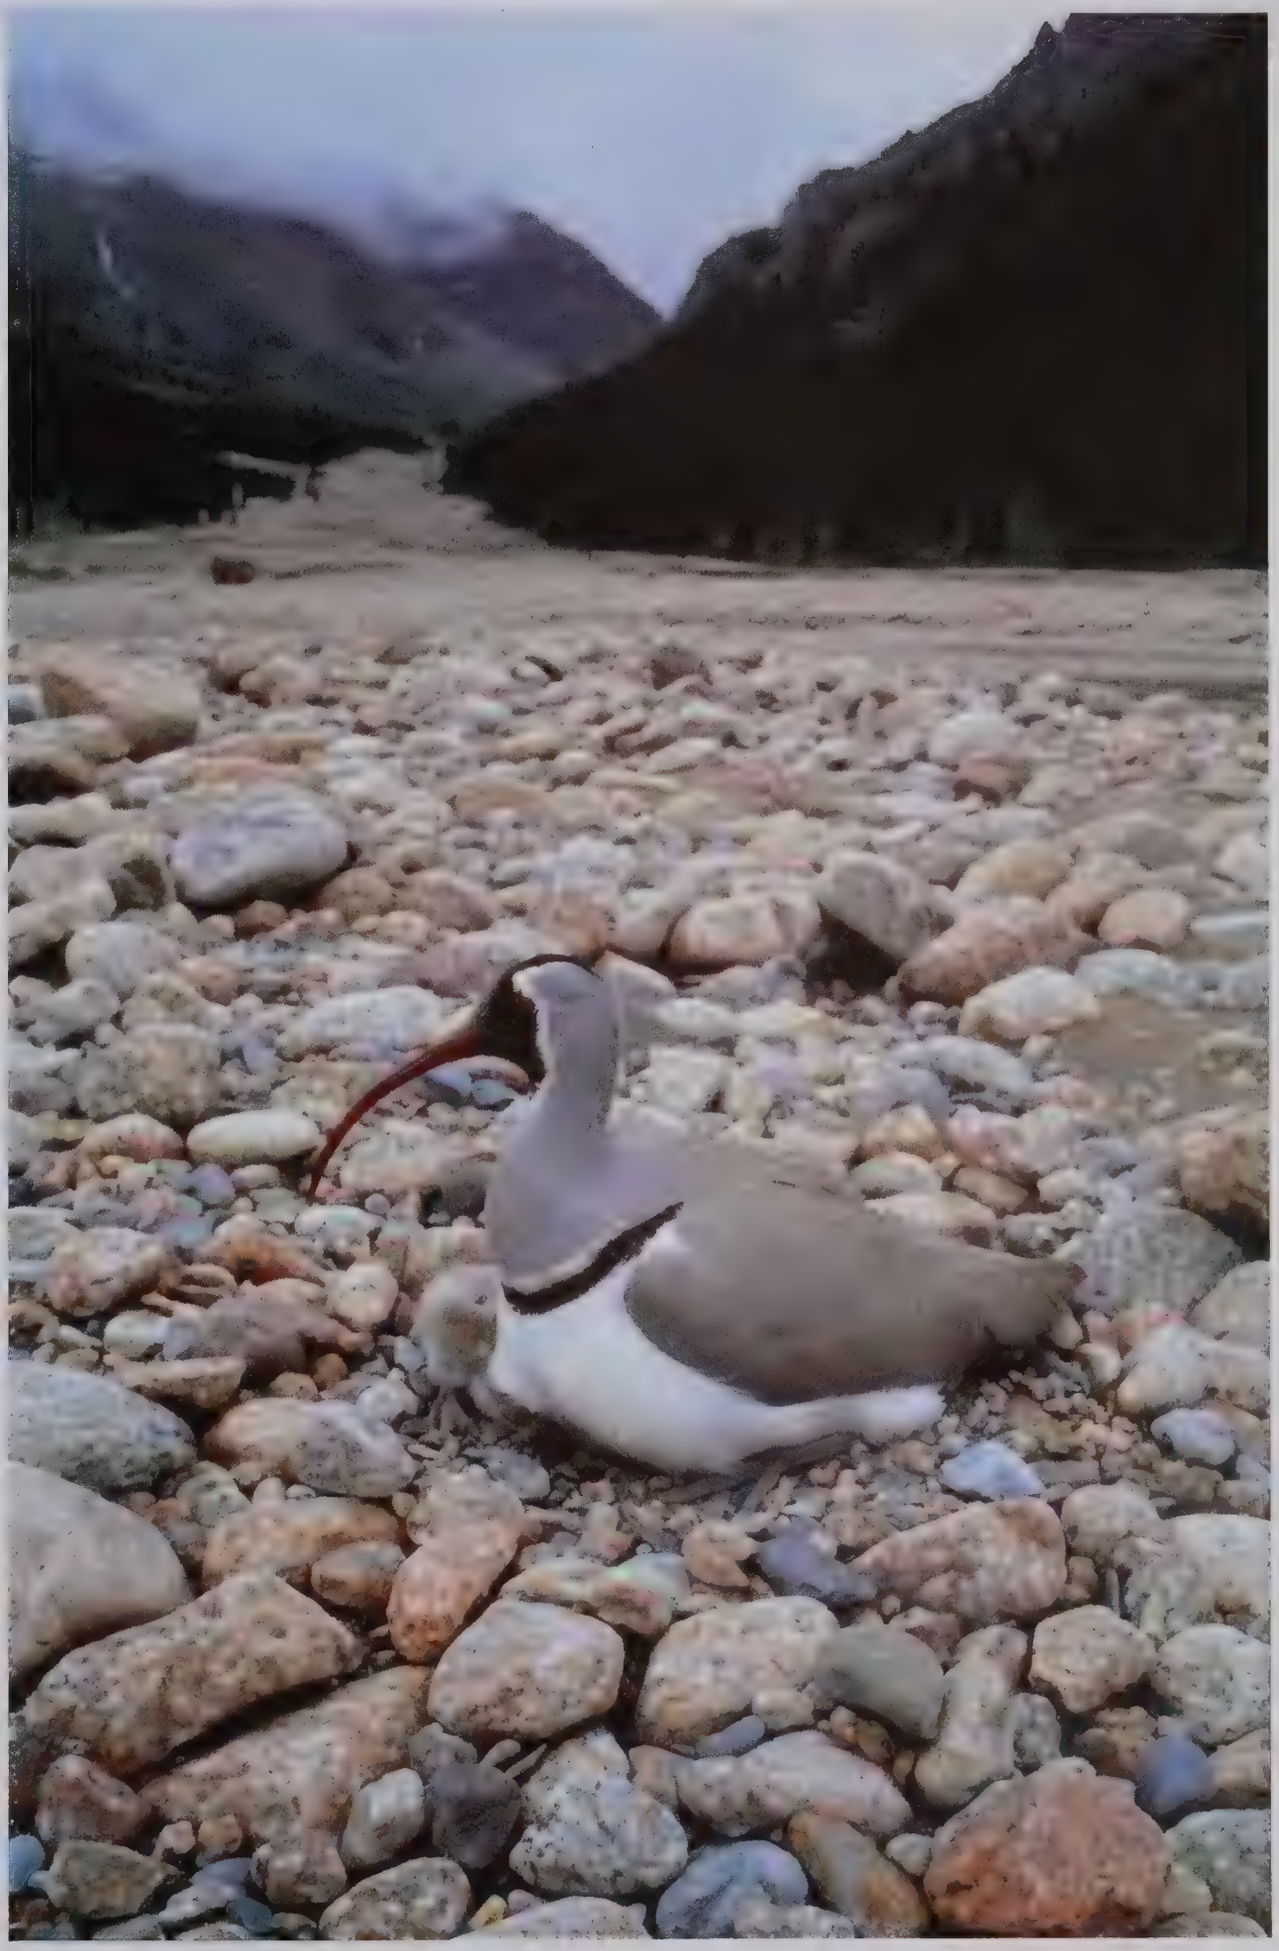
There are three main feeding methods: pecking, probing and raking. An Ibisbill will often peck drifting insects from the water surface, staying more or less at the same spot by the beginning or end of rapids; sometimes the entire foraging period of three or four hours is spent like this. However, normally birds peck while standing in the water at about belly depth and feeding singly, both members of a pair feeding together only occasionally. Probing is also carried out at about belly depth, the bill being inserted amongst all sizes of submerged stones, but the birds move about much more, taking roughly 15 minutes to cover 20 m of river edge. The third method, raking, involves tilting the head to one side and raking the bill sideways through the pebbles. When using this method, birds may dislodge invertebrates, which drift into view, enabling a bird to peck them up.

The cold, clear streams of the mountain systems of Central Asia present difficult feeding conditions. Yet the Ibisbill is very well adapted to the conditions and is able to switch its feeding method quickly in response to changing weather, as well as moving between aquatic and riparian feeding habitats. Fluctuating water temperatures affect the activity patterns of aquatic insects, which in turn affect the feeding behaviour of Ibisbills. Low water temperatures inhibit insect activity forcing the birds to feed by tactile probing, or by raking insects into view, whereas higher water temperatures permit the Ibisbills to feed on active or drifting insects.

Breeding

As with most other aspects of its biology, the breeding habits of the Ibisbill remain rather poorly known. It would appear to be monogamous, at any rate within one season, but detailed long-term studies are still required in order to clarify many points. Observations by Sálim Ali in Sikkim indicated that three adults seemed to be interested in the nest he was watching, but, while the implications of this could be many, to date there appear to be no further records of a similar sort.

The breeding season starts at slightly different times depending on the altitude, although the time delay is not as much as one might expect within a range as great as 500-4400 m. Pair formation takes place in March and early April, after which breeding territories are formed. In places where more than one pair of Ibisbills breed, territories vary in length from 90 m to 1000 m of river valley. There is also considerable variation in the width of a territory, with a minimum of over 100 m, but sometimes much more. Where there is a solitary breeding pair, for example in the delta of a mountain river, a territory may be well over 1 km², and birds move extensively around it. In the Trans Ili mountains of Kazakhstan, an area of about 1·3 km² supported three breeding pairs.



During courtship displays a male will call and move its head up and down. A female responds to this behaviour by moving slowly towards the male and then turning and standing motionless. The male then approaches rapidly and briefly simulates copulation. Eventually copulation takes place, after which both birds ruffle their feathers and start preening or foraging. Nest-site inspection involves the same initial behaviour, leading to the rapid circling of a potential nest-site.

The nest-site is situated on a bank, island or peninsula along the main river valley, sometimes as much as 100 m from the water. The nest itself is a simple pit, which in the Himalayas is about 30 cm wide and 6 cm deep, although nest bowls examined in Kazakhstan were somewhat smaller, at around 20 cm in diameter and about 2·5-3 cm deep. The nest is sometimes lined with small pebbles usually not exceeding 1 cm in size.

Laying takes place from the end of April to the first half of May. Eggs are laid daily, to produce a clutch of two to four eggs, most commonly four. The broadly oval eggs have a rather thin shell, but are fairly large for the size of the bird, on average measuring 51 x 37 mm and weighing around 37 g. They are drab grey to greenish grey with dark brown spots and speckles, mainly concentrated at the large end. If the first clutch is lost, birds may attempt a second.

The length of the incubation period has not yet been determined, but it is known that both parents take part. The female undertakes about two thirds of the daytime incubation, but the pattern at night is not clear. During the incubation period birds will not leave the nest unattended for more than 1-2 minutes at a time. Conditions can be harsh for incubating birds, and even in May snow is not a rarity in the mountains of Central Asia, so that a sitting bird may be almost covered with snow. An incubating bird often places its bill under the wing and in this posture is very difficult to detect. Approximately once an hour the duty bird will change its position, by up to 180°, but the eggs are turned less often. Observations at one nest-site showed that adults swapped duty about seven times a day. At the change over, the bird taking up incubation approaches the nest on foot. The departing bird moves away from the nest when its mate is still 10-15 m away. Both birds remain silent during the change over. This incubation pattern remains very much the same right up until the eggs hatch.

Hatching takes place from mid-May to late June. The newly-hatched chick is quite distinctive. Its brownish bill is about 18 mm long and shows slight decurvature only in its distal third. There are brown patches on the ear-coverts, while the upperparts are grey with blackish barring, the intervals increasing towards the tail, and this same pattern occurs on the wings. The belly is

A bird of specialized feeding habits, the Ibisbill is restricted to high altitude, rather flat-bottomed river valleys, where the water flows fairly slowly through a network of channels forming banks and islets of shingle, pebbles and rounded boulders. Here it breeds, and only in autumn will it move down to a similar shingle-bed valley at a lower altitude in order to be able to feed in unfrozen waters. The nest-site is a depression hollowed out in the sandy shingle, sometimes lined with pebbles. The usual clutch consists of four greenish grey eggs speckled with brown. Both parents often face severe weather conditions, even snow, as they take turns in incubation, the length of which has not yet been ascertained. The newly hatched chick already has an 18-mm-long slightly decurved bill, mainly greyish down with dark barring and very large toes. Once dry, the chicks are led away from the nest and may be brooded by both parents for up to 23 days. The parents show great agitation and sometimes present an aggressive attitude towards an intruder, while the chicks remain "frozen" when danger threatens. Both parents and young birds will remain in the same general area until the onset of bad weather in the autumn obliges them to move downhill to milder climes.

[*Ibidorhyncha struthersii*, Trans Ili Range, Tien Shan, Kazakhstan. Photo: V. Morozov]

white and the throat greyish, while the sides of the neck and nape are ash grey, producing a whitish collar. The legs are greenish grey, and the chick has huge toes, the middle toe measuring around 25 mm. The iris is brown.

When the chicks are dry, the female immediately takes them away from the nest, at which point they are joined by the male, and the adults greet one another by bobbing their heads and necks. Studies at one nest-site showed that it may take an hour for the whole family to move 100 m away from the nest. During subsequent days, the family may remain roughly 100-200 m from the nest-site. Normally one adult attends the young while the other is feeding. In guarding the young, an adult usually stands somewhere higher, for example on a small rock, and will occasionally engage in preening. Both parents brood their chicks, sometimes for as long as 23 days after hatching. Young Ibisbills move about solitarily, but will stay within 50-60 m of an adult. They can fly when about 45-50 days old.

When disturbed, an incubating Ibisbill leaves the nest quickly and runs silently away. Only when an intruder has moved some 100-150 m away will the bird return to the nest. Once the chicks have hatched, this behaviour changes dramatically. Adults take to the air at a distance of about 300 m from an intruder and, emitting loud piping calls, will fly directly at the intruder, sometimes coming as close as 10-15 m before abruptly changing direction and flying on another 10-15 m. If the disturbance persists for more than half an hour, birds may disappear altogether for some time before starting to call again, usually from the ground. As the chicks grow, the adults become less active in showing alarm and attacking intruders. Occasionally, Ibisbills may perform an injury-feigning distraction display in an attempt to draw attention away from the chicks.

The chicks themselves react to danger by sitting motionless among pebbles where they may be almost invisible. On an alarm call of the parents, they can stay motionless with their eyes wide open for up to an hour. After the chicks have fledged, all members of the family stay in the same area until autumn, when they move off with the approach of the first spells of really cold weather. Family groups are sometimes joined by single adult birds.

Very few data have so far been collected on breeding success. Observations of two breeding attempts revealed that one and two chicks respectively were reared, and the young birds were seen with their parents up until the early autumn. In both cases one egg was infertile, and this caused one of the pairs to incubate for a longer period. One of the main threats to breeding Ibisbills may be grazing sheep, which sometimes use river valleys as passageways, trampling nests on the way. The red fox (*Vulpes vulpes*) occurs in the mountains of Tien Shan and may also pose a threat to nesting Ibisbills. Many nests are at permanent risk of flooding, since water levels in the mountain rivers change dramatically, as a result either of snow and ice melting or of a sudden increase in rainfall.

Movements

The Ibisbill is an altitudinal migrant, largely staying within its breeding range and rarely moving outside it. Normally birds stay on their breeding grounds until October before gradually moving down to shingle-bed river valleys at lower altitudes. During the late autumn and winter months, in the Himalayan *terai* they may descend to altitudes as low as 100 m, while in north-western parts of their range the lower limit seems to be about 500 m. The birds usually reappear on their breeding grounds in March.

Relationship with Man

The Ibisbill has no practical importance to man and is not normally hunted or persecuted. The fact that it breeds in such bleak mountainous areas, which tend to have rather thinly distributed human populations obviously has much to do with this, and generally people are not even aware of its presence.

In some areas of greater human impact, Ibisbills have been observed breeding alongside places where heavy tractors are working, but these birds eventually showed little concern as to the presence of the tractors, appearing to become used to disturbance quite readily.

The species takes its genus and common names from a certain resemblance to the ibises (Threskiornithidae), as it presents fairly similar overall structure, and, more specifically, has a very long, decurved bill.

Status and Conservation

To provide an estimate of the size of the total world population of Ibisbills is extremely difficult. The species still occurs in reasonable numbers in suitable and often inaccessible habitats across the mountain systems of Central Asia.

On a 6·5 km stretch of suitable habitat along the Langtang Khola River, in northern Nepal, 41 birds were counted in 1984, including 18 territorial pairs. Elsewhere, there are very few precise data available, but a survey was carried out in 1989 in south-east Kazakhstan, in the mountains of Trans Ili (Zailiy Alatau) and Kungey Alatau, both northern offshoots of the Tien Shan. This revealed that the upper reaches of the Chilik River held four breeding pairs, while the valley of the Chon Kemin River, which runs between the Trans Ili and Kungey and has massive gravel-covered valleys, had ten pairs; ten more pairs were found along the Kara Kara River in the Kungey range. A record from 1957 reported Ibisbills breeding on the Great Almaty Lake in the Trans Ili at an altitude of 2500 m, but there were no further records there until 1977, when one pair bred, and numbers subsequently increased to three pairs. Another pair is reported to breed in the valley of the Little Almaty River. With so few data to hand, it would be unwise to hazard a guess as to overall population trends in this zone, but monitoring of these known territories should prove very worthwhile.

A very rough estimate of the overall population of Ibisbills in the Commonwealth of Independent States (CIS) is 200 breeding pairs. There are, in fact, no clear data to show whether the population is decreasing as a result of human activities, but the species is red-listed in the CIS, which helps to draw attention to it, increase public awareness amongst local communities and schools, and to put pressure on any possible development which might place important breeding sites at risk. Very few data are available from the Chinese part of its breeding range.

Being a highly specialized bird adapted to a rather restricted habitat, the Ibisbill could become vulnerable in the face of the increasing human pressure that is apparent in some areas, especially if its habitat becomes seriously threatened. Shingle-bed river valleys are now used for gravel extraction in many parts of the Himalayas. Also, throughout the Himalayas, rivers that are currently ideal for Ibisbills are suffering considerable damage through increasing water abstraction, and through accelerated erosion which results in sediments covering large pebble-strewn valleys, while plans for the construction of hydro-electric power stations pose major threats. Sheep grazing too is a problem for breeding Ibisbills in that the sheep often use river valleys to move between their areas of pasture, which can easily result in nest destruction through trampling. Finally, increased human presence and activity in the form of tourism and recreation are also apparently becoming significant factors in some areas, with all of the concomitant forms of disturbance they imply.

Nevertheless, the Ibisbill's habitat remains largely intact in many parts of the CIS, and, although there is some destruction occurring locally, the pressure on its populations here is undoubtedly far less than in the Himalayas. Also, there are still areas in parts of the species' range that remain essentially inaccessible, and in which development or exploitation appear to be economically unviable, at any rate within the near future.

No special conservation measures have been taken to protect the Ibisbill, although it is afforded varying degrees of protection by its presence in several Himalayan national parks. A widespread survey of the main breeding sites, to ascertain the number of breeding birds and also the level of potential threats, would be the most effective first step towards ensuring the future of this spectacular bird. An important follow-up would then be the establishment of nature reserves on the major breeding grounds, as well as on some of the wintering grounds.

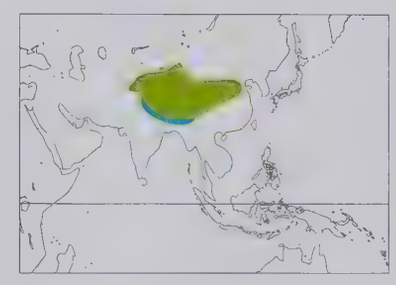
Family IBIDORHYNCHIDAE (IBISBILL)
SPECIES ACCOUNTS



Genus *IBIDORHYNCHA* Vigors, 1832

Ibisbill

Ibidorhyncha struthersii

French: Bec-d'ibis tibétain **German**: Ibisschnabel **Spanish**: Picoibis

Taxonomy. *Ibidorhyncha Struthersii* Vigors, 1832, Himalayas.
Sometimes placed within Recurvirostridae, usually in its own separate subfamily, Ibidorhynchinae; alternatively, on occasion, linked with Haematopodidae. Monotypic.
Distribution. SE Kazakhstan S to Kashmir and E through NW China, Tibet and NE India to EC & NE China. Occurs mainly in major mountain systems of C Asia, from Dzhungar Alatau S through Tien Shan, Pamir-Alay system, Hindu Kush and Karakoram to Himalayas, and E through Xinjiang, Kunlun Shan, Tibet-Qinghai Plateau, Sikkim and Arunachal Pradesh to SW Heilongjiang, Inner Mongolia, Hebei, Shanxi and Sichuan; main wintering range extends slightly further S of Himalayas.
Descriptive notes. 39-41 cm; c. 270-320 g; bill 68-82 mm. Unmistakable wader with long, decurved crimson bill and contrasting plumage; distinctive head pattern; legs greyish purple. Female similar to male, but marginally larger with slightly longer bill. Juvenile browner, with plumage pattern less clearly marked, and pale fringes on upperparts; bare part colours duller.
Habitat. Breeds in shingle-bed mountain river valleys usually devoid of any vegetation, at 500-4400 m. Occupies same habitat in winter, but at lower altitudes, occurring down to 100 m in places.
Food and Feeding. Mainly aquatic river invertebrates and fish; commonly recorded invertebrate prey include stoneflies (Plecoptera), larvae of mayflies (Ephemeroptera), caddisflies (Trichoptera), beetles (Carabidae) and crustaceans. Forages by pecking, probing and raking (see page 328), usually while wading in water roughly reaching up to belly; forages singly, rarely in pairs.
Breeding. Laying starts end of Apr and may continue for some time, with hatching mid-May to late Jun (Tien Shan, Himalayas, China). Monogamous and territorial. Nest is a shallow pit on the ground, sometimes with lining of pebbles. Usually 4 eggs, but completed clutches of 2 and 3 eggs recorded; incubation by both sexes; chicks have greyish down with darker black and brown markings, and 18 mm long brownish bill; young start to fly when 45-50 days old, and stay with parents apparently until first winter.

Movements. Altitudinal migrant; birds tend to descend in winter, in Himalayan zone to as low as 100 m. Species remains more or less within breeding range all year round.
Status and Conservation. Not globally threatened. Occupies expansive range, mostly in zones with sparse human populations, but restricted to rather limited habitat. In Trans Ili and Kungey Alatau of N Tien Shan, Kazakhstan, 27 pairs counted in 1989. Breeds in several conservation areas in the Himalayas, including Langtang National Park in Nepal, where 41 birds counted on Langtang Khola R in 1984. In some parts of Tien Shan has apparently increased insignificantly over past 15 years, though reasons not clear; included in CIS Red Data Books as rare and declining, although no evidence of such a decline is documented. Main threat, especially in Himalayas, is habitat destruction, including water abstraction from rivers, industrial use of gravel and building of hydro-electric plants; nest trampling by sheep is also a problem; disturbance of nesting birds by humans probably becoming more frequent in some areas, due to growth of recreation and tourist activities. Species not known to survive in captivity, where species might be difficult to maintain due to specialized habitat and feeding requirements; no captive breeding programmes known to be in operation.

Class AVES

Order CHARADRIIFORMES

Suborder CHARADRII

Family RECURVIROSTRIDAE (STILTS AND AVOCETS)

- Tall, elegant wading birds, with very long legs, longish and upcurved or medium-length and straight bill, and mostly pied plumage.
- 35-51 cm.

- Cosmopolitan, with greatest diversity in Australasian Region.
- Extensive open wetlands.
- 3 genera, 7 species, 11 taxa.
- 1 species threatened; none extinct since 1600.

Systematics

The distinctive recurvirostrid form is not common in the fossil record, but the group is known to have appeared by the early Cenozoic era. Over the years, the phylogenetic relationships of the Recurvirostridae have been determined primarily by morphological, molecular and behavioural comparisons. These indicate that stilts and avocets share a common ancestry with oystercatchers (Haematopodidae), the Ibisbill (Ibidorhynchidae), plovers (Charadriidae) and thick-knees (Burhinidae). Their closest relative would appear to be the Ibisbill (*Ibidorhyncha struthersii*), which has often been included within Recurvirostridae, usually with a subfamily of its own; indeed, on the evidence of DNA, it has even been included within the same tribe as the stilts and avocets.

Three genera are recognized within the Recurvirostridae. *Himantopus* and *Recurvirostra* are both near-cosmopolitan, the former containing two species of straight-billed stilt, and the latter four species of avocet, distinguished by their strongly upcurved bills. The third genus, *Cladorhynchus*, is monotypic and is confined to Australia. Its sole representative, the Banded Stilt (*Cladorhynchus leucocephalus*), combines some morphological and behavioural features of both *Himantopus* and *Recurvirostra*. Indeed, the relationships of *Cladorhynchus* have been questioned in light of morphological and behavioural similarities with flamingos (Phoenicopteridae; see Volume 1, page 508). However, these similarities are thought to be convergences rather than characters shared through common descent; recent DNA-DNA hybridization and protein electrophoresis analyses align *Cladorhynchus* with avocets and other stilts.

Of the three genera, *Himantopus* shows the most complex taxonomy. Most authors have preferred to accept only two species, the Black-winged Stilt (*Himantopus himantopus*) and the Black Stilt (*Himantopus novaezelandiae*), although some consider these two forms conspecific. However, the Black-winged Stilt is normally divided into five subspecies, and these forms are sometimes considered to constitute three to five separate species, with the recognition of: nominate *himantopus*, of Europe, Africa and Asia; *leucocephalus*, the Pied Stilt of Australasia; and *mexicanus*, the Black-necked Stilt of the Americas, which is often considered to include either or both of *melanurus*, the White-backed Stilt of more southerly distribution within South America, and *knudseni*, the Hawaiian Stilt of Hawaii. All these forms can be separated by plumage and biometrics, and they are geographically isolated, except for some overlap between *mexicanus* and *melanurus* in Peru, where hybridization does occur. Black-winged Stilts in South Africa and Sri Lanka have sometimes been accorded subspecific status, but this is generally considered to be unwarranted, as the plumage and size characteristics of these populations overlap closely with others of nominate *himantopus*. Nevertheless, this has led a few authors to list up to eight allospecies.

The Black Stilt is thought to be derived from an early invasion of New Zealand by stilts. It sometimes pairs with the Black-winged Stilt and the two forms hybridize. This indicates that the

The slender, strongly upcurved bill immediately betrays the generic identity of the Andean Avocet, the only member of Recurvirostra *to be found habitually at high altitudes. The highly specialized bill enables avocets to use a variety of feeding techniques and to find prey in various water depths. Compactly built, the Andean Avocet is much heavier in the body and appreciably shorter-legged than its congeners. The all-white head and body contrast strongly with the blackish wings and mantle to give the species its bold and attractive pied appearance.*

[*Recurvirostra andina*, Lauca National Park, Chile.

Most recurvirostrids are social birds, especially outside the breeding season, though sometimes they also breed in dense colonies. The Red-necked Avocet is gregarious all year round, and flocks gather to feed at freshwater and saline wetlands where they freely associate with other species. Roosting also is a group activity, often taking place in the water; the birds may sleep for long stretches, sometimes standing on one leg, with the head resting on the back and the bill tucked under the feathers.

[*Recurvirostra novaehollandiae*, Alice Springs, Northern Territory, Australia. Photo: M. Gillam/Auscape]

reproductive isolation of the Black Stilt was incomplete when the Black-winged Stilt invaded from Australia, probably during the nineteenth century. However, several factors are thought to promote reproductive isolation between the two species. For example, habitat choice, feeding behaviour and the extent of migratory behaviour differ between the two, as do various morphological characters, such as size, plumage, and bill and tarsal lengths. Furthermore, in areas where both forms occur, assortative mating is observed; in one study, in which Black Stilts comprised only 3% of all the stilts in the region, 70% of them were paired with other Black Stilts, the remainder being paired with hybrids (24%) or Black-winged Stilts (6%).

Morphological Aspects

Stilts and avocets are slim waders with very long flexible bills, long necks and especially long legs. These features enable them to exploit food resources in relatively deep water. The long neck and bill facilitate prey capture at the water surface, deep in the water column and in the upper layers of mud.

As reflected in the scientific name of their genus, avocets have highly specialized, upcurved bills, the curvature being strongest in the shorter-billed females. The bill is basally flattened and contains internal lamellae, which, during scything actions of the bird's bill and head, act as a filter for any small food items in the water or mud; the tongue is distinctively broad and fleshy. Avocets have bluish grey legs, strongly developed basal webbing of their three front toes, and vestigial hind toes.

Stilts of the genus *Himantopus* have straight or slightly upcurved bills which are associated with strong adductor muscles that facilitate rapid jaw actions and the gripping of prey. The tibia and tarsi are long and reddish pink, and the hind toe is absent.

The Banded Stilt combines features of both the avocets and the *Himantopus* stilts. As in avocets, the bill of the Banded Stilt is broad-based and lamellated, the tongue is enlarged, and basal webbing on the front three toes is strongly developed. However, like other stilts, the bill is straight or only slightly upcurved, the tibia and tarsi are long and orange-pink, and the hind toe is absent.

Stilts and avocets tend to be boldly pied. The Black-winged Stilt, the juvenile Black Stilt and the Andean Avocet (*Recurvirostra andina*) are generally blackish above and white below, whereas in the other species of avocets and the Banded Stilt, the black markings are more or less restricted to the primaries, the upperwing-coverts and the scapulars. Three species also have reddish brown plumage markings: the Banded Stilt has a chestnut breast band; the Red-necked Avocet (*Recurvirostra novaehollandiae*) has a dark chestnut head and neck; and the American Avocet (*Recurvirostra americana*) has the head, neck and breast orangish brown. The plumage of the adult Black Stilt, in contrast, appears almost entirely blackish. This apparent lack of a disruptive plumage pattern in the adult of this species may reflect the low levels of predation pressure that formerly prevailed in New Zealand.

Breeding and non-breeding plumages are generally similar in stilts and avocets. Exceptions to this are the chestnut breast band of the Banded Stilt, which is stronger in the breeding season, and the orange markings on the American Avocet, which are absent outside the breeding season.

Juvenile plumages are usually similar to those of adults, although pale fringes to the dark upperpart feathers give a scalloped effect. However, the juvenile Black Stilt has a markedly different plumage pattern from the adult, closely resembling that of the Black-winged Stilt; the typical all black adult plumage is not attained until 15-18 months of age.

In stilts and avocets, moult occurs twice annually, in the form of a complete post-breeding moult and a partial pre-breeding moult. In temperate areas moult is seasonal and is limited to short periods, whereas in the tropics the timing is variable. In general, adults begin the moult of their flight-feathers before their young have fledged. Concentrations of recurvirostrids frequently occur at some post-breeding moulting areas: for example, in the Jadebusen, in north-west Germany, up to 21,000 Pied Avocets (*Recurvirostra avosetta*) may collect in September before moving to more southerly winter quarters.

Habitat

Optimal feeding habitat for stilts and avocets is extensive shallow wetlands with abundant small invertebrate prey. In general, forested areas are avoided, and the highest densities of birds occur in areas of low rainfall, in treeless wetlands where there is adjacent open space for nesting and loafing.

Avocets and the Banded Stilt favour saline or hypersaline shallow inland lakes where tiny crustaceans, insects and other prey are abundant. Avocets occur in a range of coastal and inland sites, and they sometimes nest and feed at coastal estuaries.

A small group of Black-winged Stilts gives a theatrical high-leaping display with a parachute-like descent to the ground on wings spread wide; the significance of this performance is unclear. Other similarly unexplained aerial displays include the "Butterfly" flight, when an individual hovers 5-10 m above a particular spot, often flying on some 10 m or more to hover again. Another is the "Grouping-ceremony" or "Mob-display", in which a few birds come together and behave in a mildly aggressive fashion towards each other before dispersing, all for no apparent coherent reason.

[*Himantopus himantopus himantopus*, Aiguamolls de l'Empordà, Spain. Photo: Tono Folguera]

particularly in western Europe, in the case of the Pied Avocet, and on the Pacific coast of North America, in the case of the American Avocet. Usually, however, breeding takes place far inland and the birds undertake post-breeding movements to lowland and coastal wetlands, including estuarine and lagoon habitats. An exception to this is the Andean Avocet which occurs throughout the year at high altitude saline lakes, some of which are over 5000 m above sea-level; after the breeding season, some Andean Avocets descend to lower altitude lakes, but only rarely do they move to coastal tidal flats. In Asia, migrating Pied Avocets sometimes occur at altitudes of up to 5000 m.

The *Himantopus* stilts occur in the greatest variety of wetlands, with a wide range of salinity and altitude, and both lotic and lentic habitats, in other words those with fast-flowing and still water. Greatest habitat flexibility occurs in New Zealand, where both the Black-winged and Black Stilts regularly frequent the braided riverbeds that dominate the local landscape, a habitat that is similar to that frequented by the Ibisbill in central Asia. The stilts also occupy other freshwater, estuarine and artificial environments, such as irrigated fields and salt-works, and exhibit strong seasonal changes in habitat selection. In areas heavily modified by human activity, for example much of western Europe, recurvirostrids are increasingly coming to depend upon artificial wetlands, such as scrapes, salt-lakes, dams and sewage ponds, some of which are created for wildlife conservation.

All members of the Recurvirostridae are opportunistic in habitat selection. Avocets and the Banded Stilt often move long distances to take advantage of localized rains and temporarily rich food supplies, often within the same habitat type. In contrast, the Black Stilt exhibits great flexibility of habitat type over time, and is therefore able to remain relatively sedentary within smaller geographical areas.

General Habits

Stilts and avocets are considered to be mainly diurnal, although some species have been recorded feeding at night. Indeed, in estuarine areas outside the breeding season, feeding activity often follows a tidal cycle, slightly modified by a diurnal rhythm. Nocturnal foraging reflects the versatility of recurvirostrid feeding methods, particularly the ability to switch between visual and tactile feeding methods (see Food and Feeding).

With the exception of the Black Stilt, which defends some form of territory throughout the year, all species tend to be gregarious. During the breeding season, colonies typically contain 5-100 pairs, which are usually moderately to closely spaced, and in the Black-winged Stilt pairs occasionally feed around the nest. Banded Stilt colonies, however, contain thousands of pairs packed together tightly, while the feeding grounds may be many kilometres away. The breeding territories of Black Stilts generally contain significant feeding areas.

Outside the breeding season all species tend to be more gregarious, or, in the case of the Black Stilt, more clumped, although this latter species will still defend its feeding territories. Recurvirostrids usually feed in flocks of up to several thousands of birds, which may be tightly packed together, though they sometimes defend individual distances. For loafing or roosting, they gather in dense flocks on nearby dry banks where a bird will stand on one leg or sit on the ground, with the head and neck retracted to the fold of the wing and bill tucked under the wing. Sometimes flocks will roost standing in water. Interspecific associations with other recurvirostrids or other species of wading bird occur rather frequently.

When alarmed, feeding and roosting birds often head-bob, which consists of a rapid extension of the neck, followed by its rapid retraction. Wing-stretching, indirect head-scratching and other comfort movements are similar among the few species studied in detail.

Voice

Recurvirostrids are noisy, particularly when breeding or when in flight. The commonest calls are repetitive monosyllabic or disyllabic barks or yelps, and these are usually given as contact and alarm calls. The calls of stilts of the genus *Himantopus* tend to be sharp and monosyllabic and are often rendered as "yep" or "kek". In contrast, avocet calls are inclined to be a disyllabic "kluit", "kluut" or "kleet", although when the bird is alarmed these become more monosyllabic and stilt-like. The Banded Stilt

Both the Black-winged Stilt and the American Avocet breed on shallow wetlands, the former mainly at freshwater sites the latter showing a preference for lowland saline lakes and lagoons. At times both are found on estuaries and tidal flats, and also at fresh water sites. The Black-winged Stilt's bill is the less sophisticated of the two, but, aided by strong head muscles, it provides for quick jaw movement and a firm grip on prey. Aquatic insects, the Black-winged Stilt's main food, are normally taken from or beneath the surface of the water by a quick pecking action. When feeding, this species often wades in water up to or above the "knee" joint and will sometimes use the "plunge" method of foraging, totally immersing the head and neck, but only rarely does it swim. The American Avocet's long, upcurved bill is a highly specialized, sensitive instrument equipped with filtering lamellae which allow the bird to retain only the small organisms that make up its food; these are flicked into the mouth by the fleshy tongue and then swallowed. It too feeds by pecking, but it is usually to be seen "scything", sweeping the bill from side to side through the water or the underlying soft slime, thus allowing food items to be filtered out by tactile means. This species feeds on a wide variety of aquatic insects, crustaceans and worms, at times freely swimming in deeper water to forage.

[Above: *Himantopus himantopus himantopus*, Al Ansab Lagoons, Oman. Photo: Hanne & Jens Eriksen/Aquila.

Below: *Recurvirostra americana*. Photo: Arthur Morris/VIREO]

Often preceded by preening and bill-dipping, the mating ceremony of the American Avocet, like that of other avocets, begins with the female adopting a soliciting posture, with her neck stretched forward and her bill held in an almost horizontal position. The male walks in ever smaller semi-circles behind her, stopping to perform a "Dip-shake-preen Display" at each side, and drawing ever closer until he eventually brushes the female's tail feathers. Finally he mounts her and copulation quickly ensues. As he dismounts he leaves his inner wing stretched over her back; then both birds run forward a few paces with their bills crossed, before they separate.

[*Recurvirostra americana*, Alberta, Canada. Photo: Günter Ziesler]

is, yet again, intermediate in character between the *Himantopus* stilts and the avocets in that its call, "chowk", is occasionally disyllabic. In all species, calling may sound continuous when the birds are in large flocks.

Detailed studies of the Black-winged Stilt, Black Stilt and Pied Avocet have revealed that each species has a variety of calls. The simplest contact calls are based around the monosyllabic or disyllabic "yep" or "kluit", but variations are used for the following situational calls: alert calls; alarm and mobbing calls, which include different calls for ground, human and aerial predators; intensive alarm or distress calls; bathing calls; parental calls; pre-copulatory calls; nest-site selection calls; and incubating calls. Among those species studied so far, remarkable similarities are apparent, such as the way in which alarm calls increase in rate and volume with the intensity of the alarm stimuli.

Age- and sex-related variation in calls has been noted. For instance male Black Stilts have higher-pitched calls than females. Juvenile Black-winged and Black Stilts give a soft, high-frequency piping call.

Food and Feeding

Recurvirostrids feed mainly on aquatic invertebrates and small vertebrates, and less often on vegetable matter and terrestrial prey. Most commonly, the avocets and the Banded Stilt consume crustaceans, whereas the *Himantopus* stilts tend to feed on insects; molluscs, crustaceans, polychaete worms, earthworms, small fish and water plants and their seeds are also taken. Most food is obtained in shallow water or on damp land, but all species, particularly the Banded Stilt and the avocets, swim to feed in deeper water.

An avocet has a long, strongly upcurved bill which contains a complex and highly specialized system of lamellae capable of filtering out small food items. Once filtered off, this food is subsequently flicked into the mouth by the large fleshy tongue. The bill of the Banded Stilt is slightly upcurved and also contains lamellae, while *Himantopus* stilts have straight or slightly upcurved bills that lack lamellae.

The range of feeding techniques used by stilts and avocets is varied; all species use both visual and tactile methods of prey detection and capture. The most widespread feeding method is a direct peck at visible prey on or in the water column or the ground. The prey is grasped by a slightly open bill and swallowed by means of a backward and forward jerk of the head, which also returns the head to its original search position. Larger prey, such as crabs, may have to be cut up by the bill into smaller pieces. Pied Avocets sometimes feed by sight on the siphons of the bivalve mollusc *Scrobicularia plana* in intertidal areas; peck rates are low but the success rate, as gauged by swallows, is high. Other visual methods commonly used by stilts and avocets are "plunging", an underwater form of pecking or probing in which the bill and head are totally immersed; and "snatching", which involves pecking at flying insects. "Bill-pursuit", in which the bird rapidly opens and closes its bill on the water surface to grasp abundant prey such as flies or pond skaters, is less frequent.

Tactile or non-visual methods of feeding include the characteristic avocet "scythe" in which the bill is swept sideways at a low angle through water or soft mud, and small food items are filtered out. Two types of scything strategies occur in Pied Avocets, a "normal feeding strategy" and a "worm-feeding strategy", both of which have been studied in detail on the estuary of the Tagus in Portugal. The normal feeding strategy involves the neck being stretched out, while the head and slightly opened bill are swept from side to side in a regular movement. This is repeated about 25-30 times a minute, with each sweep usually being followed by the visible swallowing of many small prey items. In the worm-feeding strategy, Pied Avocets hold their bills further open and have higher sweeping rates averaging 45 per minute. However, a lower frequency of swallowing indicates a lower success rate than with the normal feeding strategy. Sometimes the two scything styles are mixed. In the normal feeding strategy on the estuary of the Tagus, the main prey of Pied Avocets were spionid worms, tubificids, and small *Nereis diversicolor* and *Capitella capitata* polychaetes. Similarly, in California, the normal feeding strategy of American Avocets was found to capture primarily spionids, capitellids and oligochaetes.

When feeding at night, scything is commonly used by the Banded Stilt and by the Black and Black-winged Stilts in New Zealand. It is used less frequently by other races of Black-winged Stilts, but is probably most effective in the worm-feeding strategy, in which large prey such as oligochaetes and chironomids

Like all members of the family except the Black Stilt (Himantopus novaezelandiae), *the Black-winged Stilt usually breeds in small, loose colonies of as many as 50 pairs. Sometimes the site may be shared with other species such as gulls, terns and waterfowl. The nest varies from a small mass of material to a fairly substantial, well lined construction made of twigs, stalks and any other available vegetation. It is normally built in the open, often amid grass and sedges and surrounded by shallow water. A normal clutch consists of four eggs, buff brown in ground colour and lightly spotted and blotched with black. Both parents share in the incubation which normally begins with the laying of the last egg, so that hatching is synchronous; if for any reason the eggs are lost a replacemant clutch is laid. The parent birds are noisy and aggressive when disturbed at the nest or with young, and various ploys are used when intruders approach too closely, among them distraction flights and injury-feigning. On occasion the whole colony may become alarmed and mob the intruder in a communal operation, creating a tremendous commotion as they screech and wheel around. Note the black hindneck characteristic of the northern American race, commonly known as the Black-necked Stilt.*

[*Himantopus himantopus mexicanus*, Oregon, USA. Photo: John Gerlach/DRK]

As its first chick hatches, this Pied Avocet is removing a piece of eggshell from the nest. The remaining chicks are likely to emerge soon, as hatching is virtually synchronous, and all will have left the nest within more or less 24 hours. Avocets are colonial nesters, the size and density of the colony varying considerably. In most cases the nests are loosely grouped and sited on the ground in the open near shallow water, or occasionally in short vegetation but still near water. The eggs, normally 3-4 in number, are brownish buff with darker spots and blotches.

[*Recurvirostra avosetta*. Photo: Eric & David Hosking/FLPA]

are captured. Banded Stilts and avocets typically feed on smaller organisms when scything.

Another non-visual method of feeding employed by recurvirostrids is "filtering", in which the bill is rapidly dabbled and swept from side to side through surface weed or soft mud. Probing is also used, and involves the bill being inserted semi-vertically into a soft substrate, usually in search of large prey such as earthworms.

On braided riverbeds in New Zealand, the Black Stilt uses a specialist sideways "lateral probing" action to capture aquatic insect larvae sheltering beneath stones. This feeding behaviour is similar to that of the Wrybill (*Anarhynchus frontalis*), a species which shares this habitat with the stilt. An extension of this behaviour is "raking", a foraging method that combines both tactile and visual cues. The bill is swept through fine river shingle to dislodge and thus reveal prey items, which are then pecked at. The strong bill of the Black Stilt enables this species to maintain high rates of prey intake from riverbeds, even during periods of low prey availability, as can be caused by low water temperatures or high solar elevation. In contrast, the Black-winged Stilt in New Zealand is often unable to exploit prey in braided riverbeds during periods such as these, and as a result it switches habitats, for example moving to ponds. This habitat switching occurs most often in early morning on high altitude rivers, when the water temperature is less than 5°C, and in the middle of the day on all rivers in general, when solar insolation inhibits the activity of many larvae. Nevertheless, both species respond opportunistically to temporal changes of invertebrate abundance, such as those that can occur during periods of flooding or insect prey emergence. At these times, birds congregate along the main river channels and their prey intake increases above that of normal feeding conditions.

Weather patterns that can disrupt feeding include strong winds and heavy precipitation, and these can bring about total switching of feeding style, for instance from pecking to scything. At night too, tactile scything is commonly employed by *Himantopus* stilts, at least in New Zealand. Black-winged Stilts engaged in tactile feeding maintain individual distances that are considerably shorter than when the birds are feeding visually. In lentic habitats recurvirostrids respond, often in spectacular fashion, to changes in prey availability. In arid continental areas, such as in Australia, birds congregate in response to sudden inundations of previously dry lake beds. In other areas sudden influxes of birds may occur if a sudden drop in water level creates a source of locally abundant prey.

Breeding

Although seasonal breeders for the most part, recurvirostrids tend to be opportunistic, and nesting is initiated only if local conditions are suitable. In this way, breeding can often be early, delayed or even abandoned. Furthermore, individuals and groups are not necessarily faithful to previous colony sites, and they often shift to new sites. Some species, particularly those in Australia, can move great distances, possibly in the order of hundreds of kilometres. The greatest opportunist of the family is the Banded Stilt, which breeds only in response to the appearance of ephemeral inland salt-lakes and the subsequent explosion in brine-shrimp abundance.

Stilts and avocets usually nest in colonies. Even the Black Stilt was once colonial, but its population is now so low that it tends to nest in solitary pairs. Colonial nesting is thought to enable the efficient exploitation of local and temporary abundance of food. It may also provide better anti-predator defences. Within colonies, nests are typically spaced 5-30 m apart, the exception being the Banded Stilt's, in which nest densities of up to 18 nests/m² have been recorded. The colonies of this species can be vast, and one was estimated to contain some 179,000 nests. Within the family, colonies are often of mixed-species composition. Avocets and stilts may nest together, and they have also been recorded nesting with plovers, pratincoles, sandpipers, gulls, terns, waterfowl and grebes.

In the species for which data are available, breeding birds are monogamous, although pair-bonds are not always maintained throughout the non-breeding season. In the Black Stilt pair-bonds are known to be lifelong. Among all species, pairing can take place *en route* to the breeding grounds or at them, and the tasks of nest-site selection and the lining of the nest are shared between the sexes.

Copulation in *Himantopus* stilts and avocets is similar. Pre-copulatory preening and bill-dipping often occur, followed by

A most attractive and fascinating Australian endemic, the Banded Stilt is the most opportunistic breeder of the Recurvirostridae: nesting depends totally on the advent of suitable climatic conditions. Where heavy rainfall has filled inland salt-lakes, and a resultant abundance of crustaceans, mainly brine-shrimps, occurs, the Banded Stilt may form huge, tightly packed colonies of many thousands of birds. Owing to the ephemeral nature of these sites a colony may be deserted at any time and the same sites can not be used every year. The species is therefore highly nomadic, whence the difficulty in locating breeding colonies, a problem aggravated by the extent of the species' range. The nests, usually sited on small islands within a lake, are saucer-shaped scrapes in the ground, sometimes sparsely lined with grass or stalks. The density of the nests varies according to the size of the colony and the availability of space, but can be as high as 18 nests/m². Average clutch size is 3-4 eggs, which can vary considerably in ground colour, but are mainly white with darker markings, though some eggs may be totally unstreaked. With predatory Silver Gulls (Larus novaehollandiae) *usually in attendance at a colony, incubating Banded Stilts are loath to leave their nests even when provoked. Surprisingly little interaction among the incubating birds has been observed, though minor fighting bouts do occur. When the whole colony takes flight on being disturbed, temporary chaos may ensue until the nests are all reoccupied by their rightful owners.*

[*Cladorhynchus leucocephalus*, Lake Ballard, Western Australia. Photos: Clive Minton]

The last of the brood to hatch, this Black-winged Stilt chick is still drying out, but will soon leave the nest. In this dry site the nest is a shallow, sparsely lined hollow in the sand amid glasswort (Salicornia). *The outstanding feature visible on this chick is the already astonishing length of the legs and toes, which make it easier to understand that within a matter of a few hours it will be able to run and feed for itself, though always attended by its parents until it becomes fully independent 2-4 weeks after fledging.*

[*Himantopus himantopus himantopus*, Camargue, France. Photo: Dominique Delfino/ Bios]

the female assuming a soliciting posture with her head lowered and her bill held more or less horizontal. The male then moves from side to side in a semi-circle behind the female several times, pausing at the side to perform a "Dip-shake-preen Display". If the ceremony proceeds, the male eventually remains at one side continuing the Dip-shake-preen Display, and then mounts the female, with copulation occurring quickly. On dismounting, the two typically cross bills and walk forward together, with their heads raised and one of the male's wings over the back of the female.

The similarity between the courtship and copulation behaviour of the avocets and the *Himantopus* stilts is such that successful interbreeding between Black-winged Stilts and American Avocets has occurred in captivity. In New Zealand, the Black Stilt and the Black-winged Stilt regularly interbreed and produce fertile offspring, which has resulted in areas of introgressive hybridization of these two species. Although the Black Stilt exhibits positive assortative mating, low productivity and the very scarcity of the species lead to unusual bond formation, such as trios, female-female pairs, and, most commonly, interspecific and hybrid pairings. The copulatory behaviour of the Banded Stilt has not been studied in detail, but it appears to be broadly similar to that of the other members of the family.

Egg-laying occurs at intervals of approximately 24 hours, occasionally 48 hours. Incubation usually begins after the laying of the third or fourth egg, or sometimes after the second. However, in areas where aerial predators pose a particular threat to unguarded eggs, sitting may begin with the first egg. Both sexes share in the incubation duties, with change-overs being frequent; for example, they can be approximately hourly in the *Himantopus* stilts. Both sexes also participate in nest defence, which can be carried out in decidedly aggressive fashion by some species. Anti-predator strategies are diverse and include sitting tight on the eggs or young in response to passing aerial predators, which may themselves be attacked and mobbed, and a variety of distraction displays that are usually directed towards predators on the ground. These include "Broken-wing Displays", in which a bird feigns injury on the ground; "Parachuting", which involves fluttering to the ground and giving distress calls; and "False Brooding", by which a bird gives the false impression that it is incubating or brooding in full view of a predator.

The normal clutch in the family is of 3-4 eggs; extremes of one egg and eight have been recorded, although the latter refers to two females laying in the same nest. Late nests may have smaller clutches. In general, the recurvirostrid egg has a yellow or brown background coloration, or, in the case of the Banded Stilt, white. The eggs are covered with darker spotting or blotching, or a combination of both. Average dimensions range from 44 x 31 mm in the Black-winged Stilt to 55 x 40 mm in the Banded Stilt. Incubation lasts 19-26 days, being shortest in the Banded Stilt. Hatching is synchronous in all recurvirostrids, and the chicks are precocial and nidifugous, generally leaving the nest within 24 hours of hatching.

Downy chicks are also disruptively marked, typically being buff, grey or fawn in background colour, with darker markings dorsally and on the sides of the head and on the thighs. The exception is again the chick of the Banded Stilt, which is unique amongst the whole suborder Charadrii in being white and completely lacking darker markings. Some camouflage may be afforded against the very pale salt-lake environment, or, alternatively, the large numbers of young produced by a colony and their subsequent crèche behaviour may reduce the effectiveness or need for a cryptic camouflage strategy.

Except in the case of the Banded Stilt, family parties remain discrete and the family group is maintained for a few weeks to several months after fledging. Black Stilt families remain together the longest, the young birds not being evicted until the beginning of the following breeding season. The Banded Stilt departs from the norm in that the downy chicks collect in large floating crèches to swim to the feeding grounds. At Lake Torrens, South Australia, one crèche covered a remarkable 130 km in only six days, in a wind-assisted movement.

Breeding success is highly variable interspecifically, and also intraspecifically between populations and seasons. The ephemeral nature of some habitats results in high fledging successes at times, but none at all at other times. For most species, a drop in water levels results in increased access for predatory mammals, as well as reduced food supplies. In Black Stilts, introduced mammalian predators such as feral cats, mustelids and brown rats account for most failed breeding attempts whilst native Pacific Marsh-harriers (*Circus approximans*) and gulls may also constitute threats on a local basis. In contrast, neighbouring Black-

winged Stilts are better adapted to deal with the introduced predators through differences in nest-site selection, coloniality, fledgling period and distraction displays. In many parts of the world, gulls prey on nesting stilts and avocets, taking their eggs and chicks; a Great Black-backed Gull (*Larus marinus*) was even reported to take a juvenile avocet. In Australia, Silver Gulls (*Larus novaehollandiae*) and raptors are quick to respond to sudden local abundances of the Banded Stilt, and in such cases the predators tend to have a particularly heavy impact on any late-nesting stilts, with few young normally surviving from such nests.

Movements

Recurvirostrids occur in a wide variety of climates and habitats and, therefore, their seasonal patterns of movement are correspondingly diverse. Some populations are migratory, others dispersive, and yet others sedentary. Northern populations of the Black-winged Stilt, the Pied Avocet and the American Avocet are typically migratory, with regular and predictable seasonal movements between temperate and equatorial regions, sometimes with local moulting areas where they stage prior to long migrations. In maritime areas a proportion of birds from these northern populations may, however, winter nearer the breeding grounds, such as in western Europe, where about 500 Pied Avocets winter in England, up to 1000 in the Netherlands and over 20,000 in France and Iberia.

This pattern is mirrored in some Southern Hemisphere populations. For example, although many coastal breeding individuals are resident, Black-winged Stilts breeding in inland areas of South Island, New Zealand, migrate to estuaries on North Island. Similarly, in south-east Australia, inland movements occur regularly in late winter and early spring, as do coastal movements in summer, with all movements corresponding to the seasonal availability of wetlands. In New Zealand, the pattern of Black-winged Stilt movements has changed during the nineteenth and twentieth centuries. In the nineteenth century Black-winged Stilts were known mainly from central New Zealand, and there were very few records from the extensive tidal flats of northern New Zealand. However, by the 1940's the northern tidal flats were being utilized by thousands of post-breeding stilts, for instance in the Firth of Thames and Kaipara Harbour, and this pattern has subsequently continued.

Stilts and avocets typically move in small parties along coastlines or river valleys, often at night. Migration occurs primarily during favourable weather conditions, and bad weather and opposing winds can delay passage for varying periods. Regular stopovers may be used for periods varying from only a matter of hours, in some cases, to several days, as in the case of the Pied Avocets that pause at the Banc d'Arguin, Mauritania.

In Australia any seasonal patterns are greatly affected by the availability of wetland habitat. Consequently, movements are often dispersive or erratic. Movements of the Red-necked Avocet and the Banded Stilt usually reflect recent heavy rainfall or the flooding of inland lakes, and birds may suddenly arrive or depart in their thousands. For example, in March 1989 the previously dry Lake Torrens was inundated by heavy rains. By late April about 100,000 Banded Stilts had collected to breed on islands in the newly formed lake; many of these birds had probably travelled hundreds of kilometres.

The least dispersive species are the Andean Avocet and the Black Stilt, although the former is little studied and might undertake significant altitudinal movements, and perhaps other local movements. The Black Stilt is known to be mainly sedentary, with most birds only undertaking short movements to different seasonal habitats within the same river systems. The wide feeding repertoire of the Black Stilt enables it to obtain its energy requirements under extremes of weather and climate in a relatively small area. Birds mated to Black-winged Stilts or hybrids often migrate to northern New Zealand.

Relationship with Man

Being noisy and conspicuous, stilts and avocets are well known to humans throughout their ranges, and, as a result, there are many local names for each species. For instance, at the Ebro Delta, in north-east Spain, the Pied Avocet is known as *Bec d'alena* or *Cusisacs*, meaning "sack-sewer", as its bill recalls the shape of traditional local darning needles used for mending sacks.

In most Western countries, recurvirostrids also enjoy a high and positive profile, and there are varying levels of effort to pro-

Three Banded Stilt chicks are being led at a brisk pace by one of their parents in order to join a crèche at the water's edge. The pure white downy chicks with their dark bills and eyes are unique in the suborder Charadrii in their totally white plumage without cryptic plumage. Even more remarkable is the organization of the chicks into large floating crèches often numbering several hundreds; they are attended by adults and swim to their feeding grounds, often covering considerable distances to do so. It is still not known for certain whether the adults ever feed their young, but chicks have been observed to feed themselves as soon as they reach water.

[*Cladorhynchus leucocephalus*, Lake Ballard, Western Australia. Photo: Clive Minton]

As Banded Stilts are opportunistic breeders, waiting for suitable climatic conditions in order to breed, they habitually perform mass movements when the time comes to occupy habitat that has just become suitable for breeding. The social behaviour of this species has been little studied, and virtually the only information available is based on observations made at its huge breeding colonies. Banded Stilts are gregarious at all times and seem to spend much time resting on sandbars and spits. If disturbed when resting, flocks take flight and wheel, dive and turn in the air in a markedly co-ordinated fashion.

[*Cladorhynchus leucocephalus*, Australia. Photo: M. P. Kahl/Auscape]

tect both the birds themselves and their habitats. Indeed, the level of interest in these species and the efforts afforded towards them can sometimes be disproportionate to their relative rarity, and are indicative of the impression that they are frequently considered very attractive birds. However, it should be remembered that this current period of favour was preceded by centuries during which these species were regularly collected both for the table and, latterly, as their rarity increased, as trophies.

However, one species in particular, the Pied Avocet, was at the centre of a successful conservation effort in western Europe earlier this century, and it was adopted as the symbol for the Royal Society for the Protection of Birds (RSPB). In this way, an image of the Pied Avocet was possibly the first to be used to symbolize the cause of ornithological conservation. More recently, the same society has used a more stylized logo, which features only the head and bill of the Pied Avocet, making powerful use of the distinctive form of the bird.

Status and Conservation

At the species level, all members of the Recurvirostridae have relatively secure, sometimes thriving, populations, with the exception of the Black Stilt. This can be attributed largely to the fact that the birds are no longer directly exploited by man, although it is probably also true to say that throughout their extensive range their habitats have not generally suffered the same critical depletions of some other habitat types. In parts of the world that have experienced major human impact only relatively recently, such as Australia, New Zealand and the Americas, the clearing of forested land for agriculture may have benefited some recurvirostrid species. All over their range, certain artificial wetlands, such as sewage ponds and salt-works, have also provided new habitat.

In western Europe, where pressures from human settlement are most marked, the two local recurvirostrid species appear to be making comebacks after declines in the nineteenth century. The Pied Avocet has increased spectacularly in the Netherlands, Germany and Britain, returning to breed in England in 1941 after a century's absence. The species has continued to increase to approximately 31,000 pairs in Europe. The Black-winged Stilt population has also increased and is now reckoned to number some 21,000 pairs in Europe. Habitat improvement, protection of nesting areas, and perhaps climatic change, are generally credited with the population increases of the twentieth century.

The return of the Pied Avocet to breed in Britain is one of the heartening conservation success stories of the twentieth century. At Havergate Island and Minsmere, Suffolk, nesting pairs were carefully protected in their wetland reserves and new habitat created for their growing numbers. As the number of pairs increased, however, their productivity declined due largely to predation by gulls and other predators in a density-dependent relationship. Further increases in the Pied Avocet population in England are likely to occur only if new and suitable habitat is provided. Elsewhere in Europe artificial wetlands have proved beneficial in the continued survival of stilts and avocets in several heavily populated areas.

On the Hawaiian islands, the local form of the Black-winged Stilt, the Hawaiian Stilt, has come under pressure principally from the loss of natural wetlands. Urban development and the replacement of traditional crops, such as taro and rice, with other agriculture, such as sugar cane, has gradually depleted wetland areas over the past 150 years. To some extent this has been countered through creation of stock ponds, ditches, settling ponds, aquaculture and some golf course ponds, but remaining natural wetlands are still threatened by drainage and by introduced plants. Introduced predatory mammals, including feral cats, dogs and rats, as well as mongooses (*Herpestes auropunctatus*), have an undetermined impact on Black-winged Stilts in Hawaii, as do human disturbance and toxic chemical spills. However, active management and the creation of new nesting habitat on the islands of Maui and Oahu have enabled the number of birds there to increase steadily since 1982 to a total of about 1800 in 1988, and this accounts for about 80% of the total population of the Hawaiian form *knudseni*. The protection of a number of core nesting areas is of paramount importance to the survival of the Black-winged Stilt in Hawaii; beyond these core areas, productivity and survival are linked closely to climatic factors, particularly rainfall. This form currently occurs on all of the main Hawaiian Islands except Kahoolawe, although sightings on some islands, such as Lanai, correspond only to wet winters.

The single globally threatened member of the family is the Black Stilt, which had a total wild population of fewer than 100

The Black Stilt, endemic to New Zealand, is Critically Endangered. After a catastrophic population crash in the 1950's, the total number of birds in the wild was estimated in 1995 at under 100 birds. Not only has it suffered serious habitat loss, but introduced mammals too have played a major part in its decline. The species is peculiarly vulnerable as a solitary nester on easily accessible dry riverbanks, with a long fledging period, and showing no effective anti-predator behaviour. To make matters even worse, it is increasingly hybridizing with the Black-winged Stilt, a relatively recent invader of New Zealand.

[*Himantopus novaezelandiae*, New Zealand. Photo: M. F. Soper/ANT/ NHPA]

birds in 1995. It was widespread and common in New Zealand in the middle of the nineteenth century but by the beginning of the twentieth it bred only on South Island. By the 1940's numbers had dropped to 500-1000 birds, and by 1960 to 50-100 birds.

The decline of the Black Stilt coincided with the introduction of carnivorous mammals, including feral cats, the rats *Rattus norvegicus* and *R. rattus*, and the three mustelid species *Mustela erminea*, *M. nivalis* and *M. furo*; native avian predators also increased, with greater availability of food. At the same time, Black-winged Stilts were also spreading, and major habitat changes were taking place, particularly with the drainage of wetlands fringing riverbeds. Nevertheless, introduced predators appear to have been sufficiently significant in their own right to bring about a decline in the population of the Black Stilt. One study showed that only about 1% of eggs succeeded in producing a fledgling and that these subsequently proved to have a relatively short life expectancy of less than 5 years. It is thought that certain features of the Black Stilt's life history render it vulnerable to predation: Black Stilts nest on dry banks, which are patrolled by hunting mammalian predators; they are solitary nesters; they have a long fledgling period; and they exhibit ineffective anti-predator behaviour. It is notable that these features are not shared by the Black-winged Stilt in New Zealand. A compounding problem, which increases in importance as population size decreases, is that those Black Stilts that do survive to maturity are not always able to find mates and often end up in unproductive groups, such as trios or lesbian pairs, or interbreeding either with Black-winged Stilts or with hybrids of the two species.

Since 1980, protective measures for Black Stilts have included a combination of anti-predator, captive rearing and habitat manipulation programmes. In the early 1980's the prime focus was on excluding predators from nesting areas, and this was attempted largely through trapping programmes, which either encircled a small nesting area or covered a large part of a river valley or delta. Two predator exclosures were also constructed around what were, at the time, dependable nesting areas. In both these exclosure areas and the trapping areas, as an additional level of protection, Black Stilt eggs were removed to an incubator and replaced with dummy eggs until the chicks were due to hatch. These anti-predator techniques succeeded in boosting productivity to fledging, but could not reduce post-fledging mortality rates.

The cross-fostering of Black Stilts to interbreeding pairs of stilts or hybrids was also attempted in the early 1980's. Eggs from the first breeding attempt of Black Stilts were removed, which also induced them to relay, while their first clutch was cross-fostered. However, imprinting and migration problems led to only 7% of cross-fostered fledglings being recruited into the Black Stilt breeding population, and this technique was discontinued.

A captive rearing programme for Black Stilts, centred at Twizel in southern central South Island, has ensured an annual production of juveniles which in some years has exceeded that of wild pairs. Many of these juveniles have been produced as a result of the removal of clutches from wild birds. Techniques for juvenile release have improved and released birds now have high survival rates, with some forming part of wild breeding pairs. This success is due partly to habitat enhancement programmes in local wetlands and river deltas, which include the removal of willows and lupins from potential and traditional breeding grounds. Current management focuses heavily on using dummy eggs in nests, captive rearing and release programmes, and habitat improvement, with localized predator control. A recovery plan for Black Stilts published in 1993, aims to increase mainland populations and explore the potential for island translocations.

All recurvirostrids live in habitats that are susceptible to environmental abuse and damage. Shallow wetlands are often the most modified and polluted habitats in regions inhabited by people. Problems that have resulted in stilt and avocet mortality and exodus have included organic pollution, PCB toxic loading, selenium pollution, lead poisoning from lead shot on lake beds, and the use of insecticides. Ultimately the continued survival of recurvirostrids and other wetland species depends on the collective abilities of national and international agencies to overcome these and other environmentally damaging effects.

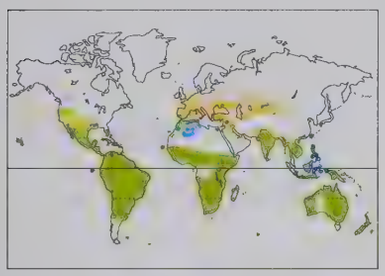
PLATE 31

inches 8

cm 20



Genus *HIMANTOPUS* Brisson, 1760

1. Black-winged Stilt

Himantopus himantopus

French: Échasse blanche **German**: Stelzenläufer **Spanish**: Cigüeñuela Común
Other common names: Common Stilt; Pied/White-headed Stilt (*leucocephalus*); Hawaiian Stilt (*knudseni*); Black-necked Stilt (*mexicanus*); White-backed Stilt (*melanurus*)

Taxonomy. *Charadrius Himantopus* Linnaeus, 1758, southern Europe.
Forms superspecies with *H. novaezelandiae*, with which known to hybridize and which is sometimes considered conspecific. Races often considered to warrant recognition of 2-5 distinct species (see page 332). Races can be split into three groups: nominate race; "pied" race, *leucocephalus*; and "black-necked" races *knudseni*, *mexicanus* and *melanurus*. Geographical variation also claimed in southern Africa and Sri Lanka, in forms *meridionalis* and *ceylonensis* respectively, but both show considerable overlap with other populations of nominate *himantopus*. Five subspecies normally recognized.
Subspecies and Distribution.
H. h. himantopus (Linnaeus, 1758) - France and Iberia S to sub-Saharan Africa and Madagascar, and E to C Asia and NC China, Indian Subcontinent, Indochina and Taiwan.
H. h. leucocephalus Gould, 1837 - Java E to New Guinea, and S to Australia and New Zealand; winters N to Philippines, Greater Sundas and Sulawesi.
H. h. knudseni Stejneger, 1887 - Hawaiian Is.
H. h. mexicanus (P. L. S. Müller, 1776) - W & S USA through Central America and West Indies to SW Peru, E Ecuador and NE Brazil.
H. h. melanurus Vieillot, 1817 - N Chile and EC Peru through Bolivia and Paraguay to SE Brazil, and S to SC Argentina.

Descriptive notes. 35-40 cm; 166-205 g (mean of all races); tarsus 101-125 mm in male, shorter in female. Very long pink legs distinctive; thin black bill; wings and back black, often with greenish gloss; white below; tail white with variable grey banding. Female has upperparts duller brown, lacking greenish gloss. Some non-breeding birds of nominate race develop more extensive grey on crown, nape and hindneck. Juvenile similar to adult female. Races differ mainly in colouring and pattern of head and hindneck, varying from mainly white in nominate race to continuous black in *mexicanus* and especially *knudseni*, but nominate too sometimes shows limited amounts of greyish or blackish in these areas; races *leucocephalus* and *melanurus* intermediate; races *mexicanus* and *knudseni* show more pronounced sexual dimorphism in plumage; juvenile of *leucocephalus* lacks black of hindneck and nape, which may be white or grey. Hybrids of *leucocephalus* and *H. novaezelandiae* very variable, typically with black collar and some black markings on breast and belly.
Habitat. Shallow wetlands of tropical and temperate regions. Breeding habitats mainly at freshwater sites, including marshes and swamps, lake edges, riverbeds, sewage ponds and flooded fields, but also salt-pans and coastal salt-marshes; frequently found on alkaline lakes; sometimes occurs on lakes in mountainous areas, up to c. 2000 m in Turkey and 2500 m in C Mexico, but commonly at 2500-4200 m in *puna* zone of Peru, Bolivia and NW Argentina. After breeding, congregates mainly at estuarine coastal habitats and on large inland water bodies.
Food and Feeding. Carnivorous, preying on great variety of small, mainly aquatic, invertebrates and vertebrates, occasionally seeds. Main prey types are larvae and adults of aquatic insects, especially beetles (Coleoptera), mayflies (Ephemeroptera), caddisflies (Trichoptera), water-bugs (Hemiptera), dragonflies (Odonata), flies (Diptera), alderflies (Neuroptera), and butterflies and moths (Lepidoptera); also bivalves and gastropods (Mollusca), crustaceans, spiders (Araneae), oligochaete and polychaete worms (Annelida), and tadpoles, small fish and their eggs. Diet often strongly seasonal, depending on habitat; for example, shifting from varied but largely insectivorous diet on inland breeding grounds to diet of crustaceans, polychaete worms and molluscs on intertidal non-breeding areas. Captures prey by a variety of visual and tactile methods including scything in soft mud when prey not visible, e.g. at night. Males often feed in deeper water than females.
Breeding. Timing very variable over massive range: seasonal or after rain in tropical regions; in Palearctic, laying begins as early as late Mar in N Africa, later further N, and not until May in N parts of range; altitude also affects timing, e.g. in New Zealand, begins nesting late Jul to Aug at sea-level, but not until late Sept to Oct at altitudes over 700 m. Sometimes solitary but usually in colonies, typically of 2-50 pairs, rarely 100's. Nests widely spaced on ground, often amongst grasses and sedges; sometimes nest is floating mass of water weeds; usually well lined. Usually 4 eggs (3-6); incubation 22-26 days, by both sexes; downy young have crown and back olive brown to ochre dotted with parallel lines of black spots, larger on back, and with black lines on flanks, underparts off-white; chicks depart nest on day of hatching or next day; fledging 28-32 days (*himantopus*, and *leucocephalus* in Australia) or 30-37 days (*leucocephalus* in New Zealand); independent of parents 2-4 weeks after fledging (*himantopus*) or often after a few months (*leucocephalus*). Age of first breeding 1-2 years.
Movements. Sedentary in places, but local movements to long distance migration elsewhere. N populations of races *himantopus* and *mexicanus* migrate in Jul-Nov to Africa and Central and South America respectively, returning in Mar-May, usually over period of less than 1 month at any one site. Local movements recorded throughout most of tropics, but patterns poorly understood. In New Zealand, S and inland breeders of *leucocephalus* migrate to N New Zealand in Jan-Mar, returning in Aug-Sept, whereas lowland and N breeders mainly sedentary. Spring passage typically involves flocks of up to 15 birds.
Status and Conservation. Not globally threatened. Huge, near-cosmopolitan range and local abundance indicate species secure for present, but controversial taxonomy calls for analysis and monitoring at subspecific level; all races apparently secure, except Hawaiian *knudseni*; local populations in decline in many countries. In W Palearctic, nominate race declined during 19th century, but since then has recovered in several areas; current population estimated at minimum of c. 21,000 pairs, with stronghold in Spain (c. 10,500 pairs in 1989) which may be crucial as buffer to fluctuations in productivity and survival in other parts of Europe; local populations greatly affected by annual rainfall and habitat protection; population declines in E Europe, e.g. in Greece, Hungary and Bulgaria, attributed to loss of wetland habitat, but series of protected wetlands in W Europe providing secure breeding and feeding grounds; probably maximum of 500-600 pairs in Azerbaijan; widespread and locally very abundant throughout Africa; abundant in Pakistan. In Australia, extensive wetland habitats available, and population of *leucocephalus* estimated at 266,000 birds; in 19th century, colonized New Zealand, where current population 30,000 birds. Race *knudseni* is rarest form of present species, numbering only c. 1800 birds; survival depends on continued protection of its core nesting areas, as it breeds elsewhere only during very wet springs. Extensive wetland habitats in Americas suggest races *mexicanus* and *melanurus* remain relatively secure, but no population estimates available; within South America, *mexicanus* commonest in *llanos* of Colombia and Venezuela, *melanurus* in C Chile and N & C Argentina.

2. Black Stilt

Himantopus novaezelandiae

French: Échasse noire **German**: Schwarzer Stelzenläufer **Spanish**: Cigüeñuela Negra

Taxonomy. *Himantopus novæ-zelandiæ* Gould, 1841, Port Nicholson, North Island, New Zealand.
Forms superspecies with *H. himantopus*, with which sometimes considered conspecific (see page 332); known to hybridize with *H. h. leucocephalus*, and the two species have very similar courtship and breeding behaviour. Monotypic.
Distribution. New Zealand: formerly widespread, but breeding now restricted to MacKenzie Basin, C South I; small numbers winter locally in North I.

Descriptive notes. 37-40 cm; c. 220 g; tarsus mean 87 mm. Distinctive all black plumage with greenish gloss to back and wings; long pink legs. Differs structurally from *H. himantopus* in having shorter legs and longer bill. Female similar to male, but averages shorter-legged. Non-breeding adult can show greyish to whitish forehead and chin. Juvenile, at fledging, very similar to that of *H. himantopus*, mainly white below; however, soon develops variable greyish black markings on underparts in first winter; second summer plumage predominantly black with scattered white spots and streaks. Hybrids between present species and *H. h. leucocephalus* very variable, typically with black collar and some black markings on breast and belly.
Habitat. Braided riverbeds, lake shores, swamps and shallow ponds of MacKenzie Basin. Breeds beside streams with stable sides, or by main flood-prone river channels; also by well vegetated ponds and swamps. Outside breeding season, birds frequent ponds, river deltas and nearby lake edges, and a few visit coastal lagoons and estuaries.
Food and Feeding. Carnivorous, taking variety of invertebrates and small fish. On riverbed breeding grounds, feeds predominantly on aquatic insect larvae and adults, including mayflies (Ephemeroptera), caddisflies (Trichoptera), stoneflies (Plecoptera), and small fish (Galaxiidae, Eleotrididae); at other lentic breeding grounds also preys on damselfies (Odonata), various flies, especially midge larvae (Chironomidae, Diptera), various water-bugs (Hemiptera), also oligochaetes and molluscs. Post-breeding diet may include same groups. Few birds move to coastal habitats where diet is extended to include various crustaceans and polychaetes. Riverbed prey often obtained by probing beneath stones; also scythes and pecks; sometimes probes in fields.
Breeding. Seasonal, taking place in Sept-Jan. Usually solitary; defends territory against other congeners. Nest bowl usually well lined, and nest located near water. Usually 4 eggs (3-6); incubation 24-26 days, by both sexes; downy chick has pale brown upperparts speckled and spotted with black, with larger spots on back and in parallel lines, greyish black patch on thighs, off-white below; fledging 41-55 days; independent of parents after 9 months. In wild, most eggs and young are eaten by predators. First breeding at 2 years, or more usually 3 years of age. Known to have lived over 12 years in wild.
Movements. Sedentary in MacKenzie Basin with local movements of up to several kilometres, usually in autumn-winter to river delta of breeding valley, with birds returning to nesting area from late winter to early spring. A few birds spend autumn and winter at coastal lagoons, and especially estuaries, of North I; most of these are associated with, and may be paired with, individuals of *H. himantopus* or hybrids.
Status and Conservation. CRITICALLY ENDANGERED. Total population crashed from 1000 birds or more in 1950 to fewer than 100 birds by 1960, and currently remains at fewer than 100 birds. Habitat loss and predation of eggs, chicks and adults by introduced carnivorous mammals have greatly reduced the productivity of wild birds, and have further promoted interbreeding with increasingly abundant *H. himantopus*, which colonized New Zealand only in 19th century. Predator control and captive rearing and release began in early 1980's with mixed success, but overall at least halted decline. At

present, New Zealand Department of Conservation is responsible for artificial incubation of most eggs, releasing numbers of captive-reared birds annually. See page 342.

Bibliography. Genus *CLADORHYNCHUS* G. R. Gray, 1840

3. Banded Stilt

Cladorhynchus leucocephalus

French: Échasse à tête blanche **German**: Schlammstelzer **Spanish**: Cigüeñuela Pechirroja

Taxonomy. *Recurvirostra leucocephala* Vieillot, 1816, Victoria.
Reported to show morphological and behavioural similarities to flamingos (Phoenicopteridae), but probably not significant (see page 332). Monotypic.
Distribution. Australia, mainly in S & C inland areas, particularly C Western Australia and South Australia.

Descriptive notes. 35-43 cm; 220-260 g; tarsus mean 87 mm in male, and 80 mm in female. Distinctive, predominantly white stilt with mainly black scapulars and upperwing; broad chestnut breast band with narrow dark upper edge; bill slender and black; legs long and orange-pink; legs shorter than in *H. himantopus*. Sexes alike. Non-breeding adult has breast band reduced. Juvenile lacks breast band.
Habitat. Shallow saline or hypersaline waters inland and along coast, including ephemeral salt-lakes, salt-works ponds, salt-pans, saline lagoons, estuaries, bays and tidal flats, only occasionally on low-salinity waters. Highly opportunistic, breeding only in arid interior at large, shallow salt-lakes temporarily filled by rain or flood water.
Food and Feeding. Feeds on variety of small crustaceans, and also aquatic insects, molluscs, fish and vegetable matter. Staple prey are small crustaceans which become temporarily superabundant in saline lakes, including: brine-shrimps (Branchipoda); *Apus*, *Triops* (Notostraca); *Artemia*, *Parartemia* (Anostraca); ostracods; and isopods. Feeds by pecking, probing (including plunging) and scything. Forages in shallow water during day.
Breeding. Not well known, but timing sporadic and dependent on inundations of salt-lakes. Colonies may contain 10,000's of nests, and one contained 179,000; can occur at densities of up to 18 nests/m². At a given moment, different parts of a colony can be at markedly different stages; species may be double-brooded, or synchronized episodes of laying may occur. Nest-sites are islands of bare soil; nest bowl is a scrape in ground, or is patch of flat ground about which vegetation is collected. Usually 3-4 eggs (1-5); egg white with dark streaks, as opposed to yellow or brown with dark markings in other recurvirostrids; incubation 19-21 days, by both sexes; chick covered in white down, unique within suborder Charadrii (see page 340); nidifugous; mobile crèches of 100's of chicks attended by adults; fledging c. 50 days.
Movements. Dispersive, with movements dependent on rainfall: frequents coastal areas when arid inland zones are dry, returning inland after rain. Pre-breeding return inland occurs more rapidly than post-breeding exodus.
Status and Conservation. Not globally threatened. Total population reckoned to number normally over 200,000 birds, probably many more. Size of population probably fluctuates greatly from year to year, depending on suitability of habitat for breeding. Much of this habitat is either protected or unlikely to be significantly altered by man. Species may benefit from artificially increased salinity of many wetlands in western and eastern extremes of range.

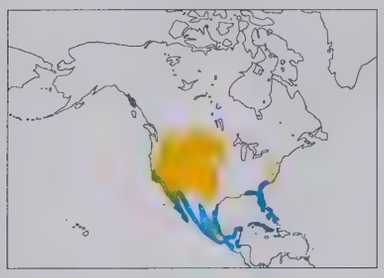
Genus *RECURVIROSTRA* Linnaeus, 1758

4. Pied Avocet

Recurvirostra avosetta

French: Avocette élégante **German**: Säbelschnäbler **Spanish**: Avoceta Común
Other common names: (Eurasian) Avocet

Taxonomy. *Recurvirostra Avosetta* Linnaeus, 1758, southern Europe = Italy.
Clinal increase in size from W Europe E across Asia. Monotypic.
Distribution. Europe through W & C Asia to SE Siberia and NE China, and locally through N Africa to E & S Africa; winters from W Europe and Africa through Middle East to NW India and SE China.
Descriptive notes. 42-45 cm; 225-397 g; tarsus 85-98 mm in male, 77-92 mm in female. Unmistakable; mainly white with black forehead, crown to below eyes, nape and upper hindneck; at rest, shows three distinctive black bands on mantle and scapulars, lesser and median upperwing-coverts, and outer



6 primaries; bill black and strongly upcurved, long legs blue-grey. Female tends to have shorter, more strongly curved bill. No seasonal variation. Juvenile similar to adult, but black less intense or tinged brownish, and white upperparts have mottling of sepia, grey-brown or buff.
Habitat. Breeds in flat, open areas typically at shallow saline lakes, lagoons, pools, salt-pans and estuaries with sparse vegetation; up to over 3000 m in Afghanistan. Outside breeding season also frequents muddy tidal flats; infrequently found on freshwater lakes and even rivers; sometimes found on agricultural land, particularly in Netherlands.
Food and Feeding. Carnivorous, taking great variety of mainly aquatic invertebrates 4-15 mm long, particularly aquatic insects, crustaceans and worms, rarely molluscs, fish and plant material. Winter diet known best from Portugal where spionid worms, tubificid worms, small *Nereis* and *Capitella* polychaetes comprise bulk of diet. Most often feeds by picking or by tactile scything of bill through water or mud; sometimes feeds communally.
Breeding. Apr-Aug in Eurasia. Usually nests in large colonies. Nest is typically a grass-lined scrape in open ground or amongst short vegetation. Usually 3-4 eggs (2-5); incubation normally 23-25 days, by both sexes; downy young silver-grey above grading to buff on sides of head, wing and sides of back, with small black spots on crown, two lines of larger parallel spots on back, and spots on thighs; chick nidifugous; fledging 35-42 days. Age of first breeding 2-3 years. Known to have lived over 24 years in wild.
Movements. Variable. N temperate birds mainly migrate Aug-Oct to tropical and warm temperate regions, staging *en route* in high numbers, e.g. in Netherlands. Roughly one third of Atlantic seaboard population migrates to sub-Saharan Africa, but average of over 10,000 birds each winter in both France and Iberian Peninsula, with up to 11,000 birds on Tagus Estuary, Portugal. Return movements in Mar-May, with many African migrants using Banc d'Arguin, Mauritania, as brief stopover. Some local overwintering elsewhere in W Europe. Patterns in Asia poorly documented, but wintering birds occupy Persian Gulf, NW India and SE China, presumably from C Asian breeding grounds. One-year-old migrant birds possibly remain on wintering grounds over following summer. E & S African birds sedentary or locally dispersive. Contrary to some reports, species is mere vagrant to Cape Verde Is, with only c. 3-4 records.
Status and Conservation. Not globally threatened. Extensive range, with over half of population reckoned to breed in Europe; locally abundant in several parts of Africa, often coinciding with presence of migrants from Palearctic. Europe reckoned to hold 31,000-56,000 breeding pairs, with largest numbers in Netherlands, Denmark, Spain (c. 4400 pairs in 1989) and Turkey; also minimum c. 37,000 birds in winter, with 14,000-16,000 in France, 7000-20,000 in Portugal, 7200-11,000 in Spain, 5000-10,000 in Italy, and 1760-6500 in Greece. After contraction of range in NW Europe in 19th century, species has increased since 1940's, recolonizing England and Sweden and extending breeding range to Belgium and Norway; numbers of breeders along coast of North Sea (including Sweden) increased from 1800 pairs in 1924/25 to c. 10,000 pairs in 1969, and 16,400-19,700 pairs in 1980's. Wetland breeding areas currently coming under increased pressure, and as this species is less opportunistic than most other recurvirostrids there is cause for concern in several regions; from E Europe to China, pressures have come about primarily through lack of protection of wetlands, both on inland breeding grounds and on wintering grounds of coastal China and Indian Subcontinent; similar problems exist in Mediterranean region, but protection and enhancement of wetlands in W Europe is believed to have assisted the recovery of populations in Britain, France, Belgium, Germany and Denmark. As with all wetland inhabitants, however, species susceptible to abuses of PCB, selenium, and lead pollution, and use of insecticides; similar problems also apply at several of African wintering areas. Over 80% of large Dutch population breeds on Wadden Sea, where depends on suitable management of salt-marsh habitat. As 90% of European winterers concentrated at 10 sites, protection of these sites is of paramount importance; over 15% of European winter population occurs at Tagus Estuary, Portugal, where threatened by mercury pollution, hunting and bridge building.

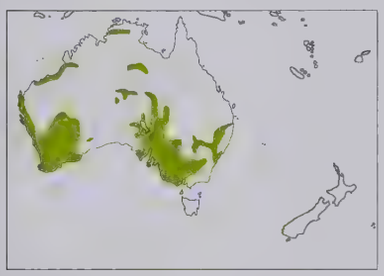
5. American Avocet

Recurvirostra americana

French: Avocette d'Amérique **German**: Braunhals-Säbelschnäbler **Spanish**: Avoceta Americana

Taxonomy. *Recurvirostra americana* Gmelin, 1789, North America.
Monotypic.
Distribution. SE British Columbia E to SW Ontario, and S to N Baja California E to C Texas; E USA; C Mexico. Winters from California and S Texas through Mexico to Guatemala and irregularly to N Honduras; SE USA and Bahamas to Cuba.
Descriptive notes. 41-51 cm; 302-461 g; tarsus 85-103 mm. Head, neck and breast orange-brown, becoming pinkish on upper mantle and upper belly, then shading into white; pattern of blackish dorsal markings resembles those of *R. avosetta* and *R. novaehollandiae*, but more extensive blackish on outerwing through dark primary and greater coverts; black bill strongly upcurved; long legs blue-grey. Female has shorter, more strongly curved bill. Non-breeding adult has crown, nape and hindneck pearly grey, rest of underparts white. Juvenile as adult, but crown pale brownish contrasting with dull chestnut nape and hindneck, merging into pinkish on upper mantle; whitish on inner primaries.
Habitat. Breeds around sparsely vegetated saline lakes and ponds, especially alkaline lakes, lagoons and marshes; also in estuaries; nests up to 2500 m in C Mexico. Outside breeding season, occurs in freshwater habitats and also coastal lagoons, estuaries and tidal flats.



Food and Feeding. Mainly carnivorous, preying on wide range of mainly aquatic invertebrates including aquatic insects and their larvae, crustaceans, molluscs and worms. In inland areas, often extends diet to include seeds and terrestrial insects such as grasshoppers and crickets. On intertidal flats in California, diet comprises mainly spionid, capitellid and oligochaete worms. Usually feeds by scything, but also by pecking. Sometimes forages in dense flocks.
Breeding. Nests in spring and summer in N of range; Apr-Aug in NW Mexico, Mar-Aug in C Mexico. Usually nests in loose colonies, but sometimes in large, dense colonies. Nest is grass-lined depression in soil. Usually 4 eggs (3-5); occasionally clutches of up to 8 recorded, due to "dumping"; incubation 22-29 days, by both sexes; chicks have pale tan down with darker spots and stripes; both adults care for chicks; fledging 4-5 weeks; young not immediately independent.
Movements. Mostly migratory. Winters in S portion of breeding range in S & E USA and Mexico, S to Guatemala and rarely N Honduras, and also Bahamas and Cuba. N migration occurs in Apr-May; S migration in Aug-Nov.
Status and Conservation. Not globally threatened. Expansive range over North America, where many important sites are officially protected. In Mexico, fairly common to uncommon breeder, common to fairly common migrant and winter visitor.

6. Red-necked Avocet

Recurvirostra novaehollandiae

French: Avocette d'Australie **German**: Rotkopf-Säbelschnäbler **Spanish**: Avoceta Australiana
Other common names: Australian Avocet

Taxonomy. *Recurvirostra Novæ-Hollandiæ* Vieillot, 1816, Victoria.
Monotypic.
Distribution. Australia, occurring mainly in S, but widespread with scattered distribution.

Descriptive notes. 40-48 cm; 270-390 g; tarsus 81-97 mm in male, 81-90 mm in female. Head and most of neck deep chestnut-red, sharply demarcated from white body; white eye-ring; pair of parallel blackish stripes on sides of back, extensive blackish on upperwing-coverts and outer 7 primaries blackish, pattern recalling that of *R. avosetta*; black bill strongly upcurved; legs pale blue-grey. Female has more steeply upcurved bill, although sexual dimorphism apparently somewhat less pronounced than in similar and closely related *R. avosetta* and *R. americana*. No seasonal variation. Juvenile similar, but head and neck paler brown; broad pale ring around base of bill.
Habitat. Breeds preferably at inland salt-lakes; also frequents, and commonly breeds at, variety of shallow, generally ephemeral, wetlands of wide salinity range, including hypersaline lakes, freshwater lakes, dams, lagoons, marshes, sewage ponds and shallow edges of rivers and estuaries.
Food and Feeding. Not studied in detail. Feeds on variety of aquatic invertebrates including annelid worms, molluscs, variety of crustaceans and insects; also seeds. Feeds by scything in lower water column or mud layer; sometimes also by pecking. Diurnal forager.
Breeding. Season Aug-Jan in some southern areas, elsewhere opportunistic, depending on wetlands being filled with floodwater. Breeds in solitary pairs or in colonies of up to 150 pairs, sometimes in company of *Himantopus himantopus* and other waterbirds; nests are minimum of 1·6 m apart, and comprise depression in ground, lined with vegetation. Usually 4 eggs (2-5); incubation probably at least c. 23-25 days; downy chicks buff above, white below, with dark brown eyestripe, dark brown spots on crown and large paired spots on back; chicks nidifugous, cared for by both parents. Hatching success 31% for 72 eggs.
Movements. Occurs mainly in S Australia, where dispersive in response to changing water levels. Seasonal pattern involving inland movement in winter and coastal movement in summer may be modified by inland drought, or rainfall and subsequent availability of food; prolonged or severe droughts cause dispersal into areas where species usually rare, e.g. E of Great Dividing Range. Possible movements into parts of N Australia also recorded. Vagrant to Tasmania and New Zealand.
Status and Conservation. Not globally threatened. Total population exceeds 100,000 birds; main site is L Eyre, with 95,000 birds in early 1980's. Gradual loss of wetlands in some areas possibly offset by creation of salt-works and sewage ponds where birds frequently occur. Species formerly present in New Zealand, where apparently became only tenuously established following irruption starting in 1859; present during latter half of 19th century, but now merely vagrant, with only 2 definite records from 20th century.

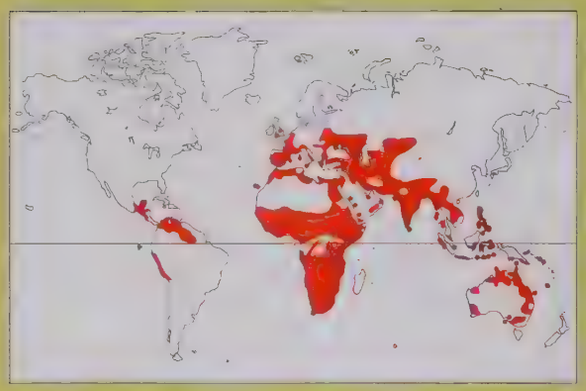
7. Andean Avocet

Recurvirostra andina

French: Avocette des Andes **German**: Andensäbelschnäbler **Spanish**: Avoceta Andina

Taxonomy. *Recurvirostra andina* Philippi and Landbeck, 1861, Laguna Parinacocha, Peru.
Monotypic.
Distribution. C Peru (Junín) S through W Bolivia to N Chile (NC Atacama) and NW Argentina (Catamarca).



Descriptive notes. 43-48 cm; 315-410 g; tarsus 77-84 mm. Compact, heavy-bodied avocet, with relatively short legs compared to other members of family; stilt-like in plumage, but with typical avocet bill; differs from all other avocets in having orange iris and yellow eye-ring; head, neck, upper mantle, rump and underparts white, often stained ferruginous below; rest of mantle and wings blackish to very dark brown; bill black; long legs blue-grey. No sexual differences in plumage known. Juvenile has inconspicuous rusty feather edges on upperparts, but these soon wear off.
Habitat. Breeds at high altitudes, above 3100 m, typically in *puna* zone of Andes; generally occupies saline and alkaline lakes; also marshes, where occurs only in rather open parts, often on exposed alkaline flats; also seasonally flooded alkaline meadows; sometimes in and around small pools. Occasionally found on other wetlands, including even tidal flats along coast outside breeding season.
Food and Feeding. Little known. Apparently feeds on free-swimming invertebrates. Forages by scything in shallow water; sometimes swims and upends like other avocets. Often feeds in association with Chilean Flamingos (*Phoenicopterus chilensis*).
Breeding. Little known. Apparently breeds in local "summer", but timing of breeding may depend on local rainfall; eggs recorded in Sept and Oct, Jan and Feb, possibly representing two seasons per year, a practice which is regular for sympatric *Himantopus himantopus*. Usually 4 eggs; chick greyish white above with dark spotting, white below. No further information available.
Movements. Little known. Probably mainly sedentary. Some altitudinal movement to lower altitudes recorded in Apr-Jul, and species rarely wanders to coastal areas of N Chile and Peru, but in Jul still recorded up to 5000 m.
Status and Conservation. Not globally threatened. Status very poorly known, but species considered to be generally sparse; small parties of 15-20 birds may be regular. Population in C & SC Peru rather disjunct and isolated in Junín and Ayacucho. Massive desiccation of L Poopó, WC Bolivia, could represent serious loss of habitat, although species persists in small pools along dried up margins. Suitable habitat still fairly extensive; not known to suffer serious hunting pressure.

Class AVES

Order CHARADRIIFORMES

Suborder CHARADRII

Family BURHINIDAE (THICK-KNEES)

- Medium-sized terrestrial waders, with long legs, long wings and cryptic plumage; bill usually short, but large and heavy in some species.
- 32-59 cm.

- All regions except Antarctic, but mainly tropical; greatest diversity in Old World.
- Semi-arid to arid open areas, sometimes linked with water; one species strictly coastal.
- 2 genera, 9 species, 19 taxa.
- No species threatened; none extinct since 1600.

Systematics

As members of the Burhinidae superficially resemble some bustards (Otididae) the family was in the past sometimes classified alongside the bustards in the order Gruiformes. However, these similarities are nowadays agreed to be the product of convergent evolution of birds with somewhat similar terrestrial lifestyles occupying much the same biotopes. The combined weight of several skeletal, biochemical and parasitological characters, as well as the patterns of the downy young, suggests that this family is correctly placed in Charadriiformes.

Its closest relatives within this order are, however, quite uncertain, although there does at least appear to be general agreement that the family is allied to Charadriidae rather than to Scolopacidae. The Crab Plover (*Dromas ardeola*), with some structural, behavioural and dietary resemblance to the *Esacus* thick-knees, is sometimes suggested to be a close relative, although again the similarities adduced may well be attributable to parallel evolution. The peculiar Egyptian Plover (*Pluvianus aegyptius*), normally included within Glareolidae but on occasion awarded a family of its own, has been linked with Burhinidae on the basis of some shared osteological characters. Other studies back up a relationship with Glareolidae, but much of the evidence, such as the poorly developed salt glands and the structure of the nostrils and the palate, can yet again probably be considered to be the result of convergence within relatively similar arid habitats. In linear classifications Burhinidae has regularly been placed alongside Recurvirostridae and related families, and the evidence of work with DNA supports the idea that this group and the plover family Charadriidae may constitute the thick-knees' closest relatives.

One to three genera are recognized within Burhinidae, but most recent authors recognize two, with seven species in the semi-cosmopolitan *Burhinus* and two in the southern Asian and Australasian *Esacus*. Some authorities would lump all nine species in *Burhinus*, but there appear to be good reasons for maintaining two genera. The Great Thick-knee (*Esacus recurvirostris*) and the Beach Thick-knee (*Esacus magnirostris*) are clearly similar to each other in structure, size and plumage, and they also share ecological similarities, for instance in their food and habitat preferences. On the other hand, the typical *Burhinus* thick-knees are generally smaller and slimmer, with smaller bills and more mottled plumage patterns. They appear to form a close-knit group, clearly distinct from *Esacus*. The one exception that might be proposed within this group is the Bush Thick-knee (*Burhinus grallarius*) of Australia, which is actually as large as the two *Esacus* species, but in all respects this species can be considered simply a largish, long-legged, long-tailed, otherwise typical, member of *Burhinus*. Formerly, the two *Esacus* species were at times considered generically distinct, with the Beach Thick-knee being awarded the monotypic genus *Orthorhamphus*, but this treatment has now fallen into disfavour, in view of the marked similarities between the two.

There is a fairly general consensus as to species limits within the family, but the one case for dispute again concerns the two *Esacus* species. Some authors maintain that these two forms should be treated as conspecific, perhaps a somewhat surprising

Over the years generic treatment of the Beach Thick-knee has been rather varied. Formerly awarded the monotypic genus Orthorhamphus, *it is now usually placed in* Esacus *together with the Great Thick-knee* (Esacus recurvirostris), *although some authors prefer to lump all of the thick-knees in the genus* Burhinus. *However, these two heavily built species differ from the typical* Burhinus *species in a number of structural details, most notably the massive bill, while both feed extensively on crabs. The two are very closely related to one another, and indeed are still occasionally considered conspecific.*

[*Esacus magnirostris*, Lizard Island, Queensland, Australia. Photo: Jean-Paul Ferrero/ Auscape]

One of two Neotropical members of Burhinidae, the Double-striped Thick-knee is a fairly tall species, somewhat longer-legged and longer-necked than most other members of the family, with a large, broad head and large, staring yellow eyes that denote a mainly crepuscular or nocturnal lifestyle. The bill is darker and slightly heavier than in other Burhinus *species, while the long greenish yellow legs, which suggest the mainly terrestrial nature of the bird, show the characteristic enlarged tibiotarsal or "knee" joint to which the birds owe their name of "thick-knees". On the upperparts, upperwing-coverts and rump the dark brown centres of the feathers with their paler edges give this species a markedly streaked appearance overall, providing good camouflage. However, it is the head patterning, with the long whitish supercilium and the equally long, well defined dark lateral crown stripe, that constitutes the single most significant feature of this distinctive thick-knee, as its vernacular and scientific names underline.*

[*Burhinus bistriatus vocifer*, Venezuela. Photo: John Cancalosi/ Auscape]

Widely distributed over the African continent, the Spotted Dikkop is a dry country species that shows no particular liking for the vicinity of water. It is to be found in open savanna or grasslands but, unlike some thick-knees, also in bushy or sparsely wooded areas, where it seeks cover and shade in which to rest during the heat of the day. It does not seem to shun the proximity of man, and occurs at times in large parks, on playing fields and on sandy beaches. It has even been known to nest on occasions in suburban gardens.

[*Burhinus capensis damarensis*, Sandwich Harbour Bird Sanctuary, Namibia. Photo: Alberto Nardi/ NHPA]

suggestion, since until relatively recently many taxonomists regarded them as different enough to merit separate genera. Until new evidence appears to the contrary, the middle course is probably the most appropriate, namely to recognize two species in a single genus.

Several species show subspecific variation, but this is generally only to a rather limited degree, involving slight differences in size and colour tones, a tendency which is not altogether unexpected in a family that can, for the most part, be considered phenotypically rather homogeneous at the species level. Variation in the widespread Stone-curlew (*Burhinus oedicnemus*) is clinal in both size and coloration, but these characters vary in differing geographical directions so the establishment of racial identity is often difficult. Northern populations are migratory and may spend the winter months within the breeding ranges of southern ones, which has further complicated past understanding of geographical variation and subspeciation within this species. At present, six races are normally accepted, but the range of variation is such that several other races have been proposed.

Two thick-knee species have long been the source of much confusion due to problems of nomenclature. Until very recently, the scientific name of the Bush Thick-knee was almost invariably given as *Burhinus magnirostris*. This caused considerable problems when authors opted to include the Beach Thick-knee in the genus *Burhinus*, as it was frequently unclear whether the name *Burhinus magnirostris* was being applied to one species or the other. The Bush Thick-knee was originally described by J. Latham in 1801, when he named two "new species", *magnirostris* and *grallarius*, on the same page; unfortunately, both of them subsequently turned out to be the Bush Thick-knee! However, the International Code of Zoological Nomenclature covers such eventualities, and, following the principle of first reviser, J. Gould's adoption of the name *grallarius* for this species in 1845 now stands as definitive.

In the meantime, though, the Beach Thick-knee's valid species name has, in turn, been the source of much debate and several proposed name changes. It was suggested that L. P. Vieillot's 1818 name *magnirostris* was not applicable to this species, as it had become a junior secondary homonym due to the grouping of this species in the same genus as the Bush Thick-knee. J. Wagler's 1829 name *giganteus* was proposed, but it was argued that this name was unidentifiable, and so should be replaced by G. M. Mathews's 1912 name *neglectus*. However, with the establishment of *grallarius* as the valid name for the Bush Thick-knee, the principle of homonymy does not come into play, so the correct species name for the Beach Thick-knee remains *magnirostris*, independent of whether it is placed in *Esacus* or *Burhinus*.

While the nomenclature should now be clear for future work, there can be no doubt that the confusion will persist with regard to many records in older literature, every time the name *Burhinus magnirostris* crops up, a situation not helped by the plethora of rather similar vernacular names that exist for both of the species involved. Scientific nomenclature is designed to clarify the identification of taxa by using unique names; this is a very clear case of the pandemonium that can result from the same name being applied to two species that are physically not even particularly similar!

Morphological Aspects

While thick-knees share some physical characteristics with similar-sized plovers and bustards, they remain a recognizably defined small group of species with distinctive traits of their own. They vary in overall length from about 32 cm in the Senegal Thick-knee (*Burhinus senegalensis*) to as much as 57 cm in the Beach Thick-knee and 59 cm in the Bush Thick-knee, although the latter is markedly slimmer, lankier and longer-tailed than both of the *Esacus* species. There are no differences between the sexes, apart from some very minor ones in plumage pattern in the Stone-curlew, and, equally, fledged juveniles are very similar to adults.

Species of the typical *Burhinus* group have rather stout but medium-short bills, with the bulbous tip tapering to a sharp point in a side view; from above or below, the bill is broad-based but compressed into a blade-like form towards the tip. Although short for a wading bird, the bill looks rather substantial in the field, more so than in plovers. In most species the bill is black with a variable amount of yellow at the base. The nostrils are long, slit-like openings perforated right through the bill, as, for example, in gulls (Laridae). The long legs are coloured pale ochre to vivid yellow, with an exposed tibia and a swollen tibiotarsal or "knee" joint, whence the name "thick-knee" given to the group, although ana-

Generally speaking, thick-knees are sociable birds, and outside the breeding season they gather in flocks of varying size, often frequenting traditional sites. A small group of Senegal Thick-knees is here seen resting during the daytime on the preferred habitat of a muddy river bank. Although sometimes occurring as solitary nesters, they mostly form loose breeding colonies and even closer nesting communities when space is at a premium, as, for example, on the flat roofs of houses, where they have occasionally been recorded as nesting.

[*Burhinus senegalensis*, Basse, Gambia. Photo: Alan Williams/ NHPA]

tomically this is a misnomer, as it is actually the "raised" ankle joint. The legs are markedly scaled, or reticulated. The hind toe is lacking, and the three forward-pointing toes are slightly webbed.

Apart from the stout bill, the large head is characterized by a broad, sometimes domed, crown. The shape of the head is the origin of the common name of both the Water Dikkop (*Burhinus vermiculatus*) and the Spotted Dikkop (*Burhinus capensis*), as the Afrikaans word *dikkop* means "thick head". In most species, the pale base of the bill may show more clearly than the pale eye at a distance, but at close range it is the eye that becomes the most arresting feature, always looking large, round and staring, an adaptation to a crepuscular or even predominantly nocturnal lifestyle. Further exaggerating the aspect of the eyes, the head is patterned with strong dark brown to black and creamy white stripes. In the four Eurasian and African species, a broad pale band continues the line of the pale base of the upper mandible as a sweeping, curved stripe underneath the eye.

The rest of the plumage is cryptically coloured, based on a pale, sandy brown ground with streaks, mottles and spots of cream, buff, brown and black. As is often the case with pale birds of open landscapes, the underside is paler still, using countershading as a means of cancelling out the effects of shadow cast by the sun or bright sky, so helping the bird to blend in with the background tone.

The closed wings have a more or less banded appearance, owing to the pale and dark rows of upperwing-coverts which create a succession of horizontal lines, an effect that is least marked on the two American species, the Double-striped Thick-knee (*Burhinus bistriatus*) and the Peruvian Thick-knee (*Burhinus superciliaris*). The latter is somewhat aberrant, having a much plainer and greyer plumage overall, although the head is boldly marked with a broad white supercilium bordered above by a conspicuous blackish stripe.

When a thick-knee takes flight, it reveals a much more striking and contrasted plumage and thus frequently becomes obvious for the first time to an observer who may have overlooked the bird as it remained motionless on the ground, relying on its camouflage to evade detection. The long wings are patterned with brownish, black and white, with a broad pale buff or greyish band across the inner upperwing-coverts. The black primaries have broad white patches, perhaps most noticeable in the Bush Thick-knee, and remarkably obvious and eye-catching compared with the cryptic colours exhibited when the bird is at rest.

The wings are long, and are held rather straight and outstretched in active flight, with a long inner wing and a marked carpal angle; the outer wing is scarcely tapered, although the extreme tip of the wing can appear rather pointed. There are 11 primaries, with the outermost minute and concealed by the primary coverts, and 16-20 secondaries. The tail, made up of 12 feathers, is generally short and rounded, except in the cases of the Spotted Dikkop's medium-length tail and the Bush Thick-knee's longer, more tapered tail. In some species, notably the Double-striped Thick-knee, the legs and toes extend beyond the tail tip in direct flight.

The two *Esacus* species, the Great and Beach Thick-knees, are generally larger, considerably bulkier birds, in which sense they are reminiscent of miniature bustards; their deep-chested, broad-backed bodies, held horizontally on strong, thick legs, create a remarkably heavy, far less elegant, appearance compared with the *Burhinus* species. Indeed, both species are almost goose-like in their body shape and proportions when on the ground, while their strange, rather long bills and long legs give an improbable mixture of features very different from all other waders, except perhaps the Crab Plover. In addition to their heavy build, they are heavy-billed, which adds a grotesque note to their facial appearance, especially in the Beach Thick-knee, which has a particularly large, deep, boat-shaped bill, whereas that of the Great Thick-knee is a little more tapered and noticeably uptilted. In both species the bill is remarkedly well adapted to the bird's feeding habits and diet: crabs and other invertebrates form a large proportion of their food, and the Great Thick-knee's heavy, upturned bill enables it to prise up stones as it searches for its prey, while the Beach Thick-knee dismembers or breaks crabs into small portions by hammering them on the ground with its massive bill before swallowing the bits. These large bills are mainly black with a restricted area of yellow at the base, and they combine effectively with the striking black and white head patterns.

These two species lack the fine streaking and mottling that characterize the plumage of most *Burhinus* species. They are more bustard-like in flight, with a protruding bill, head and neck, a stocky

Mainly nocturnal in their behaviour, thick-knees start becoming active at dusk. Most of the day is spent resting in an upright posture, usually in the shade, but sometimes even out in the open on undisturbed ground. Standing or sitting motionless, they rely on their cryptic plumage to escape detection. This Peruvian Thick-knee, which does not appear to be particularly well camouflaged against its grassland background, seems to find standing on one leg a comfortable stance.

[*Burhinus superciliaris*. Photo: Rod Williams/ Bruce Coleman]

body, long, broad, square-ended wings with more or less fingered primary tips and a particularly short, square tail. The wings have large white areas towards the tips and contrasting upperwing-covert patterns, while below the birds reveal large areas of pure white. The legs are pale, dull greenish yellow or yellowish, and the toes extend just beyond the tip of the tail in flight.

The long legs and three forward-pointing toes of the Burhinidae suggest that these birds are predominantly terrestrial in their lifestyle, as is indeed the case. Thick-knees have a measured, sedate walk, in which the head and body are held rather horizontally and maintain the same position relative to the ground, despite the long strides that the birds take. When necessary, the walk is easily accelerated into a smooth run, with the head frequently held farther forward while the legs are somewhat angled. The pale legs often appear much the same tone as the background earth or grasses and, from a distance, a thick-knee can look like simply a head and body moving smoothly, effortlessly and mysteriously forwards slightly off the ground.

Flight may be sudden or preceded by a quickening run, the long wings producing a fast, direct flight but relatively poor manoeuvrability. Landing may likewise extend into a short, forwards run before the bird settles into a walk or comes to a standstill. The Bush Thick-knee gains take-off speed with a short run and when alighting runs a short way, opens and closes its wings and then stalks away very slowly. Active flight is usually quite low, with regular, shallow wingbeats, recalling that of curlews (*Numenius*).

Adult thick-knees have a complete post-breeding moult, the primaries being shed in descendant sequence, and the whole process may take four or five months to complete. In the Stone-curlew, the moult of the outer primaries may be suspended and two or three old feathers retained during the winter, to be replaced the following spring, at which point the inner primaries may begin to moult again, so that the bird exhibits serially descendant moult. Normally, however, the pre-breeding moult is erratic and often restricted to the head and neck, sometimes extending over the body, but often apparently not undertaken at all. Juveniles have a post-fledging moult, involving the feathers of the head and body, some wing-coverts and the central tail feathers, which begins soon after fledging, but in the Stone-curlew this is suspended by late autumn. The Senegal Thick-knee exhibits a similar moult regime, with some individuals retaining some outer primaries during the winter and moulting them in the following spring.

Habitat

Although few in species, the thick-knees have representatives on all continents except Antarctica. Most live in the tropical or subtropical zones and are for the main part sedentary. Only one species, the Stone-curlew, breeds mostly in temperate climes and even then it is partly migratory in order to escape the northern winter.

Thick-knees are essentially birds of dry, open country, though several are more specific in their requirements and favour mainly waterside habitats. Most species tend to frequent a variety of exposed, largely low-lying, flat or rolling landscapes, and can breed in arid or semi-arid deserts with only a very limited amount of vegetation. They are entirely absent from all closed woodland and forest areas, but as they are essentially crepuscular and nocturnal in their principal activities they often seek the shade provided by bushes, trees, low vegetation or boulders, where they can rest inconspicuously during the heat of the day, relying heavily on the cryptic coloration of their plumage to escape detection.

The Stone-curlew is a typical member of the family in its requirements; indeed, its very name denotes the harsh, arid nature of the environment it ideally prefers to occupy. It needs open spaces with extensive visibility, dry and fairly even ground on which it can run easily, and a mixture of bare earth, shrubby or grassy vegetation. Unfortunately, in most European countries, the steppes, arid grasslands and heathlands that up to now have constituted the strongholds of the species are areas which are increasingly under threat, and, although the Stone-curlew has to some extent learnt to adapt to arable farmland conditions, its populations in several countries have suffered a marked decline (see Status and Conservation).

Although the ranges of certain species overlap, notably in Africa, it would seem that slight, but significant, differences in habitat requirement prevent their entering into competition with each other. Thus, in North Africa, where the Stone-curlew and Senegal Thick-knee co-occur, the latter, in general habits very similar to the Stone-curlew, nevertheless differs from it in avoiding open deserts. It is normally found within 2-3 km of water amd may be seen on the banks of rivers and even on rocks in mid-stream. In Africa south of the Sahara, the Senegal Thick-knee and the Spotted and Water Dikkops are all present, as is the Stone-curlew in certain restricted areas, in its winter quarters. Over this vast area, the Spotted Dikkop in general prefers dry open country and shows no marked preference for water, at least in the north of its range where it may coincide with the Senegal Thick-knee. The Water Dikkop, which is found mainly south of the equator, is, as its name suggests, closely tied to water, even more so than the Senegal Thick-knee; in addition, it is the only African thick-knee to occur in coastal areas, on the shores of creeks and islands.

In Australia, where both the Beach and the Bush Thick-knee are present, the former is a strictly coastal bird, never found inland, whereas the latter, although it is seen in coastal scrub, chiefly inhabits inland areas. The Great Thick-knee is partly sympatric with the Stone-curlew on the Indian Subcontinent, where the latter species is mainly sedentary. The Great Thick-knee is another species that favours waterside habitats, frequenting shingle banks along large rivers and the shores of freshwater lakes. It tends to visit grassland near water when the riverbanks may be flooded, but normally it stays close to its shingle sites.

Most of the Burhinidae are timid and wary of man, yet occasionally some of them can be observed in the vicinity of human habitation. The Stone-curlew is known to nest on the outskirts of villages and towns at some localities, while the Spotted Dikkop may perhaps even nest in suburban gardens. The Senegal Thick-knee does not shun humans, and apparently still nests on rooftops in the centre of Cairo, while the Bush Thick-knee, in the northern part of its range in Australia, will frequent wasteland in towns and villages.

General Habits

Thick-knees are mainly terrestrial. Most of their activities take place on the ground and, although they are capable of strong

sustained flight, even when they know that danger is approaching, they nearly always prefer to walk or run away rather than fly. Only when they are suddenly surprised will they take to the wing immediately.

They are generally sociable birds, and outside the breeding season flocks of dozens or, where they are common, even hundreds, may gather, frequently using traditional sites that have been used at least for many decades. In Europe, Stone-curlew gatherings have been known to reach 300 birds, while up to 150 have been seen together in Tunisia and 100 in Morocco. Spotted Dikkops spend the daylight hours in loose flocks of up to 50 birds. Some species may even feed and display communally during the breeding season, although roosting parties generally scatter more widely to feed. Stone-curlew gatherings in Britain in autumn now rarely number more than 30-40 birds, as the species has declined, while parties of more than 100 Bush Thick-knees in New South Wales, Australia, are now described as a thing of the past, with 5-20 individuals more usual, after this species' long population decline; however, flocks of 30-40 birds remain more frequent in northern Australia.

All *Burhinus* species are largely nocturnal in their active behaviour, spending the day resting motionless and inconspicuously in the shade of low vegetation, or standing or sitting on some undisturbed patch of open ground. At dusk, the birds become more active and may fly some distance to a suitable feeding area, or, if they are within range, they simply walk to their feeding grounds. The Water Dikkop is more likely to be active and vocal by day than the other species, but it is still essentially a nocturnal species. Both feeding and social displays take place from late dusk onwards. This is one reason why displays are not all associated with display-flights and demonstrative behaviour, as with so many waders, but are instead centred more on loud and varied vocalizations. Of the two *Esacus* species, the Great Thick-knee is largely nocturnal, but the Beach Thick-knee is much less so, and can be seen feeding by day on beaches and islands, which in any case provide little daytime cover.

When resting, a bird may adopt a more upright pose than that assumed during active feeding, with the head hunched into the shoulders and tail tilted downwards. A typical resting posture involves sitting with the full length of the tarsus on the ground and the tibia upright. If alarmed, a thick-knee will suddenly bob its head up and down, making a corresponding movement with the tail as if the bird were swivelling, pivoting on the top of its legs. Unless immediately threatened, however, it generally prefers to run or to crouch stock-still, either freezing in a hunched stance or even lying flat on the ground to avoid being seen. Bush Thick-knees have several times been reported as allowing themselves to be picked up by observers who have detected them in this position. Downy chicks have the same habit of freezing, crouched to the ground, when a parent bird signals alarm.

Whatever they are doing, to a human observer thick-knees almost invariably have a furtive, secretive look. Water Dikkops and Senegal and Great Thick-knees prefer to remain still on the side of a stream, even when closely approached by a passing boat. Beach Thick-knees are described as shy in populated areas, but extremely inquisitive in remote areas where they seldom see humans.

One of the two massive Esacus *species, the Great Thick-knee, with a range stretching from Iran through India to Indochina and southern China, favours exclusively waterside habitats since it feeds mainly on crabs and other crustaceans. It frequents shingle banks along large rivers and the muddy shores of lowland lakes. When seasonal flooding of rivers occurs it sometimes visits nearby areas of grassland, and it is also to be found occasionally on undisturbed coastal beaches.*

[*Esacus recurvirostris*, Rajasthan, India. Photo: David Tipling/ Windrush]

Voice

All thick-knees are generally silent by day, but at dusk they start to become vocal. Their calls are penetrating and often far-carrying, and sound eerie to the human ear. The *Esacus* species have loud, rather harsh, wailing calls, with a more or less rising inflection, and weaker, more yapping alarm notes, but it is the *Burhinus* thick-knees which give the more remarkable vocal performances.

All thick-knee vocalizations have much the same quality, often described as wailing, whistling, mournful and plaintive, but several species have a wide variation of sounds. The Stone-curlew makes short, sharp notes recalling those of oystercatchers (Haematopodidae), and these are repeated in an accelerating series, which builds up to a more prolonged, curlew-like "cur-leee" and then dies away. The Senegal Thick-knee has a more nasal quality to its calls, which ring around the buildings of African towns and villages after dark in a mysterious chorus. Double-striped Thick-knees, in turn, have shorter, but equally strident, calls. The Peruvian Thick-knee is locally named "Huerequeque" in an transliteration of its voice, and similarly the Aborigine name for the Bush Thick-knee is "Willaroo", an onomatopaeic approximation to its usual call, which is likened to a long-drawn, whistling scream. In this species, as in the Stone-curlew and Senegal Thick-knee, several individuals join in a prolonged chorus which gives the impression of excitement and urgency, increasingly so at the onset of the breeding season.

The precise role of thick-knee vocalizations is still poorly understood, owing to the difficulty of observing their behaviour when they are active, often very mobile, after dark. At least in the Stone-curlew, the best studied species, it is thought that groups are more vocal than pairs, so that voice may be more important in interactions between neighbouring pairs than in the relationships between a paired male and female. The members of a pair tend to be relatively silent when newly arrived in a breeding area in spring, but they become much more vocal around the prelaying period, and quieter again thereafter, until the young are fledged, when they once again become noisier.

Daytime calling is most frequent from individuals establishing a territory, or from unpaired or non-breeding birds, which are more easily attracted to an imitation or recording of a call than are settled, territorial pairs. Normally, calls begin some 30 minutes after sunset, stimulated by a single individual which is then answered by its partner and other pairs. There is less calling during the middle of the night, and vocal activity ceases towards dawn.

Some of the calls are difficult to place into a particular context, or even to match closely with published descriptions, but a dozen or more call types have been described for adult Stone-curlews. These are related to aggression; to greetings between pairs and when groups of territory-holders meet; to specific behaviour such as nest-scraping and spring displays; to distraction displays, when adults defend nests with eggs or chicks from predators; and to the conversational notes used by adults when they are brooding newly-hatched chicks.

Food and Feeding

There is a certain uniformity about the food taken by *Burhinus* thick-knees, and the method of feeding is always much the same,

Unusually, a Stone-curlew is caught drinking from a pool in the daytime. Normally Burhinus *species are nocturnal feeders; they spend the day resting, often in the shade, and only become active towards dusk when they may either fly, sometimes several kilometres, or walk to a rich feeding area. The diet of most thick-knees is imperfectly known. The Stone-curlew, the most widespread and best studied member of the family, feeds on a variety of insects and small invertebrates, such as lizards and frogs, and will even take other birds' eggs.*

[*Burhinus oedicnemus oedicnemus*, La Serena, Spain. Photo: Cristina Barros Fuentes/Desert Photos]

involving the bird picking up items from the ground with the bill, as it walks forwards. Most food items are small animals, such as insects and other invertebrates, but a variety of small mammals, reptiles and birds' eggs are also taken.

The detailed food of most species is rather poorly known, but insects probably predominate in most cases, throughout the greater part of the year. For instance, Senegal Thick-knees take insects, particularly beetles, crickets and grasshoppers, but also crustaceans, molluscs, worms, rodents and frogs, which are found by foraging near water or as much as two or three kilometres away from it.

Beetles, earwigs, chafers, moths, snails and slugs, lizards, frogs, voles and mice, eggs and, much more rarely, shoots of low shrubs make up a varied fare for the Stone-curlew, and in Russia ants have been found to be more important in the diet. In a study of this species in southern Britain, nesting birds were found to feed on earthworms, woodlice, millipedes and beetles, and much of the food was associated with the dung of large grazing livestock. Feeding often took place close to the nest, but radio-tagged birds were followed as much as two kilometres away to feeding sites, such as grassland enclosures grazed by rabbits, outdoor enclosures with pigs, and arable fields; at these sites, the birds fed near the edges, around grassy margins, or even from heaps of animal manure.

While most other studies of food have relied on stomach contents, the British study used microscopic examination of faeces, in conjunction with the examination of the faeces of a captive individual, with known diet, which was used as a control to determine the validity of the method. Useful information is also to be gained from pellets of indigestible matter, such as bones and beetle wing cases, which can be found at daytime roosts.

The larger members of the Burhinidae can be quite formidable predators. Bush Thick-knees have been seen killing larger prey, such as frogs and rodents, by hitting them on the ground before swallowing them. The Great Thick-knee has a similar diet to the smaller thick-knee species, but it takes many crabs too, while the Beach Thick-knee is much more of a crab specialist, catching crabs and other marine invertebrates by day as it feeds on reefs and rocky shores.

When actively feeding, a thick-knee moves slowly, sometimes pausing and tilting forwards like a plover, picking up food from the ground ahead. Large food items may be spotted from several metres away, while more active, lively prey, such as grasshoppers and rodents, may induce a short, quick run or a more active lunge with the bill. Moths may be caught in the air, with short leaps from the ground to snatch them, while smaller insects and caterpillars are picked more deliberately from leaves and stems. The Beach Thick-knee forages along the shore, sometimes using a stop-start run and pause action, but often stalking prey more slowly and carefully, much in the style of a heron. Feeding parties of the smaller thick-knee species may number up to seven individuals.

Breeding

The breeding habits of the Stone-curlew, in particular, are fairly well documented, as the result of a considerable amount of investigation, but those of others, especially the two American species, the Double-striped and the Peruvian Thick-knees, have received very scant attention, so information about many aspects of their breeding cycle ranges from very limited to non-existent. However, as the biological and behavioural similarities between the members of this small family are great and the known details of their breeding cycles also mainly coincide, additional information gleaned from research on the Stone-curlew may well be applicable to other members of the family too. At the same time, though, it must be remembered that the Stone-curlew in temperate Eurasia is atypical in some respects, the most important of which is the fact that it is the only member of the family that is truly migratory, flying to temperate regions to breed in spring and returning to warmer climes in autumn to escape the rigours of the northern winter.

As all other thick-knees breed principally in the tropics or subtropics, their breeding season is much more variable than that of the Stone-curlew. The pattern is largely one of opportunism, matching the reproductive cycle to the availability of suitable nesting sites and food resources, and in many cases nesting during dry seasons. The Senegal Thick-knee, for example, which frequents waterside habitats, in some areas lays its eggs in the dry season, when the lower water levels in the rivers lay bare suitable sandy banks, where it can site its nest. Likewise, the Great Thick-knee, a species even more restricted to rivers and lake sides, in India nests from February to March, well before the monsoon rains begin. The Water Dikkop times its breeding for the dry season and the early rains in southern Africa, but in the drier spell before the October rains around Lake Victoria.

Most species are known to be monogamous. In Britain some Stone-curlews are clearly paired when they arrive in spring; they retain a monogamous relationship and remain faithful in a lifelong bond, which appears to be reaffirmed and strengthened upon arrival each spring. Whether or not other thick-knees pair for life is not yet clear.

When a Water Dikkop feels its eggs or young threatened by the approach of a potential predator, like this sizeable monitor lizard (Varanus)*, it adopts an aggressive attitude towards the intruder. The typical threat posture involes the bird advancing slowly with its wings spread, revealing the striking pattern of black and white, while the head and neck are stretched horizontally forwards, as if the bird were intending a physical attack on its unwanted visitor.*

[*Burhinus vermiculatus*. Photo: P. Davey/FLPA]

Most members of the Burhinidae seem to be solitary when nesting, although at times they will form loose groups where the species is common or the area of suitable habitat is restricted, at least in the Double-striped and Senegal Thick-knees. The latter species is known to nest semi-colonially in some places: 21 nests were once found on a flat roof in Egypt, and even today the species is still said to nest on rooftops in the centre of Cairo.

Courtship behaviour has been well studied in the Stone-curlew, but difficulties of interpretation arise because of the problems of distinguishing between the sexes, owing to their identical size and plumage. Display behaviour sometimes occurs in small groups, but it is generally rather ill-defined. Males have infrequently been seen to perform short runs, skips and leaps with open wings in front of a female; the black and white wing and tail patterns may be important in such brief displays. More obvious are simple visual and vocal contacts which the pair maintain throughout the breeding period.

In this species, the nest scrape is selected in a bowing performance, in which the members of the pair adopt a forward-leaning stance with head and neck pointing downwards and, in extreme examples, the bill tip touching the ground. The male's bill finally indicates a chosen spot, which the female then shuffles onto and scrapes. The birds then take turns to sit in the prospective scrape, shuffling and turning and using the bill to pick up stones and twigs, which are thrown backwards over one shoulder. Several sites are investigated in this way, not necessarily all in the area of the eventual nest-site. The male calls the female to a scrape, which she will then shuffle onto, kicking earth backwards with her feet. The pair may then sit together, inactive, close to the scrape for long periods.

Before the eggs are laid, the male and female Stone-curlew may greet each other at the scrape with a bowing performance, which develops into a more extreme posture, as the birds run towards each other and draw themselves gradually into a very upright stance, tails pointed downwards and necks steeply arched, so the head and bill point down to the ground. The arched pose quickly subsides and the two return to a normal, relaxed stance. This "Neck-arch" display seems to be a necessary preliminary to copulation, although it can be abbreviated considerably. Copulation may be most frequent during the early stages of nest selection, after which its frequency drops for a time before a further rise again immediately before the eggs are laid.

Far less information is available on the courtship behaviour of other thick-knees, but the above details are likely to be the basis of the general pattern, at least in the case of the *Burhinus* species. Bush Thick-knees have dramatic dancing displays, and their performances when calling during the breeding season have been more fully described. They stand erect, often with wings fully spread and twisted vertically to reveal the striking black and white patterns, with the underside clearly visible from in front of the bird. Meanwhile they "run on the spot" with high-stepping feet, producing repeated wails which increase in speed, before a final flourish of screams and trills. This sequence may be repeated many times over a period of an hour or so. The Beach Thick-knee, though poorly known, is said to indulge in acrobatic flights above the territory, as well as dancing and bowing displays on the ground.

The location of the nest-site would seem to vary with the species. For example, the Bush Thick-knee favours areas in the shade, under a bush or a tree or near tall vegetation. Other species are content to nest in very open sites with little or no cover to protect them, either from predators or from the glare of the sun. The cryptic coloration of their plumage, both in young and adult birds, and also of their eggs, is a powerful aid in avoiding detection. The eggs are laid into a simple scrape or depression in the ground, sometimes totally unadorned, but more often lined with variable quantities of stones or shells taken from the immediate environs. The Senegal Thick-knee may surround the eggs with small pieces of grit, straw, wood and shells. The Water Dikkop can have a little more lining in its nest, which is often close to a piece of driftwood or a tussock of vegetation. It sometimes lays its eggs on dried animal dung, such as the scattered droppings of elephants, whereas the Spotted Dikkop uses smaller animal droppings and pieces of vegetation to line its nest. The Double-striped Thick-knee is similarly said to prefer dried animal dung as a base for its nest.

Except in the case of the Beach Thick-knee, which lays a single egg, the normal clutch is two, much more rarely three. Cases of four eggs in a single Stone-curlew nest appear invariably to be the result of two females laying in the same scrape. The eggs are laid at intervals of two days. They vary in size and slightly in shape according to the species. The large Beach Thick-knee lays eggs of 65 x 45 mm, whereas in the Bush Thick-knee they average 58 x 39 mm, in the Stone-curlew 54 x 38 mm, and in the Senegal Thick-knee 49 x 32 mm. In general they are rather rounded ovals, smooth and slightly glossy, generally whitish or buffish with brown spots and mottles. This cryptic pattern is said to vary somewhat in the Bush Thick-knee according to the local colour of the soil. Usually a single brood is reared, but a replacement clutch may be laid after the loss of the first, or even after the death of small young in the first brood.

The largest member of the genus Burhinus, *particularly long-legged though slim of body, the Bush Thick-knee will defend its territory courageously and adopt a variety of threat and distraction postures to deter and lure away any predator found in the vicinity of either its nest or its chicks. In the threat posture the wings are drooped until they almost touch the ground, forming a complete arc, and the tail is cocked and fanned. In this posture the apparent size of the bird is substantially increased and the effect of the threat intensified. If the intruder has not located the nest or chicks, the adult bird will attempt to distract it from its purpose by simply walking away from the sensitive danger zone with the intention of drawing the intruder away with it.*

As far as is known, incubation is carried out by both parents and lasts around 24-27 days. It usually begins after the laying of the final egg, but it can start before the second egg is laid, and two eggs may hatch on the same day or on consecutive days. The broken eggshells are carried away from the nest by the parents.

The chicks are precocial and nidifugous, already active and moving from the nest when just a day old. They have long, stout legs and a thick covering of down. The parents guard them and collect food for them in the early stages, and may move them to favoured feeding areas considerable distances from the nest itself. The Bush Thick-knee has been seen to lift its chicks from the ground as it stands up to brood them under a wing, and Senegal Thick-knees are strongly suspected of carrying their young. When warned of danger by their parents, young thick-knees lie flat on the ground, adopting the prone position with head and neck outstretched, in which posture they are extremely difficult to spot.

Approaching predators may cause an incubating or brooding bird to leave the nest unobtrusively, but should the nest be more seriously threatened, distraction displays and aggressive behaviour may occur. The off-duty Stone-curlew is quick to spot danger and warns its sitting mate. Alarm is shown by a special upright, taut and thin posture. The sitting bird almost always walks away from the nest very furtively, then breaks into a run and only a little later a low, fast flight. Flight direct from the eggs or chicks is exceptional and seems to happen only when the bird is taken completely by surprise. The off-duty mate may fly in a different direction, but eventually turns to meet the other and both stand at a distance to watch developments. If the intruder leaves, the male bird follows until he is about 100 m from the nest, at which stage the female walks back cautiously. If the danger comes from a ground predator, the bird called from the nest by its mate will dive at the predator and attack it, or stand its ground and face the predator with the long wings opened and the neck thrust forwards. It will also stand very upright with the wings fanned and raised, or partly opened, and with the tail fanned, in an effort to drive off threatening animals, such as sheep, which sometimes trample eggs or chicks.

If an intruder discovers small chicks, but does not prey upon them, the parent bird will later lead them to a new-site. Adults have been seen to carry chicks in their bills for short distances, but this was probably after eggshells had recently been removed and may have been a continuance of such behaviour.

Injury-feigning appears to be rare, and some observers who have regularly handled small young have reported it only on exceptional occasions: an adult may lie on the ground, with one wing spread and the other flapping, perhaps then jumping up, or flying a few metres, to repeat the performance once more.

Senegal Thick-knees may be rather tame at the nest in the face of a human intruder, moving only 15 m away when the nest is examined, and returning again when the person moves away, even if he remains to watch from a distance of 15-20 m. Bush Thick-knees defend their territories boldly and are aggressive towards potential predators which approach the nest, adopting a threat posture with drooped wings. If a ground predator has not apparently discovered the nest or chicks, the adult moves away on foot to lure the predator from the vicinity.

The chicks quickly become independent, and generally fledge at about six or seven weeks old, depending on the species, slightly earlier in the Stone-curlew, slightly later, at 47-50 days, in the Bush Thick-knee. Although there are records of one-year-old Stone-curlews breeding, the normal age for first breeding in Burhinidae is probably two to three years.

Little is known about the rate of breeding success in most species of thick-knees, but precise figures are available yet again for the Stone-curlew in Britain. In one study, out of a total of 128 eggs, 73% hatched, with failures being attributed to destruction by farm machinery, predation and egg-collectors. In another British study, 105 eggs were located, of which 65·7% hatched; of 44 chicks, 77·3% survived until they were at least half-grown.

Movements

Most species perform no more than local movements and some individuals are likely to live their whole lives within a few kilometres of the site where they hatched. The Stone-curlew is the major exception to the rule, as some populations in the north of its range make long migrations to escape the continental or cool temperate winter conditions which prevail in these breeding areas.

In Australia, Bush Thick-knees gather into loose groups or "clans" after the breeding season, and these roam widely in search of food, but they do not undertake true migrations. Nevertheless, from an area of some 10-20 ha occupied during breeding, these groups may increase their ranges in winter to 100 km² or more.

As in other aspects, the American species are poorly known, but they rarely occur outside their known breeding ranges. In Africa, Senegal Thick-knees are mostly resident, but in north-east Zaire birds arrive after the rains in November and remain until April or May, while the species is present during and after the rains in Senegambia (December to March) and Ivory Coast (November to April), indicating a more organized and regular movement. Water and Spotted Dikkops, however, are strictly sedentary.

The Stone-curlews of Europe and Central Asia, however, are strongly migratory. Those breeding in Britain and France, eastwards to Italy, Greece, Turkey and beyond through the Caucasus

The Stone-curlew's nest is a scrape of variable depth often in stony ground, sometimes lined with dry grass and ringed with small stones and pieces of vegetation. Though generally a wary, timid bird, it will on occasion nest quite near human habitation, as in this case. The clutch normally consists of two eggs which are buff in ground colour with dark streaks and blotches. Incubation is carried out by both sexes and lasts roughly 26 days. Note the very big glaring yellow eye, the sharply defined bill coloration, and the distinctive pattern of the wing-coverts on this adult as it prepares to incubate.

[*Burhinus oedicnemus oedicnemus*, Loire Valley, France. Photo: Roger Powell/ Aquila]

and Transcaspia into western Siberia, move out in autumn, whereas Iberia is occupied all year round. Small numbers occasionally remain in winter in France, many more in Spain, but most northern birds move across the Mediterranean into Africa. Ringing recoveries have shown that some birds spend the winter north of the Mediterranean, while populations that move to zones south of the Sahara are difficult to relate to particular breeding areas, particularly given the complicated subspecific variation within this species (see Systematics). Nevertheless, those found in Senegambia include birds of nominate *oedicnemus* and perhaps also of the race *saharae*, of the Mediterranean and the Middle East; *oedicnemus* is also known to reach Sudan, Uganda and Kenya.

Birds begin to leave Britain in August although many linger late into October, and rarely even into November. Departures from Africa are noted in March, by which time early arrivals are reaching Britain. Farther east, European breeding ranges may not be reached until late April or May. Siberian populations, south to Afghanistan, are thought to winter farther south and on into parts of the Middle East, but the north-west Indian populations seem to be resident and apparently remain quite separate. Breeding populations in North Africa and the Middle East appear to be largely resident, and these areas are certainly occupied by Stone-curlews all year round, although there may be a withdrawal from higher ground in winter. In the Canary Islands birds move from island to island, but do not, as far as is known, leave the archipelago.

Relationship with Man

The chief impact that thick-knees have had on man originate from their typical habit of calling loudly, with often strange, wailing voices, at dusk and on through the night. This has led to a series of local names based on vocalizations. The vocal performances of displaying groups of Bush Thick-knees, involving screams and hysterical screeching, naturally caused unease among early white settlers, as well as amongst Aboriginal peoples, and there are many references to them in Australian literature. Folklore and local names, for instance "Weeloo" and "Willaroo", reflect these sounds. The fact that the birds are difficult to see at night and tend to "melt away" into the slightest cover of vegetation by day were additional grounds for fear and superstition.

On the other hand, the Great Thick-knee has been described as "an engaging pet". Similarly, the Double-striped Thick-knee is sometimes kept as a semi-captive, or semi-domestic, bird around South American farms and villages in order to keep insect pests under control.

Thick-knees have not figured very strongly in traditional folklore except as rather vague, disembodied voices of the night. However, in western Europe a medieval tradition, common to several species with yellow plumage, and in the case of the Stone-curlew relating to its striking yellow eyes and bill, was that such birds were efficacious in the treatment of jaundice!

Status and Conservation

Due in part to the secretive habits of the family, little is known about the status and population trends of the different species. Nevertheless, sufficient data are available to see that by and large they have suffered from human interference and pressure.

Nearly always the problems revolve around habitat loss and disturbance. In Australia, most populations are in steep decline; indeed, in many areas that formerly held thick-knees the birds are now altogether absent. The Bush Thick-knee was common in much of south-east Australia until the 1930's. It had already disppeared from Tasmania by about 1900, and gradually vanished from most settled areas, so that by the 1980's, although a few widely scattered pairs remained, the species had mostly gone from south-eastern Australia, even from rural parts. The causes of this decline include overgrazing and disturbance by livestock, and predation by introduced cats and foxes. Indeed, outbreaks of disease in local fox populations have been reflected in temporary increases in Bush Thick-knee numbers. Nevertheless, it is clear that the fox is not the only problem, or indeed even a major one in some areas even where foxes are common: in several other parts of Australia, Bush Thick-knee populations have persisted in the face of fox presence. Urban development, intense grazing pressure, burning and cultivation of hitherto semi-natural habitats have been more serious causes of decline.

Beach Thick-knees choose remote beaches with little disturbance. The increased human recreational use of beaches for a whole series of activities including a number of obviously dis-

A bemused sheep is confronted by a pair of Stone-curlews valiantly endeavouring to protect their nest-site from this lumbering great intruder by adopting spectacular threat postures. The bird on the left has raised and spread its wings, at the same time lowering its fanned tail, while the one on the right has drooped its wings, but cocked and fanned its tail. Unfortunately, it is not infrequent for cattle and sheep to trample Stone-curlews' eggs and chicks, although investigation indicates that more losses are actually caused by farm machinery.

[*Burhinus oedicnemus*. Photo: Chris Knights/ Survival Anglia/Oxford Scientific Films]

A solitary nester, the Stone-curlew normally lays two eggs and raises a single brood, although a replacement can be laid if eggs or even small chicks are lost. The downy chicks, buff-coloured with black streaks, are precocial and nidifugous. They are cared for by both parents and do not attain independence until fledging at about 6 weeks old. They will not begin breeding themselves until they are 2-3 years old.

[*Burhinus oedicnemus oedicnemus*, Bárdenas Reales, Spain. Photo: José Antonio Martínez]

ruptive beach and water sports has, not surprisingly, resulted in a contraction of range and a steady decline in this species.

In Africa, where thick-knees have generally shown either a healthy disregard for man or even a relatively positive relationship with people, their livestock and villages, thick-knees have generally fared well in the face of increasing human pressure. Senegal Thick-knees still nest on Cairo roofs and feed around the abundance of droppings of assorted cattle, goats, camels, horses and donkeys along the banks of the Nile. Spotted Dikkops adapt well to suburban areas, choosing to nest in many semi-developed areas with tracts of derelict or waste ground, and even feeding on football pitches.

Several thick-knees, including the two American species, draw benefits from human presence in some ways. Roads at night, cultivated fields, and other open areas near habitation offer opportunities for feeding, although they cause some losses too. Thick-knees suffer casualties on roads at night: a potential benefit suddenly turned into a death-trap. The long-term effects of such mortality are unknown.

It is the Stone-curlew in Europe that has, perhaps, suffered most from the advance of man. In Britain alone, there were 1000 pairs or more in 1930, but by 1994 just 145 pairs. This massive decline, followed by a shaky consolidation in numbers at this low level, has occurred despite great public and professional interest in conservation and years of expensive research into the needs of the species.

In Britain, the extent of suitable habitat available has been greatly reduced. There has been a movement away from semi-natural habitats of downland and lowland heath, where grazing by sheep and rabbits kept the vegetation short, to farmland. Reduced stocking of sheep has made the downland habitat less tenable, while heaths have been subject to extensive afforestation with conifers. However, the arable land alternatives are not good for Stone-curlews, as the crops are too tall and dense by the time the hatching period comes round, and changes in seeding and harvesting times have rendered Stone-curlews on farmland less productive, as eggs fail to hatch, are deserted when the crop becomes too tall, or are destroyed, as, like chicks, they fall foul of machinery. In parts of Britain, chick production is sufficient to maintain the population, but these levels are achieved only with wardening of nests and constant liaison with farmers.

British Stone-curlews now receive direct protection from illegal egg-collectors, and also from over-enthusiastic birdwatchers, who are guided to special hides at Stone-curlew reserves. Agricultural policies in important areas have, through lengthy debate and political lobbying, been altered to favour Stone-curlew conservation, necessitating some management of land by conservationists, payments to farmers to encourage sensitive land use and the increased use of set-aside agreements, in which land is taken out of agricultural production. At the same time, individual threats, ranging from proposals to build golf courses and new roads to laying gas pipelines through breeding territories, have been fought in the planning process, while discussions with military authorities have been aimed at improving Stone-curlew productivity on army training grounds. Electric fences have been used to deter foxes from predating nests, newsletters have been published for farmers with Stone-curlews on their land, individual birds have been fitted with transmitters and radio-tracked, and pesticide usage and effects have been monitored. This is all expensive, labour-intensive and difficult work carried out by voluntary organizations, but the results have still been less than dramatic. The population decline appears to have been stabilized, but by the mid-1990's there is no clear sign of an increase. Nor has the range of the species in Britain been extended or returned to former dimensions. There is still, it seems, much to learn and much more to be done to ensure the Stone-curlew's future.

In other parts of Europe where Stone-curlew populations have been less studied and are for the most part totally unprotected, the species is under similar pressure. The main causes of death recorded in the Stone-curlew would seem to be collisions with fences and overhead wires, as well as hunting in southern Europe and Africa. There appears to be no evidence, however, that these threats are causing significant increases in the numbers of casualties. In southern countries, agriculture is changing rapidly, as European Union policies are having an effect. Semi-arid and other hitherto unproductive stony steppe-like areas are coming under the plough as farmers, with the aid of costly irrigation schemes, have been given incentives to produce cereal crops. In the last few years conservationists in Spain have launched a campaign to protect the "steppes" and their important avifauna, of which the Stone-curlew is only one of the threatened species. Coastal habitats, such as dunes and shingle, are under ever-increasing pressure, especially in Spain and France, as tourism and other recreational uses take a firm grip on the shoreline and its immediate hinterland. Farther east, agricultural development must also spell problems for Stone-curlew populations, as land-use trends follow those that have already caused declines in the west. There can be little doubt that the population trends of all species require regular monitoring, in order to ensure that any significant declines are detected before it is too late.

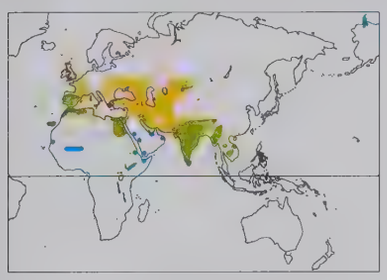
PLATE 32

inches 10

cm 25



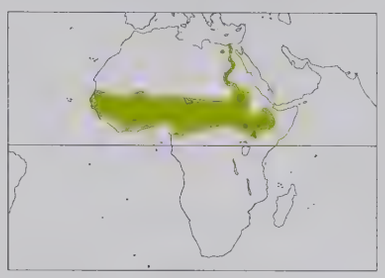
Genus *BURHINUS* Illiger, 1811

1. Stone-curlew

Burhinus oedicnemus

French: Oedicnème criard **German**: Triel **Spanish**: Alcaraván Común
Other common names: (Northern/European) Stone-curlew, Common/Northern/Stone Thick-knee

Taxonomy. *Charadrius Oedicnemus* Linnaeus, 1758, England.
Non-parallel clines in size and coloration confuse subspecific definition (see page 350) and several other races proposed; possible races *jordansi* of Balearic Is and *astutus* of Afghanistan and Persian Gulf normally included within nominate race and race *saharae* respectively. Six subspecies recognized.
Subspecies and Distribution.
B. o. distinctus (Bannerman, 1914) - W Canary Is.
B. o. insularum (Sassi, 1908) - E Canary Is.
B. o. saharae (Reichenow, 1894) - N Africa, Mediterranean islands, Greece and Turkey to Middle East, E to Iraq and Iran.
B. o. oedicnemus (Linnaeus, 1758) - S Britain and Iberia E to N Balkans and Ukraine and Caucasus.
B. o. harterti Vaurie, 1963 - R Volga area E through Transcaspia and Turkestan to Zaysan basin, and S through C Iran to Pakistan and extreme NW India.
B. o. indicus (Salvadori, 1865) - India and Sri Lanka E to Indochina.
Winters in S of breeding range, and patchily in Sahel zone, E Africa and Arabia.



Descriptive notes. 40-44 cm; 338-535 g. Sandy brown with white belly and vent, upperparts streaked darker; head finely streaked dark, with whiter lores, line above eye and broad band from upper mandible beneath eye to rear cheek; dark malar stripe; white chin and throat; breast heavily streaked blackish; upperwing-coverts marked by parallel bands of dark brown and white, with black lower border; inner primaries have square white patch at base and fine white tips; outer primaries have white central patch; bill yellow with black tip; eyes yellow; legs pale yellow-buff. Juvenile very similar to adult but with bright rufous buff tips to scapulars and inner wing feathers. Races vary in colour tone from pinker to greyer types; variation in overall size and leg length, but much individual variation too, especially in race *saharae*.
Habitat. Semi-arid, arid and steppe grassland, heath, arable fields with bare, stony patches, coastal dunes and shingle; also short-grass plains and semi-desert. Requires open, level ground with sparse vegetation cover, where running is easy; not normally near water.
Food and Feeding. Mainly terrestrial invertebrates and small vertebrates: insects and their larvae, especially beetles, grasshoppers, crickets, ants, earwigs, caterpillars and flies; also earthworms, slugs, snails, small rodents and reptiles; occasionally some seeds. Mainly nocturnal and exclusively terrestrial feeder. Walks slowly along in search of prey, taking beetles, grasshoppers, earwigs, ants, small lizards and similar prey with bill; uses sudden, short run to capture prey, or a swift lunge, or simply picks less active prey from the ground with deft movement; also leaps to catch moths, and takes insects from vegetation. Forages singly, in pairs or small groups up to 6 birds.
Breeding. Breeds in spring in most of range, Mar-Jun in N Africa, Feb-Jun in Canary Is; starting from Apr in Britain and from late May in Siberia; in India, mainly Mar-Apr; in Sri Lanka, mainly Jun-Jul. Monogamous. Solitary, although pairs often nest within visual contact on restricted areas of habitat. Nest is scrape in ground, lined with a little grass or unlined, but often with a ring of stones or shells and pieces of vegetation around rim. Usually 2 eggs (1-3); single brood; incubation 24-26 days; downy chick pale with dark markings; fledging 36-42 days. Success varies according to habitat, predation and degree of protection: in Britain c. 0·65 young raised per pair; 77% of young hatched survive until half-grown. May breed at 1 year old, but normally at 3 years old.
Movements N European and C Asian populations migrate in autumn to S Europe, Middle East and beyond into Africa. Populations of Iberia, N Africa, India and SE Asia resident; N African breeders sometimes move S beyond Sahara, but normal extent of migration poorly known. Canary Is birds remain within the island group, but sometimes move from island to island
Status and Conservation. Not globally threatened. Widespread but restricted to small areas of suitable habitat, often widely separated. European population estimated at 41,000-160,000 pairs, but species has experienced considerable overall decline in recent decades: still numerous in Russia, probably with 10,000-100,000 pairs, although figures very uncertain; 22,000-30,000 pairs in Spain, but in decline; 5000-9000 pairs in France, where population stable; 1000-10,000 pairs in Portugal; probably 1000-5000 pairs in Turkey; in addition, several thousand pairs in Israel. Declines in many areas, sometimes substantial, e.g. in Britain, from 1000+ pairs in 1930's to 145 pairs in 1990's; marked decline in Poland since 1945. Pressure from habitat loss and disturbance, particularly associated with forestry, agricultural intensification, decline in sheep rearing in places, and human recreational pressure on coasts. Many birds shot and trapped on migration in Mediterranean region but numbers and effects on populations uncertain; collisions with overhead wires and fences, and predation by foxes also cause numerous losses. Conservation in Europe largely depends on future modifications of land-use policies, and also on mutual understanding with farmers. See page 359.

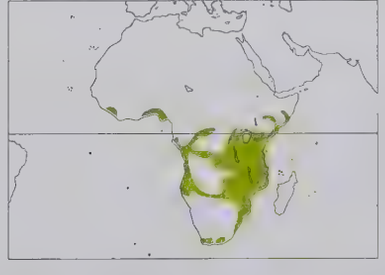
2. Senegal Thick-knee

Burhinus senegalensis

French: Oedicnème du Sénégal **German**: Senegaltriel **Spanish**: Alcaraván Senegalés
Other common names: Senegal Stone-curlew

Taxonomy. *Œdicnemus Senegalensis* Swainson, 1837, Senegal.
E populations sometimes separated as race *inornatus*, but differences rather slight and broad zone of intergradation through N Cameroon, Chad, Central African Republic and NE Zaire. Monotypic.
Distribution. Senegambia E through Nigeria and Central African Republic to Sudan, whence N to Egypt, E to Ethiopia and Somalia, and S to Kenya.



Descriptive notes. 32-38 cm. Very similar to both *B. oedicnemus* and *B. vermiculatus*, but somewhat smaller, and large, pale panel on median and greater upperwing-coverts lacks sharp white bar above; has slightly longer, heavier bill than *B. oedicnemus*, with less yellow at base, and shows rather more white on primaries, and, in flight, more rounded tip to shorter wing. Juvenile very similar to adult but with bright buff tips to median wing-coverts and tertials.
Habitat. Damp, muddy riversides to sandy ridges, extensive grassy flats beside rivers, irrigated fields, burnt woodland, and semi-arid grassland close to water. Also adapted to use urban and suburban areas with access to open ground and water margins.
Food and Feeding. Small invertebrates, reptiles, amphibians, molluscs and small rodents. Mainly nocturnal and exclusively terrestrial feeder. Forages by walking along, taking prey from ground with quick forward peck, or after short run and forward stoop. Forages singly or in small groups, up to 1 km from water.
Breeding. Season varies, but usually breeds before rains in areas with seasonal rainfall, when river levels are low, exposing suitable banks and islands: eggs in Apr (Mar-Jun) in Egypt, Apr-Aug in Senegambia, Apr in Sierra Leone, mostly Mar-Aug in Nigeria, May-Sept in Mali, Mar-Jun and Sept-Nov (wet seasons) in Kenya. Monogamous. Solitary and territorial or loosely colonial on riverbanks; but forms closer nesting groups in more restricted sites, e.g. on flat roofs of houses. Nest is shallow scrape, often ringed with grit, shells or pieces of twig. Normally 2 eggs; single brood; downy chick grey above with black speckles. No further information available.
Movements. Mostly sedentary but seasonal movements in parts of W Africa related to flooding and drought, both of which cause temporary exodus: species present Dec-Mar in Senegal, Nov-May in Zaire. Resident in Sierra Leone and Nigeria, with some local movements.
Status and Conservation. Not globally threatened. Generally common and shows ability to survive well in areas populated by man, although few solid data available. Common in Gambia and Nigeria; not uncommon in SE Ghana. Flocks along R Nile in Egypt frequently exceed 20 birds, and up to 60 birds have been recorded together.
Bibliography. Archer & Godman (1937-1961), Bannerman (1953), Britton, P.L. (1980), Cave & Macdonald (1955), Chapin (1939), Cramp & Simmons (1983), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Étchécopar & Hüe (1964), Glutz von Blotzheim *et al.* (1977), Goodman *et al.* (1989), Gore (1990), Grimes (1987), Mackworth-Praed & Grant (1957, 1970), Meinertzhagen (1930), Pinto (1983), Pitman (1931), Schönwetter (1967), Shirihai (1994), Short *et al.* (1990), Snow (1978), Symens & Werner (1994), Urban *et al.* (1986).

3. Water Dikkop

Burhinus vermiculatus

French: Oedicnème vermiculé **German**: Wassertriel **Spanish**: Alcaraván Acuático
Other common names: Water Thick-knee

Taxonomy. *Oedicnemus vermiculatus* Cabanis, 1868, Lake Jipe, near Taita, Kenya.
Two subspecies recognized.
Subspecies and Distribution.
B. v. buettikoferi (Reichenow, 1898) - Liberia to Nigeria and Gabon; sometimes claimed to occur E to Uganda.
B. v. vermiculatus (Cabanis, 1868) - Zaire E to SC Somalia, and S to E & S South Africa.

Descriptive notes 38-41 cm; 293-320 g. Similar to *B. oedicnemus* and *B. senegalensis*, but generally rather darker; broad, pale covert panel has thin white upper line on lesser coverts but lacks fine black lower edge; bill longer and rather heavier, with less yellow at base. Unlike other *Burhinus*, has fine vermiculated patterns on upperparts but only visible at close range; in flight, has rather broad, blunt wings and short tail, with feet projecting slightly beyond tip. Juvenile very similar to adult, but has buff spotting on grey upperwing-coverts, and more abundant vermiculations on upperparts and tail. Race *buettikoferi* rather darker and browner, less grey.
Habitat. Riverbanks and lake edges, estuaries and mangroves; also undisturbed, sheltered beaches; prefers areas with some bushes for cover. Light woodland or other cover provides the shade that is essential by day.
Food and Feeding. Feeds on insects, crustaceans and molluscs. Nocturnal and terrestrial feeder. Feeds by tilting forwards to grasp food in the bill. May forage more than 1 km from water.
Breeding. Season variable, but generally dry season and early rains in S Africa; Jan and Mar-Dec in Kenya; Nov in Tanzania; Aug-Dec in Zimbabwe and South Africa. Monogamous. Solitary. Nest is a

Bush Thick-knee (*Burhinus grallarius*); 8. Great Thick-knee (*Esacus recurvirostris*); 9. Beach Thick-knee (*Esacus magnirostris*).

scrape on ground, sometimes sparsely lined, often close to water and near a landmark, e.g. piece of driftwood or bush. Normally 2 eggs, rarely 1; single brood; incubation c. 24 days. No further information available.
Movements. Sedentary, apart from some local movements to avoid flooding; birds subsequently return to exposed riversides as water recedes.
Status and Conservation. Not globally threatened. Very little precise information available, partly due to secretive habits, and, in N of range, confusion with very similar *B. senegalensis*. Species still said to be locally abundant; locally common in southern Africa; common in Angola; probably uncommon in Nigeria. Precise distribution in W Africa still poorly known: status in Ghana uncertain, but probably very uncommon resident.
Bibliography. Ash & Miskell (1983), Benson & Benson (1975), Bregnballe *et al.* (1990), Britton, P.L. (1980), Brown & Britton (1980), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Gatter (1988), Ginn *et al.* (1989), Grimes (1987), Lewis & Pomeroy (1989), Lippens & Wille (1976), Louette (1981), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Newman, K. 4. Spotted Dikkop
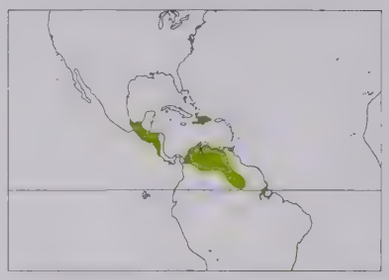
Burhinus capensis

French: Oedicnème tachard **German**: Kaptriel **Spanish**: Alcaraván de El Cabo
Other common names: Spotted Thick-knee, Cape Dikkop/Thick-knee

Taxonomy. *Oedicnemus capensis* Lichtenstein, 1823, Cape of Good Hope.
Several other races proposed: doubtfully distinct are *ehrenbergi* of Dahlak I in Red Sea, and *affinis* on Red Sea coast of Ethiopia; also *psammochromus* included in *maculosus*, and *csongor* included in nominate *capensis*. Four subspecies normally recognized.
Subspecies and Distribution.
B. c. maculosus (Temminck, 1824) - Senegal E to Eritrea and Somalia, and S to Uganda and Kenya.
B. c. dodsoni (Ogilvie-Grant, 1899) - coastal Somalia and S Arabia.
B. c. capensis (Lichtenstein, 1823) - Kenya S to South Africa, and W from Zambia to Angola.
B. c. damarensis (Reichenow, 1905) - Namibia, Botswana and SW South Africa (Cape Province).



Descriptive notes. 37-44 cm; 375-610 g. Distinctive thick-knee, with upperparts clearly spotted, rather than streaked; upperpart feathers have basal bar and distal spot, rather than simple shaft-streak; face rather dark and poorly marked; wing-coverts more uniform with rest of upperparts than in other *Burhinus* species. Juvenile more streaked, less spotted; breast more finely streaked. Races vary according to general plumage hues, *damarensis* pale, *maculosus* more tawny; *dodsoni* more barred, less spotted than nominate race.
Habitat. Prefers arid areas, away from watersides; found in open woodland and savanna, grassland close to cover of bushes or trees; also fields, stony slopes and all kinds of eroded or waste ground; even large parks, playing fields and beaches. Prefers some daytime cover and shade, under trees or bushes or amongst boulders.
Food and Feeding. Main food probably insects, but also known to take small amphibians, molluscs, crustaceans and some seeds. Feeds mainly at night but also active on dull, cloudy days; terrestrial. Typical *Burhinus* feeding action, leaning forward to pick food from ground with bill, during pauses in steady forward walk, or after short run.
Breeding. Laying around end of dry season and beginning of wet season, or within the dry season. Monogamous. Solitary. Nest is a shallow scrape, lined with pieces of grass and leaves, small stones, pieces of earth and animal droppings; often sited next to small landmark, such as a stone, or in shade of a bush. Usually 2 eggs (1-3); incubation c. 24 days, beginning with 2nd egg; downy chick pale grey with black markings; captive young flew at 8 weeks old.
Movements. Resident and apparently wholly sedentary, although occasional records from sites outside normal breeding range suggest infrequent dispersal towards S Sahara and into Zaire.
Status and Conservation. Not globally threatened. Generally quite frequent, locally rather numerous; has benefited from ability to accept disturbed ground and occupy areas near presence of human activity. No precise details available on population sizes or trends.
Bibliography. Ash & Miskell (1983), Benson & Benson (1975), Bigalke (1933), Britton, P.L. (1980), Broekhuysen (1964), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Evans (1994), Gallagher & Price (1990), Gallagher & Woodcock (1980), Gichuki (1989), Ginn *et al.* (1989), Gore (1990), Grimes (1987), Hattingh (1993), Hollom *et al.* (1988), Koen (1983), Kok (1993), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1966, 1993), Newby (1979), Newman, K. 5. Double-striped Thick-knee
Burhinus bistriatus

French: Oedicnème bistrié **German**: Dominikanertriel **Spanish**: Alcaraván Venezolano
Other common names: Double-striped Stone-curlew, Mexican Thick-knee

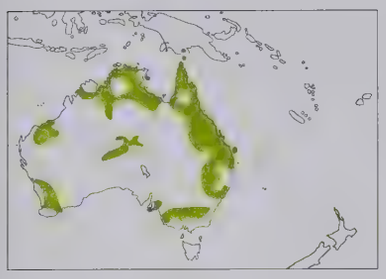
Taxonomy. *Charadrius bistriatus* Wagler, 1829, Mexico.
Proposed race *vigilans* synonymous with nominate *bistriatus*. Four races recognized.
Subspecies and Distribution.
B. b. bistriatus (Wagler, 1829) - S Mexico S to NW Costa Rica.
B. b. dominicensis (Cory, 1883) - Hispaniola.
B. b. pediacus Wetmore & Borrero, 1964 - N Colombia.
B. b. vocifer (L'Herminier, 1837) - Venezuela, Guyana and extreme N Brazil.
Descriptive notes. 43-48 cm. Large thick-knee, with long neck and legs; long white supercilium bordered above by black line. Rather similar to *B. superciliaris*, but larger, darker and more heavily patterned above, with heavier bill and darker crown; more distinct contrast between dark breast and white belly; in flight, shows less contrasted wing pattern. Juvenile paler than adult, with head and neck tinged buff. Races separated mainly on measurements, with rather slight variations in overall colour tones: *dominicensis* smaller; *pediacus* palish and cinnamon; *vocifer* darker and browner, less grey, on breast.
Habitat. Open grassland and bushy savanna, mostly in semi-arid to arid areas; also farmland and ranchland with dry dirt tracks. Prefers flat landscape, with or without scattered trees and bushes, but essentially open in character.

Food and Feeding. Poorly known. Feeds on small animals such as insects, worms, molluscs and occasionally lizards and small rodents. Feeds at or after dusk, often visiting open, unpaved tracks and roads where insects and small animal casualties can be found with ease. Picks prey from the ground, using typical plover-like walk with pause to tilt forward.
Breeding. Essentially breeds in dry season, e.g young in Apr and early May in Colombia. Solitary, but found breeding in loose groups where common. Nest is a scrape in ground, often among animal droppings. Lays 2 eggs; incubation 27-29 days (*dominicensis*), by both sexes but perhaps mainly by male. No further information available.
Movements. Sedentary, although with some exceptional occurrences beyond normal range, e.g. recorded in Texas, USA, in Dec 1961, and also in S Brazil in Nov.
Status and Conservation. Not globally threatened. Increasing locally as habitat changes open up new areas for colonization, especially deforestation, with forest giving way to pasture. Fairly common to common but local in S Mexico; in Guatemala and Costa Rica, more typically a bird of the W Pacific slope; uncommon on Hispaniola (1978), where formerly much more abundant, with decline attributed to hunting and habitat alteration; in Colombia, relatively common on Caribbean coast and E of Andes but much more infrequent and localized to W. Frequent victim of road traffic at night; long-term effects of such mortality could conceivably become more important. Sometimes semi-domesticated around ranches, where species is held to be a useful controller of insect pests and is kept on patios and in corrals of country houses. CITES III in Guatemala.
Bibliography. Anon. (1983a), Blake (1977), Bond (1985), Dickey & van Rossem (1938), Freese (1975), Friedmann & Smith (1955), Hellmayr & Conover (1948), Hilty & Brown (1986), Howell & Webb (1995a), Jones, T. (1987), Land (1970), Lowery & Dalquest (1951), Meyer de Schauensee & Phelps (1978), Monroe (1968), Pinto (1964), Ruschi (1979), Scott & Carbonell (1986), Sick (1985c, 1993), Slud (1964), Snyder (1966), Stiles & Skutch (1989), Stockton (1978), Verrill & Verrill (1909), Voous (1983), Wetmore & Borrero (1964).

6. Peruvian Thick-knee
Burhinus superciliaris

French: Oedicnème du Pérou **German**: Peruanertriel **Spanish**: Alcaraván Peruano

Taxonomy. *Oedicnemus* [sic] *superciliaris* Tschudi, 1843, coast of Peru.
Monotypic.
Distribution. Pacific coast, from extreme S Ecuador to S Peru.



Descriptive notes. 38-43 cm. Fairly large thick-knee, with long neck and legs. Smaller and greyer than *B. bistriatus*, with which shares white supercilium with black upper border; bill smaller, with more pale yellowish green at base; less heavily streaked above; in flight, shows more contrasted, unmarked grey wing-coverts, which stand out much more clearly against dark flight-feathers. Juvenile has feathers of upperparts darker brown with warmer buff fringes.
Habitat. Typically found in dry agricultural land with open aspect, semi-desert and dry grassland; also in denser areas of bush in Andean foothills above coast.
Food and Feeding. Virtually nothing known. Species presumed to take small animals, such as insects and small lizards. Feed after dusk; terrestrial. Uses typical thick-knee feeding actions.
Breeding. Little known. Probably solitary, but, where common, small aggregations are likely to occur during breeding season. One nest found in Jun 1978, dry season, in NW Peru, contained 2 eggs; site was on a plateau c. 15 m above extensive plains, on a rocky slope with scattered clumps of low shrubs and cacti and sparse grasses; nest scrape was a slight depression, cleared of plant debris. No further information available.
Movements. Sedentary. One record from N Chile in 1851 may have referred to a vagrant, or perhaps to an extension, presumably temporary, of range as currently known.
Status and Conservation. Not globally threatened. Very limited range, so total numbers are likely to be relatively small, but species may be fairly frequent in N of range. Species was described as "very popular" with the local people, due to the mystique associated with its nocturnal habits and loud calls. No threats identified at present, but species requires monitoring; research into basic ecological requirements also highly desirable.
Bibliography. Blake (1977), Bolton (1993), Butler (1979), Dunning (1982), Hellmayr & Conover (1948), Howell & Webb (1995b), Johnson (1965b), Koepcke (1970), Meyer de Schauensee (1982), Ortiz & Carrión (1991), Parker *et al.* (1982), Scott & Carbonell (1986), Williams (1981).

7. Bush Thick-knee
Burhinus grallarius

French: Oedicnème bridé **German**: Langschwanztriel **Spanish**: Alcaraván Colilargo
Other common names: Bush Stone-curlew/Curlew, Southern Stone-curlew, Stone-plover, Australian Dikkop

Taxonomy. *Charadrius grallarius* Latham, 1801, New South Wales.
Considerable confusion concerning correct nomenclature: species name traditionally given as *magnirostris*, but this is replaced by *grallarius* as the valid name, due to principle of first reviser (see page 350). Sometimes divided into three races, with recognition of *rufescens* (NW & NC Australia) and *ramsayi* (N Queensland), but these forms are poorly marked and species probably more realistically treated as polymorphic. Monotypic.
Distribution. N & S Western Australia through Northern Territory to Queensland, then S to SE South Australia and Victoria; also Trans-Fly area of S New Guinea.
Descriptive notes. 54-59 cm; 625-670 g. Polymorphic, with rather similar grey and rufous morphs. Particularly long-legged, long-tailed thick-knee; slim and small-bodied, with proportions more akin to American than Eurasian and African congeners; streaked, cryptic plumage typical of genus, as well as large, pale eyes in big, round head, but bill rather fine, all dark; long wings have rather broad,

square, fingered tips; legs long, pale yellowish green, trailing well beyond tail tip in flight. Female similar to male but slightly smaller. Juvenile has eyes milky white, less yellow; more coarsely marked pale upperwing-coverts.

Habitat. Open forest and woodland with clearings; also cleared ground with mixed farmland and woodland fragments remaining, but lacking shrub or tall herb layer; dry grassland and cropland near cover; rarely swampy ground, mangroves or salt-marsh bordered by bushy cover or trees; avoids rain forest or other thick forest cover, preferring ground with scattering of fallen dead timber, or carpet of dead leaves, but otherwise open. Inland, associated with water courses and edges of lakes, but also sand dunes and shingle ridges.

Food and Feeding. Insects, molluscs, centipedes, crustaceans, spiders, amphibians, small reptiles and occasionally seeds. Nocturnal, but particularly active in bright moonlight. Takes food from ground and vegetation in tall grassland, from fallen, dead timber and also from among debris and stones along edges of water courses, by probing with bill. May feed on insects attracted by artificial lights. Typically forages for 20-30 minutes at one site, before moving on to another; may also change general feeding areas regularly, even each night.

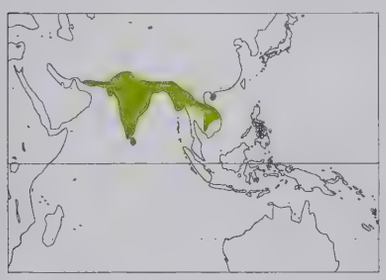
Breeding. Breeds in spring, generally earlier in N than in S, e.g. laying Jun-Dec in Queensland, Aug-Jan in Victoria. Monogamous. Solitary. Nest on ground, often under trees in short or quite long grass, in open spots, averaging c. 12 m from nearest tree, with good visibility for 250+ m all round; more rarely nests on salt-marsh or beach; nest is bare scrape, often edged with animal dung; same site may be reused for many years. 2 eggs; incubation 25 days, by both sexes; chick has grey down with broad blackish longitudinal stripes; young brooded by both sexes, male perhaps taking greater share; young fly when 59 days old (perhaps as early as 47-50 days); cared for by parents for up to 138 days, but less if 2nd clutch laid. Success rather variable; some eggs destroyed by farming operations, flooding, or trampling by stock, and eggs and chicks taken by foxes.

Movements. Sedentary. No large-scale seasonal movements, but breeding territories break down after breeding season, when some local movements may occur and birds gather into flocks; apparent seasonal movements and changes in numbers probably always due to this flocking behaviour, producing ostensible erratic fluctuations. Accidental in Tasmania.

Status and Conservation. Not globally threatened. Species appears generally secure, but locally vulnerable. Total Australian population estimated at c. 15,000 birds; fairly common but local in Trans-Fly area, S New Guinea. Range has contracted especially in E & S Australia, owing to habitat changes; declines in many regions, withdrawals from traditional breeding areas and reduction in size of post-breeding flocks clearly evident. Losses normally attributed to predation by foxes, eating of poisoned bait put down for rabbits, illegal shooting and egg-collecting, but they principally reflect loss of habitat and increasing fragmentation of remaining populations.

Bibliography. Anderson (1991), Bedggood (1977), Beehler *et al.* (1986), Bigg (1988), Blakers *et al.* (1984), Bright (1935a), Christidis & Boles (1994), Coates (1985), Flegg & Madge (1995), Frith (1969), Garnett (1985b), Johnson & Baker-Gabb (1993), Lane & Davies (1987), Larkins (1989), Leach (1988), Lindgren (1971), Lindsey (1992), Macdonald (1988), Marchant & Higgins (1993), Pizzey & Doyle (1980), Pringle (1987), Schodde & Mason (1980), Schodde & Tidemann (1986), Simpson & Day (1994), Slater *et al.* (1989), Trounson (1987), Wilson (1989).

Genus *ESACUS* Lesson, 1831



8. Great Thick-knee

Esacus recurvirostris

French: Grand Oedicnème **German**: Krabbentriel **Spanish**: Alcaraván Picogrueso Indio
Other common names: Great Stone-plover/Stone-curlew

Taxonomy. *Œdicnemus recurvirostris* Cuvier, 1829, Nepal.
Genus sometimes merged into *Burhinus*. Forms superspecies with *E. magnirostris*, with which occasionally considered conspecific. Monotypic.

Distribution. SE Iran through Indian Subcontinent and Sri Lanka to Indochina and Hainan (S China).

Descriptive notes. 49-54 cm; c. 790 g. Large, massive thick-knee with proportions somewhat recalling bustard; unstreaked greyish upperparts; face strongly patterned with white around and behind eye above black cheek patch and short malar stripe; bill massive, with more slender, uptilted tip and thick yellow base; in flight reveals largely black flight-feathers with striking white primary patches and broad pale grey band across median and greater upperwing-coverts. Differs from somewhat similar *E. magnirostris* in white forehead, black rather than pale grey secondaries, and slightly more slender and pointed bill. Juvenile very similar to adult, but has buff fringes to feathers in fresh plumage.

Habitat. Riverbed shingle and rocks, stony banks and mud (in preference to sand) around large lakes; sometimes visits nearby grassy flats when rivers flood. Infrequently on coastal beaches, sandy flats, tidal estuaries and salt-pans; inhabits coastal district of dry zone in Sri Lanka, but restricted to undisturbed beaches.

Food and Feeding. Feeds mainly on crabs and other crustaceans; also insects, and record of eggs of Kentish Plover (*Charadrius alexandrinus*). On oligotrophic reservoir, where crabs infrequent, young birds found to have eaten: young monitor lizard (*Varanus*) c. 21 cm long, intact but with head battered; whole shrew (*Suncus*) c. 6 cm long; and small fish c. 8 cm long; also winged termites. Mainly active after dusk, but sometimes feeds by day. Prises up stones with massive upcurved bill. Uses typical thick-knee feeding actions: wary and deliberate, walking slowly forward and tilting to take prey with large bill.

Breeding. Laying Feb-Jul in India, mainly Apr-Jul in Sri Lanka. Monogamous. Territorial; sometimes breeds in colony of River Tern (*Sterna aurantia*). Nest is scrape in ground on shingle bank, stony islet or on edge of lagoon in sparse grasses, usually close to water. 1-2 eggs; incubation by both sexes; chick has thick "pepper and salt" down with black speckles. No further information available.

Movements. Sedentary, apart from local movements forced by rising water levels in rivers and lakes, and temporary changes in feeding conditions.

Status and Conservation. Not globally threatened. Apparently still locally common, forming small parties after breeding. Scarce in Pakistan; no recent records from Thailand, where may have been extirpated. Tolerant of altered habitats and colonizes reservoir edges; however, is generally rather wary, and requires large undisturbed areas for breeding.

Bibliography. 9. Beach Thick-knee

Esacus magnirostris

French: Oedicnème des récifs **German**: Rifftriel **Spanish**: Alcaraván Picogrueso Australiano
Other common names: Beach Stone-curlew/Curlew, Australian Stone-plover, Reef Thick-knee

Taxonomy. *Œdicnemus magnirostris* Vieillot, 1818, Depuch Island, Western Australia.
Formerly awarded monospecific genus *Orthorhamphus*; genus sometimes merged into *Burhinus*. Forms superspecies with *E. recurvirostris*, with which occasionally considered conspecific. Considerable confusion concerning correct nomenclature, resulting in recent proposals to adopt either *giganteus* or *neglectus* as valid species name, but *magnirostris* is the correct name (see page 350). Monotypic.

Distribution. Andaman Is and Malay Peninsula through Philippines, Indonesia and New Guinea to Australia and SW Pacific islands.

Descriptive notes. 53-57 cm; 870-1130 g. Massive, thick-set thick-knee with heavy head and stout bill; head boldly marked with black, white and grey-brown stripes; bill black, with yellow restricted to basal area; staring yellow eye; upperparts unstreaked; broad wings rather square-ended and deeply fingered in flight, enhancing somewhat bustard-like appearance; medium-long, sturdy legs. Differs from *E. recurvirostris* in bill shape and face pattern; on closed wing, blackish band across top edge of broad pale panel more marked; in flight, secondaries all grey, inner primaries uniform white. Juvenile has duller bare part colours; buff fringes to feathers of upperparts, especially upperwing-coverts.

Habitat. Exclusively coastal, on islands and mainland beaches. Adaptable, occupying beaches of sand, mud, stones and rock, both narrow and wide, sheltered or swept by surf; often at mouths of rivers, more rarely in tidal creeks. Frequents sandbars offshore and at mouths of estuaries; also on coral reefs and atolls; also prepared to use mangroves, readily entering mangroves 1·5 m high. Often flies out to sea when disturbed, before returning to beach; sometimes also found short distance inland on dunes, or around edges of coastal lagoons.

Food and Feeding. Probably feeds almost exclusively on crabs, where these are readily available; also takes other small crustaceans. Usually observed by day, when feeds actively at times, but true time preferences for feeding unknown. Forages on rocks and large intertidal areas of sand, mud or shingle. Feeds in manner recalling large *Ardea* heron, watching for prey then stalking it, or running forward with sudden, powerful forward lunge; also probes into mud, sand and even short grass, but does not usually wade. Crabs are dismembered or broken into small pieces by hammering with massive bill, before swallowing.

Breeding. Breeds Sept-Nov in temperate Australia, Jul-Nov farther N. Probably monogamous. Breeds in isolated pairs, at lower density than other shorebirds; pairs may be resident in the same area for several years; often associated with Little Terns (*Sterna albifrons*). Nest on sandbank, sand spit or island, at back of extensive beach, among mangroves or grass; shallow depression, unlined but sometimes ringed with dead leaves and twigs. 1 egg; incubation at least 30 days, roles of sexes unknown; young begins to grow feathers at 5 weeks; resembles adult at 7 weeks except for remnant down for 5 more weeks; cared for by both sexes; able to fly well at 12 weeks, but may not become independent for 7-12 months. Raptors, cats and dogs take eggs, which also suffer losses to high tides; also vulnerable to human disturbance.

Movements. Essentially sedentary, but some vagrants far S of usual range; some pairs observed on same area of beach for 10 years or more.

Status and Conservation. Not globally threatened. Very widespread, but generally rather sparsely distributed. Total population of Australia estimated at c. 1000 birds; rare and local on small islands off SW Thailand; only 2 recent records on Sulawesi; occurs sparingly on coasts of New Guinea. Species may be vulnerable due to loss of habitat, low reproductive rate, and widespread increase both in numbers of introduced predators and in human disturbance of beaches. Expansion southwards in mid-20th century probably occurred before disturbance became a serious factor; at present, holidaymakers and weekend visitors to beaches pose greatest potential threat in many areas.

Class AVES

Order CHARADRIIFORMES

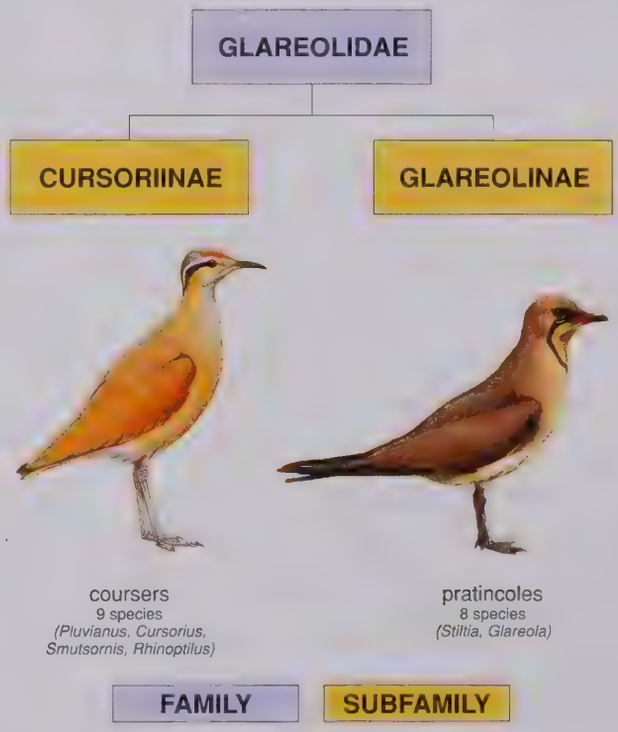
Suborder CHARADRII

Family GLAREOLIDAE (COURSERS AND PRATINCOLES)

- Plover-like or tern-like waders, with long or very long wings, and long or relatively short legs.
- 17-29 cm.

- Old World tropics, with greatest diversity in Afrotropical Region.
- Desert to savanna, with some species usually adjacent to water; mostly at lower elevations, but sometimes up to 2000 m or higher.
- 6 genera, 17 species, 33 taxa.
- 1 species threatened; none extinct since 1600.

Systematics



While the glareolids are undoubtedly members of the order Charadriiformes, their exact position within the order and their relationships with other charadriiform families have been open to much debate. Even the internal relationships of some of the coursers with each other have not been fully resolved. On the basis of neonatal plumage patterns (those of the downy chicks), they have been placed close to the plovers (Charadriidae); however, this kind of evidence also placed the somewhat aberrant Inland Dotterel (*Peltohyas australis*) of Australia with the coursers, yet it has been shown to be an undoubted plover, very close to, if not in fact a member of, the genus *Charadrius* itself (see page 385). Neonatal plumage patterns among the coursers and the aberrant Australian Pratincole (*Stiltia isabella*) are highly variable, and in some cases rather unhelpful for indicating systematic relationships, especially within the genera *Smutsornis*, *Rhinoptilus* and *Stiltia*.

Osteological evidence points to the peculiar Magellanic Plover (*Pluvianellus socialis*), the sheathbills (Chionidae), the Crab Plover (*Dromas ardeola*) and the thick-knees (Burhinidae) as being the glareolids' closest relatives and sharing a common ancestor with them. On the other hand, the syringeal structure of the glareolids resembles very closely that of the plovers. Evidence from DNA-DNA hybridization advocates the glareolids' positioning in a superfamily consisting of two families, one for the gulls, terns, skimmers and auks, and the other for the coursers and pratincoles and also the Crab Plover, which is separated in its own subfamily. This relationship with the Laridae is supported by evidence derived from electrophoresis of proteins from liver and muscle tissue, which suggests that the Australian Pratincole is closer to the gulls and terns than it is to any of the other wader groups.

The family Glareolidae is divided into two well defined subfamilies, the coursers (Cursoriinae) and the pratincoles (Glareolinae), with the monotypic genus *Stiltia*, reserved for the Australian Pratincole, forming a link between the coursers and "typical" pratincoles. The Egyptian Plover (*Pluvianus aegyptius*) is very different from the other glareolids and may constitute its own family, Pluvianidae, or at least subfamily, Pluvianinae; on the basis of osteological evidence, it seems that it might be most closely related to the Burhinidae.

Fossils of the genus *Glareola* belonging to an extinct species, *Glareola neogena*, are known from the Middle Miocene of Europe, while of similar age is the extinct *Mioglareola gregaria*, also from European deposits. The oldest glareolid fossils are of the genus *Paractiornis* from the Lower Miocene of North America. On the basis of their present distribution, however, the Glareolidae appear to be of African origin, whence they probably spread later into Eurasia and Australasia. Alternatively, they might be the remnant of a more widespread Gondwanan ancestry. More recent remains of the Collared Pratincole (*Glareola pratincola*) have been found in Middle Pleistocene deposits in France.

Further evidence of an African origin for recent species can be concluded from the apparently close relationship between

Subdivision of the Glareolidae.

[Figure: Hilary Burn]

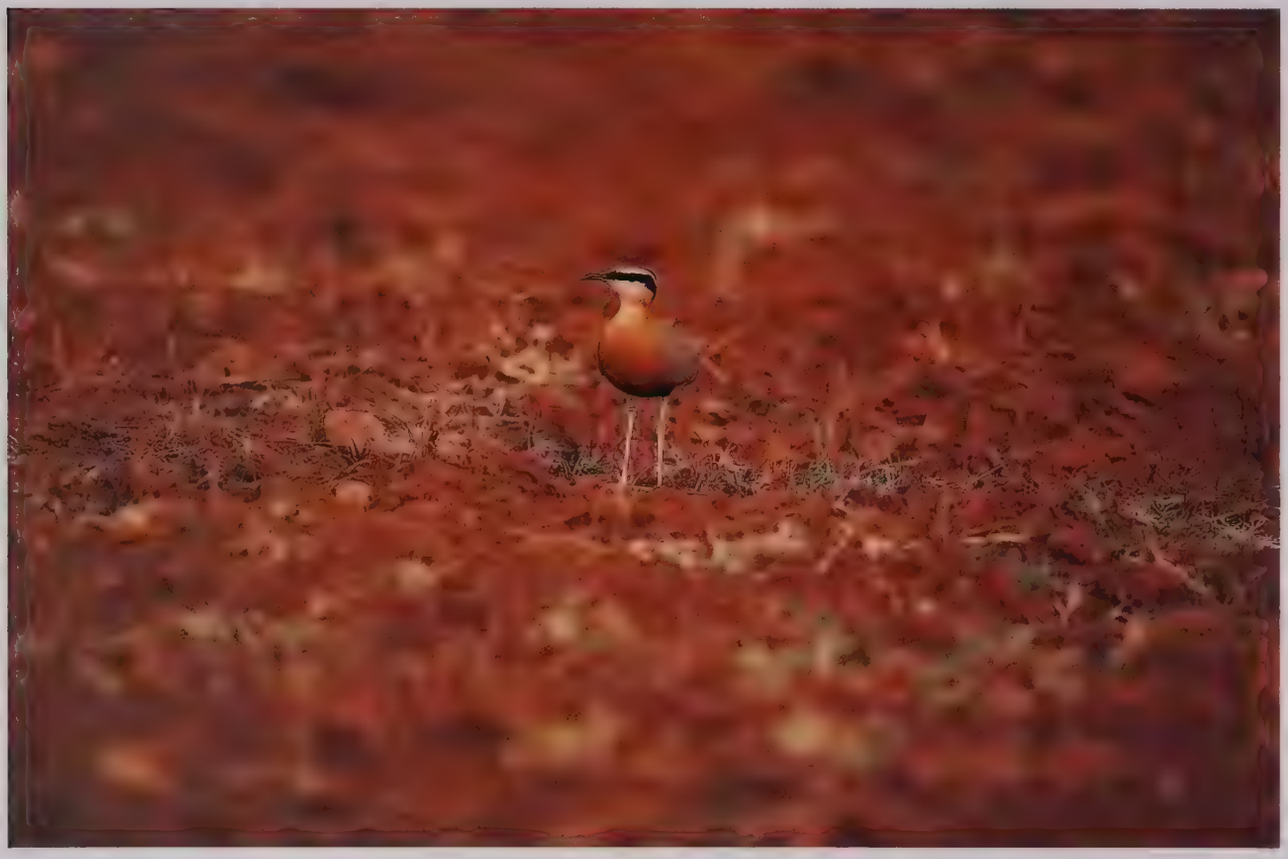
Of graceful tern-like flight, pratincoles are small to medium-sized birds that feed by hawking for insects. They are characterized by long, pointed wings, a forked tail, an arched bill with a wide gape and largely brown-grey plumage. The Rock Pratincole, one of the smaller African species, has a distinctive white collar that extends from the eye round to the nape of the neck; its black bill shows a red base and its legs too are red. As its name indicates, it frequents exposed rocks, often on fast-flowing rivers, especially during the breeding season.

[*Glareola nuchalis nuchalis*, Namibia. Photo: R. J. Chandler/ Windrush]

each of the Indian species of glareolid and their African equivalents. Temminck's (*Cursorius temminckii*) and the Bronze-winged Coursers (*Rhinoptilus chalcopterus*), like their Indian counterparts, the Indian (*Cursorius coromandelicus*) and Jerdon's Coursers (*Rhinoptilus bitorquatus*), are adapted to open savanna woodland; it seems likely that a vegetation corridor of this type connected Africa and India at some time in the past during a wetter period, perhaps in the Plio-Pleistocene, allowing the common ancestors of these closely related species pairs to spread from Africa to India. The Indian birds subsequently became isolated following climatic deterioration which destroyed the woodland corridor connecting Africa and India. The small riverine pratincoles, the Grey (*Glareola cinerea*) and Small Pratincoles (*Glareola lactea*), from Africa and Asia respectively, also form a species pair, sharing similar behaviour and habitat requirements.

Internal family relationships are also the subject of debate: on the evidence from feather lice (Mallophaga), which, because they are often highly species-specific, have been used as indicators of avian relationships, it has been suggested that the Double-banded Courser (*Smutsornis africanus*), host to the allegedly most primitive feather louse found among the coursers, is itself primitive; it also shows patterned plumage in the adult. More advanced species of feather louse, in order of their apparent evolution, parasitize respectively the Bronze-winged Courser, the Cream-coloured Courser (*Cursorius cursor*) and the Egyptian Plover. From this arises the possibility that the plain-backed genera of coursers, such as the Bronze-winged and Cream-coloured, are more advanced than those with patterned dorsal adult plumage, and that *Pluvianus* is the most advanced genus in the subfamily Cursoriinae. Certainly, the plumage patterns of the Egyptian Plover and the Double-banded Courser represent the extremes in appearance of this group. The argument is persuasive, though not necessarily supported by the morphological evidence, which places *Pluvianus* closer to the thick-knees than to the coursers. Only further evidence, perhaps from DNA-DNA hybridization, will help to establish the true relationships among glareolids in general, and coursers in particular.

It is, however, entirely possible that the evolutionary trend suggested by the feather-louse evidence is correct, indicating increasing specialization in bill morphology, from a generalized type in *Smutsornis* to the long, decurved bill shape of *Cursorius*, adapted for digging. Digging in sand, mainly for the purpose of covering its eggs and small chicks, is also a regular aspect of the Egyptian Plover's behaviour. Other behavioural characters, such as distraction displays of "False Nest-scraping" and "Mock-brooding", are shared by both the Egyptian Plover and the Cream-coloured Courser, supporting a close relationship of the Egyptian Plover with the coursers.



All the living species of courser are sometimes included in the single genus *Cursorius*, though a convenient split is usually made into the diurnal *Cursorius* and the largely crepuscular or nocturnal species of *Rhinoptilus* and *Smutsornis*, these last two frequently being considered congeneric.

There is also debate on the limits of the superspecies in the diurnal members of the genus *Cursorius*: although all four species are clearly closely related and are sometimes included in a single superspecies, as here, there is also a persuasive argument that *cursor* and *rufus* have been separate from *coromandelicus* and *temminckii* for some time as they are ecologically distinct, the former pair adapted to very arid savanna and semi-desert habitats, the latter pair preferring less arid regions such as open, dry woodland savanna. Indeed *temminckii* overlaps in range with both *cursor* and *rufus*, as does *coromandelicus* with *cursor*. It has also been proposed recently that the species limits within Cream-coloured and Burchell's Coursers (*Cursorius rufus*) be revised, with the East African races of *cursor* perhaps properly belonging with *rufus* on the basis of structure and wing pattern.

Within the pratincoles, in addition to the small riverine superspecies of the Grey and the Small, the large species of *Glareola*, namely the Collared, Oriental (*Glareola maldivarum*) and Black-winged Pratincoles (*Glareola nordmanni*), are all very closely related, though range overlap of the Black-winged with the Collared means that some authorities exclude the Black-winged from the superspecies.

Morphological Aspects

The Glareolidae are characterized by a short, arched bill with the nostrils at the base, not in a groove, and a nasal septum separating the nasal cavities. The tarsi have transverse scales on both

Much longer-legged than pratincoles, coursers are terrestrial birds rather similar to plovers in shape and size. The Indian Courser is a strikingly marked bird with black lores and eyestripe, and above them a distinctive white supercilium extending onto the nape; it has a warm cinnamon breast and upper belly, and white uppertail-coverts. It has the arched black bill typical of the Glareolidae, rather long in this case and well adapted for digging in soft soil for food. The long legs allow for swift running on the ground, where it spends much of its time, although, when the necessity arises, it can fly well, with rather jerky plover-like wingbeats.

[*Cursorius coromandelicus*, Karnataka, India. Photo: K. Ghani/NHPA]

the front and the back, except in the Egyptian Plover, which may belong to a family of its own (see Systematics), and has the tarsal scales arranged in two rows front and back. The hind toe is absent in the Egyptian Plover and the coursers, and reduced and elevated in the pratincoles; and the claw of the middle front toe is equipped with comb-like serrations, except in *Pluvianus* and *Stiltia*. In spite of its considerable differences from other glareolids, however, the jaw muscles of the Egyptian Plover generally resemble those of other members of the family.

Glareolids are small to medium-sized terrestrial birds with a range in length of 17-29 cm, and in weight from 37 g in the Small Pratincole to as much as 172 g in the Bronze-winged Courser. They have long and pointed wings, especially in the pratincoles; the wings of coursers tend to be proportionately shorter and somewhat more rounded, though still long in comparison with the wings of most other ground-dwelling birds. Coursers are long-legged terrestrial runners with short toes and square tails, whereas pratincoles are largely aerial feeders with very long wings, especially in *Stiltia*, relatively short legs, longish toes and forked tails, though in these latter respects *Stiltia* is an exception, with legs as long as those of the coursers and a square tail. The Egyptian Plover, at 73-92 g, is intermediate in weight between the generally lighter pratincoles and the heavier coursers.

The arched bill, unique among the Charadrii, characterizes all members of the family Glareolidae. In the pratincoles the bill is red at the base, often brighter in the male than in the female, and has a wide gape, presumably to facilitate the catching of flying insects on the wing. The bill of the coursers and the Egyptian Plover lacks the wide gape and is usually uniformly dark throughout, though yellow at the base in the Three-banded (*Rhinoptilus cinctus*) and Jerdon's Coursers and purplish red at the base in the Bronze-winged Courser; these three species appear to be closely related, on the basis not only of bill coloration, but also of plumage characteristics. In the genus *Cursorius* the bill is relatively long and is used for digging for food in soft sandy soils. The Egyptian Plover also uses its bill for digging, though mainly as a means of covering its eggs or chicks in sand when disturbed.

The long legs of coursers and the Australian Pratincole enable the birds to run at great speed on the ground, hence the European names "courser", *courvite*, *Rennvogel*, *corredor* and so on. Species inhabiting open country, such as *Cursorius* and *Smutsornis*, are much faster runners than those of the woodland genus *Rhinoptilus*. Coursers have legs characteristically coloured white, yellow or red. Though much shorter-legged, pratincoles too may run on the ground like plovers. The *Rhinoptilus* coursers, especially the Bronze-winged Courser, have proportionately larger eyes, as befits their nocturnal activity.

The flight of pratincoles is particularly buoyant and free, with deep wingbeats and periods of agile gliding, and this allows them to exploit flying insects as their principal source of food. It also permits the larger species to undertake sometimes lengthy migrations, which, in the case of the Black-winged Pratincole, is apparently non-stop at high altitude. The flight of the Australian Pratincole, with its rather stiff, tern-like wingbeats, is very graceful, like that of the sometimes sympatric Oriental Pratincole, but it catches a higher proportion of its food on the ground. The flight of the smaller species, such as the Rock Pratincole (*Glareola nuchalis*), is more erratic.

Coursers tend to fly with more sustained, generally rather rapid, wingbeats, but most usually prefer to run away from danger rather than fly, unless hard pressed; some species have characteristic panels of contrasting white or rufous in the secondaries, and sometimes also the primary flight-feathers, allowing easy identification in the field. The flight of members of the genus *Cursorius* is characterized by quick, jerky wingbeats like those of a small plover, though the wingbeats of the Cream-coloured Courser appear leisurely but powerful when migrating, while the Indian Courser can easily evade capture in flight by a falcon. The Double-banded Courser tends to fly more buoyantly, rather like a lapwing, while members of the genus *Rhinoptilus* are altogether more sluggish birds, taking wing reluctantly and looking more like owls in flight. The flight of the Egyptian Plover is fast and low with flicking wingbeats; the black and white wing pattern is particularly striking, the birds often holding the wing open briefly on landing, usually as a display to the mate or young.

Adult plumage in the family, chiefly in shades of brown and buff, is generally cryptic when birds are on the ground, except in the boldly patterned, aberrant Egyptian Plover. However, in flight most species show striking wing or tail patterns, which suddenly disappear when they land. It is tempting to compare this strategy

A typical courser in most respects, the Double-banded possesses several distinctive features all its own. The head is relatively small and rather dove-like, and the black bill is short, thin and hardly decurved at all and is never used for digging. Whereas most adult coursers have plain buff or brown backs, the Double-banded, like the Three-banded (Rhinoptilus cinctus)*, is typified by having the upper body and crown strongly scaled; all feathers have dark brown centres and broad pale fringes, visible here to perfection at close quarters. The Double-banded further differs from other coursers in its bold double breast band, while on the open wing it shows a bright cinnamon band across the trailing edge of the flight-feathers. This species lives in dry, open habitats on mainly sandy or stony substrates where its scaly plumage provides excellent camouflage. Often when it senses the presence of an intruder it will simply turn its back, thereby becoming well-nigh invisible. Another singularity is the fact that as many as eight subspecies are normally recognized, each differing slightly in coloration according to the type of habitat and colour of soil.*

[*Smutsornis africanus traylori*, Etosha National Park, Namibia. Photo: Günter Ziesler]

With its unique breeding habits and unmistakable plumage, the Egyptian Plover is an aberrant species very different from other glareolids. A bird of broad lowland tropical rivers with sandbars, it habitually covers its eggs with sand on leaving the nest and even young chicks are periodically buried in sand during their first 3-4 weeks. During the hottest hours of the day the parents soak their belly feathers every few minutes and use them to keep the eggs or chicks cool. This ploy is useful in times of danger as it permits the conspicuously plumaged parents to retreat to a safe distance, leaving the eggs or chicks both hidden and protected from the sun.

[*Pluvianus aegyptius*, Africa.

with that of those cryptic grasshoppers which burst into colour when they spread their wings to fly, and just as suddenly disappear as soon as they land, confusing potential predators. Indeed, the Bronze-winged Courser sits tight until the last moment, getting up right under the feet of an approaching human, and only flying 30-40 m before landing again and again remaining absolutely motionless. The Double-banded Courser becomes all but invisible when it presents its back to the observer, its basic plumage colour varying according to the soil colour of the region, and the species is doubtless often overlooked. In immature plumages pratincoles and coursers are mottled above, presumably to aid in camouflaging the young; adult plumage is attained within a year after hatching. Collared Pratincole chicks in Malawi at first are almost black and crouch in hippo footprints in an area of black mud; later on, when they become mottled brown, they move to areas of dappled shade.

The unique purplish iridescence on the wing of the Bronze-winged Courser is unexplained, though it has been suggested that as the species is chiefly nocturnal it may be used in display to catch the moonlight; more mundanely, it may simply help to reduce abrasion.

Living in hot, dry climates means that the plumage of Burchell's and other coursers may bleach as it wears, resulting in considerable variation in colour tone according to the age of the feathers. Moult in Collared and Black-winged Pratincoles is undertaken after breeding, but before migrating, to ensure that the feathers are in good condition for the journey.

Habitat

Coursers are predominantly birds of dry regions where the rainfall is less than about 800 mm per year, from *Acacia* woodlands and semi-arid scrub to true desert. Most prefer relatively low altitudes, though Burchell's Courser can be found in the Afro-alpine regions of South Africa at 2000-3000 m above sea-level. Several species are adapted to overgrazed and recently burnt grasslands and semi-desert, and may have benefited to some extent from human activities; however, this is offset by their extreme vulnerability to disturbance, so that most species have suffered a considerable decline in numbers and a decrease in range.

Three-banded and Bronze-winged Coursers, and to a lesser extent Temminck's Courser, are more or less woodland species, seldom occurring in open country. Temminck's and Bronze-winged overlap in habitat and distribution almost throughout Africa south of the Sahara. They are separated partly by the more nocturnal habits of the Bronze-winged Courser, and partly by the greater preference of Temminck's Courser for burnt and overgrazed areas. The Three-banded Courser is almost entirely confined to mopane (*Colophospermum mopane*) woodland in the southern parts of its range, though it may also occur less often in other open woodland types; within its northern distribution it lives mainly in sparse *Acacia* thornbush. Jerdon's Courser, like its presumed close relative the Bronze-winged Courser, has a specific preference for dry "forest" and scrub.

The remaining species of courser are all birds of open habitats with little or no woody vegetation, apart perhaps from low shrubby growth. Cream-coloured and Burchell's Coursers favour the most arid country, followed closely by Double-banded and Indian Coursers. Within a given area, the degree of competition between species of courser is reduced by differences in habitat occupation: on the Wembere Steppe of East Africa, for example, the barest parts are occupied by the Double-banded Courser, the rather less bare parts by Temminck's Courser and the scrub zones by the Three-banded Courser.

Pratincoles and the Egyptian Plover are all more or less closely associated with inland waters or, more rarely, estuaries. Even the desert-nesting Australian Pratincole nests no more than 1-2 km from a water-filled pan or dam, as it needs to drink frequently. Most species are birds of riverine habitats, especially exposed rocks and sandbars. Sandbars are the preferred habitat of the Egyptian Plover and the Grey Pratincole, at least when breeding, when they may occur together; and the Small Pratincole of India is also an inhabitant of riverine sandbars. The Black-winged Pratincole is something of an exception among pratincoles in that it nests on the open steppes of central Eurasia and spends the non-breeding season in the steppes of sub-Saharan Africa, including the high open grasslands of the South African plateau region which approximate ecologically to a steppe habitat. However, it too frequents sandbanks along large African rivers, a habitat seldom used by Collared Pratincoles. On its breeding grounds, water may still be nearby,

though it is not a prerequisite, and colonies may be as much as 10 km from the nearest wetland.

General Habits

Pratincoles are more or less gregarious at all times, and this includes when they are nesting, although solitary pairs are not unknown. Flocks of Black-winged Pratincoles formerly numbered tens of thousands of birds on the Russian steppes, even during breeding. As with most other pratincoles, the nests of this species are often deserted during the day while the birds repair to the nearest water to drink and bathe in numbers. The Australian Pratincole is also gregarious, but tends to nest in more widely scattered pairs 45-500 m apart on the open desert floor or on the shoreline of an inland lake.

Pratincoles are usually conspicuous birds, even when breeding. Members of a colony co-operate in defending their eggs and young against predators, attacking birds of prey with loud cries, and often successfully driving the raptor away. When approached by humans, the nesting birds perform elaborate injury-feigning displays, in which the striking black and white rump and tail patterns are flashed at the intruder.

Black-winged Pratincoles readily associate with other steppe species, especially the Northern Lapwing (*Vanellus vanellus*), and when nesting the Grey Pratincole may associate with skimmers and terns, as well as Egyptian Plovers. All species are highly sociable outside the breeding season, and flocks, sometimes numbering hundreds or thousands of birds, may join other gregarious waterbirds, such as terns, plovers and other charadriiforms. Collared Pratincoles sometimes mix with Black-winged or Oriental Pratincoles, while the latter species sometimes associates with Oriental Plovers (*Charadrius veredus*) in Australia, or, more rarely, with Australian Pratincoles. Rock and Grey Pratincoles occasionally feed together. When the rivers are in flood in West Africa, flocks of 300-500 Grey Pratincoles gather at Lake Chad and in coastal habitats near Lagos, in Nigeria; whereas their close relatives in India, Small Pratincoles, frequently feed at dusk in the company of swifts and bats.

Among the coursers, members of the genus *Cursorius* are somewhat gregarious, usually in flocks of fewer than 20 individuals, though the Cream-coloured Courser may occur in flocks of 25-30, while Temminck's Courser is said to form flocks of as many as 40 birds. Significantly, these are the species of the more arid habitats, and flocking may enable the birds to exploit patchy food resources more easily. In contrast, the *Smutsornis* and *Rhinoptilus* coursers are usually found singly, in pairs or in family groups of 3-4 birds, seldom of 5-6 birds. They are often highly cryptic and inconspicuous, especially by day. Unlike pratincoles, they seldom advertise their presence by flying about, and they lack elaborate distraction displays when nesting. The inconspicuousness of these coursers, especially those of woodland habitats, is further enhanced by their being largely crepuscular or nocturnal, birds remaining standing, but immobile, in the shelter of scrub during the heat of the day. The Bronze-winged Courser, if approached, will crouch facing the observer; it rests in the same area on successive days. Competition with lapwings (*Vanellus*) is avoided by the larger coursers by their adoption of largely nocturnal habits. Although coursers of open country are generally somewhat less secretive, they too show appropriate cryptic behaviour: for instance, the Cream-coloured Courser displays a natural curiosity and will crane its neck when curious, but when crouched it too becomes well camouflaged.

Many of the pratincoles are also more active at dawn and dusk, spending the heat of the day resting against an appropriate background: Grey and Small Pratincoles are superbly camouflaged when at rest on sandbanks, as too are the larger pratincoles on dried mud. Rock Pratincoles roost by day, huddled together on rocks, but in the early morning and late afternoon they swarm into the sky to feed on aerial insects. Similarly, the Small Pratincole is especially active towards dusk; when not feeding, it spends much time resting, either standing or sitting in habitual resting spots. A vagrant Oriental Pratincole in New Zealand adopted a typical daily regime, catching shore-flies on the ground between 07:00 and 08:20; later in the day most of its foraging was in the air, but it spent the middle of day roosting on mudflats. The Australian Pratincole regularly flies on moonlit nights, especially when migrating.

Birds living in these hot environments adopt a variety of strategies to survive the high temperatures. The adult Australian Pratincole never seeks shelter from the sun, even when the ambient shade temperature reaches 46°C, but because it drinks frequently it can afford to use water freely to promote heat loss through evaporation; it also pants when overheated. The chick can not drink but has active salt glands to allow for the excretion of excess salt with minimal fluid loss. The Double-banded Courser uses wing-spreading to lose heat, and more generally the long-legged coursers are able to lose heat through their legs, which can be particularly important during incubation (see Breeding).

The Australian Pratincole bobs its head and tail, and indulges in various forms of comfort behaviour, such as direct head-scratching, yawning, one-sided wing and leg stretching, preening and body-shaking.

Voice

Pratincoles are noisy birds, with sharp, rather tern-like chipperings, uttered in flight, as they commute back and forth to their breeding colonies, or as large flocks pass over on migration. The larger species, such as the Collared and Madagascar Pratincoles (*Glareola ocularis*), tend to produce harsher notes, while the smaller species generally have more musical voices.

Coursers have a singularly plover-like manner of seeking their prey by running fast over the ground, stopping abruptly to stoop and peck when a suitable morsel is found, then running on once more. The preferred prey item of Burchell's Courser is harvester termites. It takes food from the surface but may also use its long, curved bill to dig for insects in loose sandy soil.

[*Cursorius rufus*, Africa. Photo: David Hosking/ FLPA]

Calling to reinforce their protest, both members of a pair of breeding Collared Pratincoles adopt an unequivocally antagonistic attitude towards a Pied Avocet (Recurvirostra avosetta) *that has strayed too close to their nest-site or chicks for comfort. When dealing with a human intruder, pratincoles are past-masters at the art of subterfuge and will lure the person away from a danger zone using a variety of display strategies, one of the most frequent being injury-feigning.*

[*Glareola pratincola pratincola*, Doñana National Park, Spain. Photo: Günter Ziesler]

Grey Pratincoles are strongly vocal, communicating with liquid contact notes and a trilling song, as they wheel about in the air in noisy flocks. The Small Pratincole has a high-pitched rolled call, and the beautiful trilling song of the Rock Pratincole is usually uttered in flight, but also at times by birds standing on rocks. The flight call of the Australian Pratincole is a distinctive shrill sweet whistle. Pratincole alarm calls are loud and sharp.

Coursers are generally less vocal and have rather harsher and more grating calls. They often call in flight, especially the members of *Cursorius*, and the grating calls of these species can be heard at a great height as the birds migrate at night. Some courser calls have been likened to the sound of a rusty hinge and a soft rattle, and other notes are sandpiper-like. However, the calls of the Double-banded Courser, often heard on moonlit nights, are altogether more musical than those of other coursers, including a plaintive, mellow "peeu-wee" and a sharp "wik-wik" on take-off. The Bronze-winged and Three-banded Coursers are also vocal mainly at night, the "wicky-wicky-wicky-wick" song of the latter even having been confused with the song of a nightjar (*Caprimulgus*).

Food and Feeding

The coursers and the Egyptian Plover catch all their food on the ground, whereas the pratincoles take much of theirs while on the wing, whence they receive their alternative English name, little used today, of swallow-plover.

The food of all glareolids is principally insects, and larger insects such as locusts and beetles are especially favoured. Although pratincoles forage mostly in flight, they will catch insects on the ground as well. The Australian Pratincole is especially adept at this: it has a unique method of trapping ground prey by extending a wing to stop the prey from escaping, before catching it in the bill. The way in which pratincoles capitalize on swarms of locusts is well described in an early account, by A. Haagner and R. H. Ivy, of a flock of Black-winged Pratincoles feeding on these insects in South Africa in the first decade of the present century: "In January, 1906, at Brandfort, Orange River Colony, a large flock of these birds were busy making a morning meal off a swarm of locusts. The sun had not yet warmed the insects up to a proper degree of activity, and the birds had in consequence a fairly easy time of it. Flying in a crescent-shaped flock they would bear down on the insects and sweep over them with the effect of putting them on the wing. As soon as this was accomplished and the insects were about 2 or 3 feet [60-90 cm] from the ground, the flock of birds wheeled with the rapidity of thought, the outer edges of the crescent converging to the centre, and enclosing the insects in a living circle. The startled locusts, in their half lethargic condition, immediately settled again amidst a perfect hail of dropping wings, and the birds would repeat the manoeuvre."

Collared Pratincoles may occur in flocks of several thousand, accompanying herds of lechwe (*Kobus leche*) in Zambia, and feeding on insects disturbed by the grazing mammals. Similarly, Rock Pratincoles have been recorded feeding in hundreds around street lamps in the centre of Livingstone, Zambia, in October and November. Pratincoles are opportunists, taking advantage of temporary insect swarms, a favourite food being the winged termites which perform a mass emergence before rains. Pratincoles are often crepuscular feeders.

Coursers may add molluscs and seeds to their insect diet, although the ingestion of seeds may be fortuitous. They catch their food on the ground in a very plover-like fashion by running rapidly, stopping abruptly, pecking at the food item and running on again. The genus *Cursorius* is equipped with a longish, curved bill which is used for digging for insects, probably mainly larvae, in soft sandy soil. Differences in body size and in bill shape may determine the type of prey eaten, and therefore help to avoid competition in those species which occupy the same habitat. There are also differences in the timing of daily activity, some species being more nocturnal than others, and thus exploiting a different range of insect species.

Both pratincoles and coursers take relatively large insects, including locusts, large tenebrionid and dung beetles up to 25 mm and dragonflies up to 80 mm in body length, and even sometimes small lizards and scorpions. Chicks may be fed on insect larvae.

Pratincoles of all species drink frequently, though both they and coursers have functional nasal glands for the excretion of excess salt. This function is especially useful in coursers which are not known to drink and must obtain all their water require-

The Australian Pratincole is an enigmatic species thought to form a link between coursers and pratincoles. In general appearance and behaviour like a pratincole, it has some structural features in common with coursers, notably long legs and a short, unforked tail. It breeds in small, loose colonies in semi-desert habitats inland, but never very far from water, for it needs to drink frequently. No pretence of a nest is made: the 2-3 eggs are laid directly on the bare, often stony ground. More remarkably, though, the chicks may quite literally go to earth when danger threatens, by seeking refuge in a rabbit burrow; the adults are not recorded as ever joining them underground.

[*Stiltia isabella*, Australia. Photo: Hans & Judy Beste/ Animals Animals]

ments from their insect food, and must therefore be able to process the body fluids of their prey in order to extract the greatest amount of water.

Breeding

Although the nesting habits of some glareolids, such as the Egyptian Plover, the Double-banded Courser, the Collared Pratincole and the Rock Pratincole are very well known, those of most other species have been poorly studied.

Pratincoles all breed in loose colonies, sometimes of just a few pairs, at other times of hundreds of pairs, though the nests are usually several metres apart, and a small territory is defended. In the Australian Pratincole, intraspecific aggression is shown by territorial adults with a head-down threatening run toward an intruding bird. Coursers, on the other hand, are always solitary nesters.

The Rock Pratincole performs a display flight in which birds glide for several seconds with both wings raised high above the back. At dusk great numbers fly round low over the surface of the water, occasionally uttering a weak piping call. Greeting displays involve holding the collar flared to show the maximum expanse of chestnut for as long as 20 seconds; the head is also bobbed up and down, with the bill slightly open. Courtship in the Collared Pratincole includes a wings-spread, tail-up, head-bowed posture, and a stiff-winged display flight.

Courtship in coursers is not well known and appears to be rather simple. The Cream-coloured Courser has a poorly developed circular or gliding display flight in which the male flies diagonally up with shallow, rapid wingbeats, then planes down, uttering a warbling plover-like cry. Copulation is initiated by the female, as she crouches flat and is approached by the male with a pattering foot action and upright gait; he mounts the female, with his wings outspread and fluttering. Other displays of coursers have not been specifically linked with pair formation and need detailed study.

The glareolids appear to be typical waders in their nesting habits. The nest in all cases is on the ground, sometimes in a shallow scrape, or in a hollow on a rock. The clutch consists of 1-4 eggs, which are typically cryptic, having a dull whitish to yellowish or greyish ground colour, spotted, blotched and streaked more or less heavily in shades of black and grey. They tend to be rounded in shape, except in the case of the Three-banded Courser, which has rather elongate eggs. This species and the Egyptian Plover are unique in the family in incubating their eggs partially buried in the sand of the nest scrape. Perhaps the rounded shape of the exposed eggs of most species assists in their camouflage by making the eggs look very much like stones; this is certainly the case for those species of courser which nest on stony ground, as well as the Australian Pratincole. The very dark, heavily marked eggs of Burchell's and Temminck's Coursers confer excellent concealment when laid among tufts of burnt stubble or among sun-darkened antelope droppings.

Clutch size in the glareolids follows the pattern of other members of the Charadrii: those nesting at higher latitudes lay larger clutches than those nesting in the tropics, and those nesting in the most arid habitats lay the smallest clutches of all. For example, the Black-winged Pratincole, which nests in the steppes of southern Russia, as a rule lays 3-4 eggs, European-nesting Collared Pratincoles lay 3 eggs, while African-breeding populations of this species usually lay only 1 or 2 eggs. Coursers, most of which are birds of arid regions in tropical latitudes, seldom lay more than 2 eggs per clutch. The Double-banded Courser of Africa occupies some very arid regions indeed and lays only a single egg; however, it compensates for this small clutch size by raising at least 2-3 broods a year. This is probably a mechanism for keeping the population fairly sparse at any given time in a habitat of limited carrying capacity.

The roles of the sexes in incubation are known for most species, and appear to be about equal. The frequency of changeover at the nest depends to some extent on air temperatures: under very hot conditions, nest relief is relatively frequent, as often as every 15-20 minutes, but in milder conditions each parent may incubate the eggs for one to four hours at a time. The Cream-coloured Courser appears to be unusual in this regard, since an incubating parent may have to sit unrelieved for as long as six hours at a stretch. In mild conditions the eggs may even be left unattended, their camouflaged coloration giving them the necessary protection from predators. Nest-relief behaviour in coursers is similar to that of many other waders: the departing parent

tosses small stones or other objects toward the nest scrape in a movement called side-throwing.

One of the main problems to be solved by those species nesting in hot environments is how to keep the eggs from overheating, which would kill the embryos. Adjustments of body posture in coursers help to regulate the temperature of the eggs. When the air temperature is well below normal body temperature, the eggs are incubated in the normal way, in contact with the brood patch and covered with the ventral feathers. As ambient temperatures rise to about 35°C, the incubating courser exposes its legs as areas for heat loss, and may merely crouch over the clutch to shade the eggs. When temperatures exceed about 36°C, the eggs may still only be shaded and the sitting bird will pant to keep cool. Above about 40°C, however, overheating of the egg becomes a real problem, and the incubating parent will again incubate the egg, panting as it does so, thereby shielding the eggs from direct radiation and withdrawing heat from the eggs by means of its own evaporative cooling mechanisms.

Pratincoles appear not to expose their legs or shade their eggs during incubation, as coursers do. This may have something to do with their shorter legs, but even the long-legged Australian Pratincole behaves in this regard just like other pratincoles. Off-duty pratincole parents do, however, use their legs as a heat loss centre, since they stand with the legs exposed to the air, but shaded by the body, during the midday hours, often on a raised stone or clod where the ambient temperature is 3-4°C lower than at ground level.

The purpose of covering the eggs with nesting material by the Egyptian Plover and the Three-banded Courser is not always clear: in most instances it appears to be for concealment only, but in the case of the Egyptian Plover there may be the secondary function of helping with temperature regulation of the eggs. When leaving the nest, the Egyptian Plover uses its bill to gather sand over the eggs until they are completely buried, with a 2-3 mm covering of sand on top; they are sometimes covered even while the adult is sitting on the nest, though it may at times scrape the sand from the tops of the eggs, using its feet. At night the eggs are uncovered for about two thirds of their volume and incubated continuously. During the hottest hours of the day, from about 10:00 hours to 16:00 hours, each incubating parent frequently soaks its belly feathers in the nearby river and returns to sit on the covered eggs, thereby keeping them surrounded by wet sand. In this way the eggs are kept at a mean temperature of around 37·5°C throughout the day, even when ambient temperatures reach 45°C or more.

The Egyptian Plover's chicks hatch under the sand and leave the nest scrape within a day of hatching. When danger threatens, the parents will cover chicks of up to the age of three weeks with sand, using the bill as in egg-covering. They may also wet the sand over the chicks with their soaked belly feathers. Although it has been claimed that the Egyptian Plover regurgitates water over the buried chicks, this appears not to be the case. Since adult Egyptian Plovers are highly conspicuously coloured, the covering and wetting of eggs and chicks allows them to be left concealed and protected from the sun for considerable periods of time in the face of danger, while the parents run or fly away to a safe distance.

Off-duty parents of Rock, Small and Collared Pratincoles may, like the Egyptian Plover, soak their belly feathers in water before flying back to relieve the incubating bird at the nest. Coursers do not do this, as they seldom have water nearby.

Egg-covering in the Three-banded Courser is also done with the bill. In all other Charadrii which cover their eggs, the feet are used for the task, so use of the bill is a glareolid feature, and points to the Egyptian Plover being a true glareolid. The eggs of the Three-banded Courser are incubated in a partly buried condition, usually with no more than a third of their volume showing above the sand of the nest scrape, which is filled by the parents, using a side-throwing action of the bill. Since this species usually nests under the shade of a small tree or bush, the function of egg-covering is probably more for concealment than for protection from the sun, but it is curious that this behaviour has not evolved in any other courser, possibly because most species of courser nest on hard soils, rather than sand.

Parental care in the glareolids is well developed. Injury-feigning behaviour at the nest or near young is developed only in the pratincoles, both *Glareola* and *Stiltia*, although some injury-feigning has also been noted in the Double-banded Courser. In such performances, the parent bird spreads its wings, collapses to the ground on bent legs, and often raises the wings or beats them noisily on the ground, either facing the intruder or moving away from the nest or young, at the same time exposing the conspicuous black and white rump and tail patterns so characteristic of pratincoles. This behaviour is extremely effective for luring predators away from the nest. False-sitting is also recorded in the Small Pratincole, in addition to the broken-wing display. Predator avoidance in those pratincoles that nest next to water, such as the Rock Pratincole, is further enhanced by the ability of the young to jump into the water and swim away. Even very tiny chicks of only 2-3 days of age do this, and may leap into the rushing waters of a powerful rapid. Once they reach the safety of a rock, they clamber out and crouch in a crevice until danger has passed.

Coursers usually simply run from the nest or young, keeping a safe distance of 50-100 m from the predator. Sometimes a parent will give agitated alarm calls, but injury-feigning is not part of the coursers' behavioural repertoire, even though many possess conspicuous rump or wing patterns. In the face of disturbance by non-predatory large mammals, however, most species of courser will defend the nest by approaching the mammals with wings and tail spread and often also with the bill open. Sometimes the incubating parent may simply threaten the intruder with open bill, and wrists slightly parted from the body. False Nest-scraping or Mock-brooding are also adopted by Cream-coloured and Burchell's Coursers, as well as by the Egyptian Plover.

Part of parental behaviour in all glareolids involves feeding the young for their first few days or weeks of life. The young birds often adopt a refuge, most notably in the Australian Pratincole, which may use a rabbit burrow in which to hide. Parental care of the young ensures enhanced survival of the chicks, and almost certainly compensates for the small size of the clutch in most members of the family. Reduction of clutch size in birds, especially if food resources are few or unpredictable, is a sound evolutionary economy measure, which has been adopted with great success by the coursers.

Movements

The long wings of pratincoles allow them not only to spend much time foraging in the air, but also to migrate long distances. The Black-winged Pratincole has probably the longest migration of any glareolid, from the steppes of southern Eurasia to Chad, Ethiopia and as far as South Africa, a maximum straight-line distance of about 10,000 km. Prior to migration, both Collared and Black-winged Pratincoles gather at moulting sites in late summer. The entire population of the latter spends the non-breeding season in Africa south of the Sahara, moving southward on a broad front through Iran, Iraq, Turkey and the northern parts of the Arabian Peninsula, probably entering Africa across the Red Sea. Non-breeding flocks of Black-winged Pratincoles may number up to 10,000 birds. The apparent absence of this species from parts of its route, such as the Middle East and central Africa is a result of its flying very high over inhospitable desert and forest regions. The first birds to return to the breeding grounds in Russia and Kazakhstan do so in late April, the main body arriving in May.

The Eurasian populations of the Collared Pratincole, by contrast, overwinter mainly along the southern edge of the Sahara between Senegal and Ethiopia, overlapping in parts of this range with the two resident or nomadic African subspecies. Birds returning to their breeding grounds in Europe do so around both ends of the Mediterranean, arriving in April and May.

The third member of this group, the Oriental Pratincole, also undertakes a long migration from north China south to Australia, while vagrants have appeared many thousands of kilometres out of range in several parts of the world. After breeding in Aus-

The Three-banded Courser, a species of nocturnal habits living in scrub and open woodland, is a solitary nester. A rather deep scrape is made and in it the two elongate eggs are laid. Then, with sideways sweeps of their bills, the parent birds proceed to more than half-bury the eggs under loose soil, a practice not known in other courser species; incubation takes place with the eggs partially covered. The exact purpose of this strategy is still a matter for conjecture, but it is thought that it probably helps mainly with concealment rather than affording the eggs protection from the sun.

[*Rhinoptilus cinctus emini*, East Africa. Photo: Jonathan Scott/ Planet Earth]

tralia, the rather aberrant Australian Pratincole moves in the opposite direction, to winter in Indonesia and northern Australia, north and north-west of its breeding range.

Within Africa, the Rock Pratincole migrates from equatorial regions to more southerly nesting grounds on the Zambezi River and its tributaries, but not all populations of this species are migrants. Non-breeding birds of the more southerly subspecies *nuchalis* may occur together with populations of the northern race *liberiae* in October in West Africa. As with many other intra-African migrants, the exact movements of the Rock Pratincole still need to be worked out, but it appears to be a true medium distance migrant, with highly seasonal arrivals and departures. The Madagascar Pratincole breeds only in Madagascar, but the entire population then migrates to East Africa when not breeding, following the same strategy as the Madagascar Pond-heron (*Ardeola idae*). Non-breeding pratincoles of several species tend to wander, often in response to rainfall, seeking out and exploiting temporary food gluts.

Coursers are not generally migratory, but most are highly nomadic, moving about according to rainfall and feeding conditions. The same applies to the Egyptian Plover, which performs strictly local movements that are determined by changing water levels in its riverine habitat. The absence of a regular migratory tendency among most coursers is reflected in the relatively large number of geographical races in those species with a fairly wide distribution, such as the Cream-coloured and Double-banded Coursers of Africa, which have five and eight subspecies respectively, though many of the more northerly populations of the Cream-coloured Courser do migrate. Temminck's and Bronze-winged Coursers appear also to have migratory populations, since regular seasonal fluctuations in numbers are documented, but these movements are poorly known. It appears that some populations of Temminck's Coursers may migrate from the Sahel to southern Africa, while the Bronze-winged Courser, in the extreme south of its range is essentially a non-breeding visitor and in the extreme north only a breeding visitor.

The daily movements of pratincoles when breeding often follow a pattern. For instance, on occasion on mild days there may be a complete absence of adult Australian Pratincoles from the breeding colony at certain times of the day, when birds gather at the nearest water.

Relationship with Man

Collared and Black-winged Pratincoles have in the past both had some economic value for man. In the case of the former, eggs were collected on a commercial scale in Hungary until some breeding colonies were eliminated altogether and others became too small to be viable. Even as recently as the 1970's, egg-collectors still took large numbers of pratincole eggs, ostensibly for scientific reasons, but in reality as part of a large illegal "oology industry". The loss of clutches of eggs is unavoidable when farm machinery and implements are used to work the land. Again in Hungary, for instance, camomile (*Matricaria recutita*) flowers are gathered by means of a box-like tool fitted with a set of long tines in front, which destroys large numbers of eggs of all ground-nesting birds, yet the camomile crop is of such significant financial importance that the practice is unlikely to be discontinued.

The Black-winged Pratincole used to occur in far greater numbers in the past and may have had a significant impact on locust swarms, especially in southern Africa. Now, however, numbers of this magnificent bird have dwindled to the point at which they probably have little, if any, noticeable effect on locust numbers in their non-breeding quarters, though they may still have some value as predators of insect pests on their Russian and Kazakh breeding grounds. Indeed, in Africa pratincoles are sometimes known as "locust birds", along with the European White Stork (*Ciconia ciconia*), the Wattled Starling (*Creatophora cinerea*) and others. Again, in Australia the Oriental Pratincole is popularly known as "grasshopper bird" or "swarmer" for the same reason.

Members of this family appear to be palatable, as the Cape Verde race *exsul* of the Cream-coloured Courser was first discovered by Boyd Alexander, who reported that it was by no means bad eating. According to Bannerman: "he was unaware he was enjoying an interesting new subspecies for his dinner, for it took another 23 years before it was described as such"! Both Oriental and Australian Pratincoles are hunted in Indonesia for food.

Both pratincoles and coursers have great aesthetic value, and birdwatchers tend to place them high on their lists of special birds to see in the regions where they occur. Many species are notoriously tame, including such diverse members of the family as the Egyptian Plover, Australian Pratincole, Grey Pratincole

Pratincoles are gregarious birds, usually breeding in loose colonies; even when nesting, during the day they often leave their nests to gather in numbers at the nearest water source to drink and bathe. After the breeding season Collared Pratincoles assemble in flocks to moult at riversides, coasts and lagoons. Whereas birds of the Eurasian population, once they have completed their moult, fly south to winter in Africa south of the Sahara, the movements of African populations, like these birds, are apparently mainly on a local basis, although at present they remain imperfectly understood.

and Double-banded Courser, which only serves to enhance their appeal.

An interesting and curious story is that of the so-called "Crocodile Bird", which has its origins in the visit of Herodotus to Egypt in 459 BC. His account of a small bird picking food from the teeth of a gaping crocodile referred, it has been suggested, to the Egyptian Plover. Whether or not this is so, the tale was further romanticized by A. Brehm in the nineteenth century and R. Meinertzhagen in the twentieth century, both of whom stated that they had personally seen the Egyptian Plover picking the teeth of crocodiles on more than one occasion. Meinertzhagen also implicated the Spur-winged Lapwing (*Vanellus spinosus*) in this behaviour, but no reliable observer since then has seen either bird species acting as a crocodile toothpick. Brehm and Meinertzhagen were recalling observations from their distant past, and therefore the accuracy of their statements can not be relied on. However, the myth has been perpetuated in the literature and needs finally to be laid to rest, unless contrary proof can be found.

Status and Conservation

Human impact on populations of glareolids is usually negative, and though only a single species is threatened, many are undergoing long-term declines.

The only threatened member of the family is Jerdon's Courser of eastern India, which was considered extinct for much of the present century, until its rediscovery in 1986. Probably never very numerous, its small populations were pushed to the edge of extinction by disturbance and overgrazing, two human activities which have repeatedly acted against the welfare of the world's wildlife. Jerdon's Courser was first described in 1848, having been obtained by T. C. Jerdon in about that year from "hilly country above the Eastern Ghats...in rocky and undulating ground with thin forest jungle." It was recorded again in 1871 in Andhra Pradesh above the Godavari River in similar habitat. The last authentic sighting, in 1900, was in the Pennar River Valley near Anantapur, a linear distance of no more than 170 kilometres from the original site. A preliminary survey of this valley in June, July and October 1985 in the districts of Anantapur, Cuddapah and Nellore revealed no trace of the species. However, a subsequent visit in January 1986 to the more easterly parts of the Pennar Valley was successful: a specimen of Jerdon's Courser was caught alive near Reddipalli just north of the Pennar River. After 86 years of presumed extinction, the species was rediscovered! A nocturnal survey in the same area that night revealed two more birds. Although not extinct, Jerdon's Courser must still rate as one of the world's rarest birds. Its occurrence in Anantapur in the upper reaches of the Pennar Valley rests on presumed sightings in the past, while the Nellore region downstream from Reddipalli is subject to much human disturbance and the chances of the future survival there of Jerdon's Courser must be slim. However, its nocturnal habits have undoubtedly contributed to the long period with no sightings. Rediscovery came just in time to divert an irrigation scheme planned to pass through the area. Subsequently, two reserves have been designated for the species with a third also proposed. It is hoped that further surveys may yet reveal the continued presence of the species in more than its tiny currently known range.

Though not yet a Red Data Book species, the Black-winged Pratincole is now ranked as near-threatened, primarily as a result of the conversion of steppes to arable agriculture and the increase of Rooks (*Corvus frugilegus*) and other corvids in the area. It urgently needs full legal protection in its breeding areas, while practical measures that might be adopted include the regulation of grazing at permanent colonies and the sheltering of individual nests with metal frames to prevent trampling and predation; also, where nesting on ploughed land, pratincole-friendly farming methods need to be encouraged; and Rook numbers may also need to be controlled in places. In Africa, too, locust control programmes may be having an adverse effect on this species.

The Collared Pratincole is declining, at least in Europe, again through loss of suitable habitat. It also shows poor breeding success because of high levels of disturbance from agricultural operations and other sources, while in its African wintering quarters water-management programmes in the Sahel are dramatically changing the structure of the original habitat, together with pesticide use on newly planted rice fields. Suitable habitat needs to be maintained in both the European breeding and African non-breeding ranges. In addition, it is to be hoped that pratincole-

friendly farming methods might be adopted in western Europe under the new Agri-environment Regulation of the European Union, whereby farmers would receive financial help for adopting environmentally beneficial practices.

In eastern Europe, in years gone by, much of the former breeding habitat of this species was kept suitable by huge flocks of free-ranging long-horned cattle and sheep, which kept the vegetation short on the saline soils so favoured by the pratincoles. Since the sharp decline in the keeping of these traditional breeds and their replacement with more productive but less hardy stock, as well as the replacement of draught animals with mechanized farm machinery, the vegetation of saline steppes has been allowed to grow too tall. Furthermore, the steppes have increasingly been put under artificial fertilizers and irrigation, rendering them inhospitable for the pratincoles. In addition, the use of both insecticides and herbicides has reduced their insect food. All these factors, together with the formerly indiscriminate collection of eggs, have led to the disappearance of the Collared Pratincole from many of its east European breeding sites. Since the early 1970's, however, measures have been taken to declare nature reserves in parts of Austria and Hungary, such as the Hortobágy, where pratincoles and other ground-nesting birds like terns, plovers, lapwings, avocets, thick-knees and larks can breed successfully. The maintenance of these breeding places by the reintroduction of grazing ungulates is part of the management programme and gives hope for the future.

A major threat to certain river-dwelling pratincoles, and to a lesser extent the Egyptian Plover, is the damming of Africa's rivers. The main effects are the flooding of breeding habitats, such as exposed rocks and sandbars, above the dam, and unpredictable flooding regimes below the dam. Indeed, floods may threaten breeding colonies when water levels would under natural conditions be low; such effects are especially severe in narrow reaches of the rivers, where waters are deep and the water levels change most markedly. It is possibly for this reason that the Egyptian Plover has disappeared from Egypt, where formerly it was quite common in the upper reaches of the Nile; there seem to be no reliable sightings from this area for more than half a century.

A similar fate may befall the Rock Pratincole on the Zambezi and other large African rivers. Although it occurred formerly in the Kariba Basin of the Zambezi Valley, it no longer does so because of the damming of the river to form Lake Kariba. Two further dams are planned for the Zambezi, one upstream and one downstream of Lake Kariba: the Mupata Gorge Dam below Kariba will flood a section of the middle Zambezi River where about 73% of that zone's population of Rock Pratincoles breeds; while the Batoka Gorge Dam above Kariba will flood sites on the upper Zambezi below Victoria Falls, where some 6% of the population of the upper Zambezi nests. Most potential breeding sites on the Zambezi are therefore below Kariba. Conservation of high-density breeding sites is essential, since over 90% of Rock Pratincoles recorded on the upper and middle Zambezi occur along only about 17% of its length. The threat from direct human disturbance appears to be quite small because of the relatively low human population density in the Rock Pratincole's breeding areas.

In general, however, most coursers and pratincoles either seem to be able to adapt fairly well to man's activities, or else inhabit regions, such as deserts and remote woodlands, where human population densities are very low. Nevertheless, the game reserves and nature reserves of Africa are important refuges for the woodland species, notably Temminck's, Bronze-winged and Three-banded Coursers. Temminck's Courser is the most catholic in its choice of habitat, and therefore the least vulnerable. The Bronze-winged Courser's preference for *Acacia* and other types of wooded savanna brings it into some conflict with domestic livestock, notably cattle and goats, but it seems to be holding its own, while the mopane country favoured by the Three-banded Courser is usually very thinly populated by humans and their stock, which means that this courser is not in any immediate danger.

The western populations of Burchell's Courser appear to be maintaining their numbers in their very arid habitats, but in the more easterly parts of their range their habitat has suffered from agricultural change, leading to a marked decline, especially in the last 30 years. One adverse effect in the high grasslands of South Africa is a change in livestock grazing regimes, which results in the animals being moved around more frequently than previously, causing increased disturbance to the birds, especially when they are nesting. A similar adverse impact is being experienced by cranes and other ground-nesting birds in these grasslands. Ironically, though, desertification caused by overgrazing by sheep and goats in the drier parts of southern Africa and in the Sahel has probably favoured the spread of the Double-banded Courser in the south and the Cream-coloured Courser in the north, though properly quantified information on these effects is, however, wanting. On the debit side, the population of Cream-coloured Coursers on Fuerteventura, in the Canary Islands, is under threat from disturbance by tourist development and military exercises, leading to habitat damage. Many sites holding glareolids are protected at the regional level, but in practice these are often poorly managed.

An interesting conservation measure adopted by some enlightened sugar farmers in the coastal regions of northern Natal is the ploughing of land immediately before the return of breeding flocks of Collared Pratincoles. The bare soil of such places provides suitable nesting substrate in a habitat so modified by the planting of sugar cane as to be otherwise totally uninhabitable by the birds. The ploughed land is then left unplanted until the birds have bred and their young are on the wing. It is to be hoped that in time such positive measures may be adopted elsewhere, for the benefit of wildlife, and also for those who delight in it.

Sadly, many glareolid species are currently in a state of decline. However, the only one believed to be in imminent danger is Jerdon's Courser. This bird, inhabiting rocky hilly country in Andhra Pradesh, India, was thought to be extinct until rediscovered in 1986, after having remained unrecorded since 1900! Recent observations from six localities have confirmed its continued survival, but the present known range is of only 2000 km². It can only be hoped that further searches will discover the species in other similar areas. Meanwhile it must rank as one of the world's rarest birds.

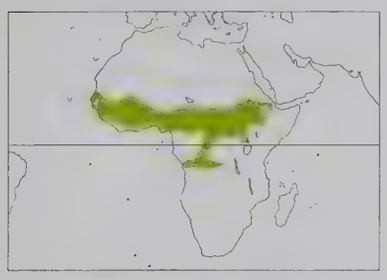
PLATE 33

inches 5
cm 13

Subfamily CURSORIINAE



Genus *PLUVIANUS* Vieillot, 1816

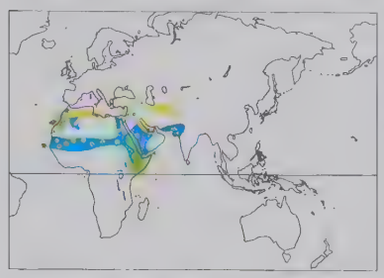
1. Egyptian Plover

Pluvianus aegyptius

French: Pluvian fluviatile **German**: Krokodilwächter **Spanish**: Pluvial
Other common names: Crocodile-bird, Crocodile-plover, Egyptian Courser

Taxonomy. *Charadrius ægyptius* Linnaeus, 1758, Egypt.
Affinities uncertain: sometimes placed in its own family (Pluvianidae), or subfamily (Pluvianinae), or regarded as closer to subfamily Glareolinae. Birds from N Angola and Zaire somewhat smaller, sometimes regarded as race *angolae*, but variation is clinal and this form poorly defined, so not normally recognized as separate race. Monotypic.
Distribution. Sub-Saharan Africa from Senegal to Ethiopia, S to N Zaire and Uganda and narrowly into the lower basin of R Congo (Zaire) and extreme N Angola; formerly N along R Nile into Egypt, where now extinct.

Descriptive notes. 19-21 cm; 73-92 g. Centre of back, crown, broad eyestripe and breast band black, edged with white; supercilium white; wing-coverts and tail blue-grey, latter tipped white; striking black and white wing pattern formed by white on coverts and flight-feathers, contrasting with black diagonal bar and black-tipped primaries; underwing brilliant white, also crossed by black diagonal bar; rest of underparts cream to tawny buff; bill black; legs and feet blue-grey. Sexes alike. Juvenile like adult, but lesser and median coverts rusty, and feathers of back edged brownish.
Habitat. Large lowland tropical rivers with sand and gravel bars; generally avoids heavily forested regions and also estuarine waters. Tame, often occurring around human settlements near rivers, e.g. at Tompari Ferry, Sierra Leone, in area without sandbanks feeds on slipway, dodging pedestrians quite unconcernedly.
Food and Feeding. Worms, molluscs, aquatic insects (both adults and larvae), small flies; said also to eat seeds and particles of scavenged fish. Food obtained by variety of methods, including surface-picking, catching flying insects on the run (these sometimes flushed by bird running with wings slightly spread), stalking insects, probing or foot-scratching in damp sand, turning over stones and occasionally bill-dipping in water. Occasionally seeks food on open ground away from water. Drinks water directly. No reliable evidence of assertion that species picks food from the jaws of crocodiles (see page 374).
Breeding. Jan to Apr or May N of equator when water levels low; season not recorded in S parts of range. Solitary nester. Eggs laid in deep scrape on exposed sandbank in riverbed. Usually 2-3 eggs (1-4); incubation 28-31 days, by both sexes; eggs partly or completely buried during incubation, covered by parents on departure, invariably using bill, and cooled during incubation by wetting sand with soaked belly feathers every few minutes in heat of day. Chick speckled black and buff above; broad black stripe through eye and down sides of hindneck; broad white band from above and behind each eye to join wide white patch on nape; black occipital stripe; white below and on wings; bill and legs as in adult; white nape patch very conspicuous when chick running; when danger threatens and chick crouches this recognition mark disappears. Chicks leave nest on first day, but may be buried with sand by parents while still in nest scrape or away from scrape until 3-4 weeks old; in heat of day buried chicks are cooled by wet belly plumage of brooding parent; chicks start feeding selves after c. 7 days; estimated age of fledging c. 30-35 days.
Movements. Local movements in response to changes of water levels are common, but longer distance migrations also recorded from Ethiopia to Sudan (600-800 km) and in Nigeria and Chad where birds make irregular northward movements during wet season, May-Oct, when rivers flood; similarly, no records in Sierra Leone from Jun to late Nov. Moves in flocks of up to 60 birds. During floods, birds may appear in unexpected habitats. Vagrant to Canary Is, Libya, Israel. Bird recorded in Poland in Oct-Nov 1991 presumed escape.
Status and Conservation. Not globally threatened. Appears to be common over most of range. In 19th century numerous everywhere along R Nile S of Cairo, Egypt, where it became extinct in early 20th century. Not uncommon in Ghana and Sierra Leone; in former, often occurs in flocks of 10 to 20 birds. Damming of rivers, causing change in habitat, is probably main threat.
Bibliography. Bannerman (1931, 1951), Beaman (1994), Britton, P. L. (1980), Butler (1931), Cramp & Simmons (1983), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Étchécopar & Hüe (1964), Goodman *et al.* (1989), Gore (1990), Grimes (1987), Howell (1978, 1979, 1983b, 1984), Hüe & Étchécopar (1970), Lippens & Wille (1976), Louette (1981), Mackworth-Praed & Grant (1957, 1962, 1970), Meinertzhagen (1959), Paz (1987), Pinto (1983), Reichenow (1900-1901), Richards & Boswall (1985), Rutgers & Norris (1970), Serle (1939a), Seymour & Ackerman (1980), Short *et al.* (1990), Steinbacher (1981), Tyrberg (1993), Urban *et al.* (1986), Zielinski (1992a, 1992b).



Genus *CURSORIUS* Latham, 1790

2. Cream-coloured Courser

Cursorius cursor

French: Courvite isabelle **German**: Rennvogel **Spanish**: Corredor Sahariano
Other common names: Desert Courser

Taxonomy. *Charadrius cursor* Latham, 1787, Kent, England.
Forms superspecies with *C. rufus*, *C. temminckii* and *C. coromandelicus*, although overlap in range of *C. temminckii* with present species and *C. rufus* indicates that *C. temminckii* and *C. coromandelicus* may represent a separate superspecies. Sometimes considered to include *C. rufus*. Smaller, darker races *somalensis* and *littoralis* of E Africa are more distinct and may actually belong to *C. rufus*. Some intergradation between races *exsul*, *cursor* and *bogolubovi*. Canary Is population sometimes racially distinguished as *bannermani*, but separation from *cursor* dependent on size alone and probably not significant; proposed races *dahlakensis* and *meruensis* nowadays included in races *cursor* and *littoralis* respectively. Five subspecies normally recognized.
Subspecies and Distribution.
C. c. bogolubovi Zarudny, 1885 - SE Turkey through E Iran to SW Afghanistan, S Pakistan and NW India.
C. c. cursor (Latham, 1787) - Canary Is, N Africa, Arabian Peninsula and Socotra; winters S to Sahel, N Kenya and Saudi Arabia.
C. c. exsul Hartert, 1920 - Cape Verde Is.
C. c. somalensis Shelley, 1885 - Eritrea, E Ethiopia and Somalia.
C. c. littoralis Erlanger, 1905 - extreme SE Sudan, through N Kenya to S Somalia.

Descriptive notes. 19-22 cm; 115-156 g (*bogolubovi*), 102-119 g (*cursor*), 93-107 g (*littoralis*). Above pale sandy buff or sandy rufous with striking black stripe from behind eye to nape, bordered above by white stripe, with hindcrown blue-grey; below pale sandy, lower belly white; upperwing has black primaries and primary coverts, sharply contrasting with sandy secondary coverts and secondaries; underwing black with narrow white trailing edge to secondaries; bill black; legs and feet yellowish white. Plumage subject to bleaching and wear. Pale belly, lacking sharp contrast with rest of underparts, separates from other members of genus. Juvenile finely mottled above and below with buff and black; head pattern inconspicuous; primaries tipped buff. Races distinguished on shades of difference in coloration, presence and extent of darker colouring on belly, and on size, though this last feature is clinal; *exsul* darker with reddish sand-coloured upperparts and breast. In size and structure, the smaller, duller E African races are closer to *C. rufus*, and they show same pale brown-grey underwing-coverts contrasting with black outer half of underwing, and broader white trailing edge to secondaries.
Habitat. Arid, open, usually fairly flat, warm to hot desert and semi-desert, both stony and sandy, including dune troughs, with or without low sparse vegetation; also short-grass and gravel plains, saltflats, semi-arid ground among sparse *Acacia*, semi-cultivated steppe and gravel roads. Usually occurs below 800 m. In Kenya, 87% of population occupies semi-arid areas with rainfall less than 500 mm a year. In N Kenya wintering nominate *cursor* found in sparsely vegetated or bare desert, whereas *littoralis* occurs in well vegetated thornbush savanna.
Food and Feeding. Mostly adult and larval insects, including beetles, grasshoppers, ants, flies; also molluscs, isopods, arachnids, seeds. Feeds by running over ground and stopping to pick up prey which is swallowed whole, even large insects up to 8 cm long. Sometimes catches locusts in flight. May dig for food using bill.
Breeding. Mar-Jun in N Africa, Mauritania, Israel and Iran, May-Jul in Turkmenistan, Apr in Pakistan, Apr-May in Jordan, Feb-May in Cape Verde Is, Dec-May in Senegal, Apr-Sept in Kenya; small chicks in NW India in Feb and Jul; possibly double-brooded. Nest is shallow unlined scrape on bare ground; in Kenya, eggs surrounded by antelope droppings. Usually 2 eggs; incubation 18-19 days, by both sexes. Chick finely mottled sandy rufous and white above; crown streaked dusky; below white, washed buff on breast. Adults recorded mock-brooding to distract observer from presence of chick; fledging c. 30 days. First breeding at one year old.
Movements. Nominate race makes extensive movements, much of N population apparently crossing Sahara for winter, when range extends to Sahel, Sudan and N Kenya; 30 birds of race *cursor* found in Jan-Feb 1987 along 165 km stretch of E shore of L Turkana, N Kenya; scarce in N Sahara at this season; main northward movement in Sahara in Mar-Apr, sometimes into Jun; movement of c. 1000 birds over front of a few kilometres reported in Mar in Tunisia. Winters in W Negev Desert, Israel, Dec and Jan; immigration into Saudi Arabia in winter, probably from Middle East, when numbers increase and birds spread into deserts of Nafud and Empty Quarter. Breeding birds arrive Jordan early Mar and depart late Jun; then late autumn arrival of small numbers of migrants. Race *littoralis* present in Kenya Sept-May. Race *bogolubovi* mainly winter visitor to Pakistan and NW India; occurs Aug-Apr from Baluchistan, Sind and Punjab to Rajasthan and Gujarat, in loose flocks of 6-10 birds, occasionally up to 30 or more. May occur in small flocks in most seasons; up to 45 birds together in Egypt, Aug-Sept. Has occurred widely in Europe as a vagrant, chiefly in autumn, including 10 birds seen together in Netherlands, Sept 1969.
Status and Conservation. Not globally threatened. Perhaps increasing in W Africa due to southward march of Sahel; increased grazing pressure may lead to desertification which may be of benefit to species; first recorded in N Nigeria, Jan 1988, in three flocks totalling 34 birds. Populations appear to be stable throughout most of range; however, reduced vagrancy in C Europe may indicate decrease since last century. In Cape Verde Is, race *exsul* occurs on all but two of the inhabited islands, with population 120-150 pairs. In Canary Is, known to breed only on Lanzarote and Fuerteventura, considered to have declined considerably in period 1970-1990; current population estimated at 200-250 pairs; in past, heavy egg-collecting pressure contributed to species' rarity; main threats now are destruction and alteration of habitat through development of tourist resorts, building of new roads and increase in off-road vehicles; need for site protection which would also benefit the endemic race of Houbara Bustard (*Chlamydotis undulata fuertaventurae*). Many hundreds of pairs of nominate *cursor* reported in Azraq Desert National Park, Jordan, and several hundred pairs in Israel; found breeding on Socotra in 1993. Noted at 23 localities in W Mauritania between 17° N and 18°20' N during breeding season in 1979 and 1980. Little information on numbers present in E Africa.

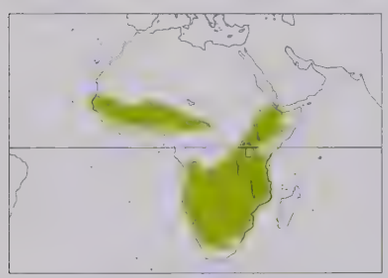
3. Burchell's Courser

Cursorius rufus

French: Courvite de Burchell **German**: Rostrennvogel **Spanish**: Corredor Rufo

On following pages: 4. Temminck's Courser (*Cursorius temminckii*); 5. Indian Courser (*Cursorius coromandelicus*); 6. Double-banded Courser (*Smutsornis africanus*); 7. Three-banded Courser (*Rhinoptilus cinctus*); 8. Bronze-winged Courser (*Rhinoptilus chalcopterus*); 9. Jerdon's Courser (*Rhinoptilus bitorquatus*).

Taxonomy. *Cursorius rufus* Gould, 1837, islands in Indian Ocean; error = Potchefstroom, Transvaal, South Africa.
Forms superspecies with *C. cursor*, *C. temminckii* and *C. coromandelicus*, though last two taxa may represent a separate superspecies. Has been regarded as conspecific with *C. cursor*. E African races *somalensis* and *littoralis* of *C. cursor* may belong in present species. Proposed race *theresae* not generally recognized, as coloration too individually variable. Monotypic.
Distribution. S Africa, mainly in drier regions, from SW Angola through most of Namibia and Kalahari Basin of Botswana to W Cape, Karoo and high plateau of South Africa.

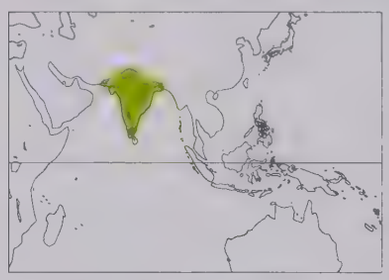


Descriptive notes. 20-22 cm; c. 75 g. Above mainly pale rufous brown, including upperwing-coverts; forecrown sandy rust, merging into blue-grey hindcrown, bordered below by black-white-black stripes behind eye, meeting in V on nape; throat and face whitish, merging to light rufous brown of breast bordered below by blackish brown band, sharply demarcated from white of lower belly; flight-feathers black, secondaries broadly tipped white; underwing black with grey-brown coverts and largely white secondaries; bill black; legs whitish grey. Shade of brown of upperparts highly variable individually and seasonally, though darker than in *C. cursor*; new feathers darker and more richly coloured than the old bleached plumage. Combination of dark belly patch, blue-grey hindcrown and extensively white secondaries separates from other members of genus. Juvenile mottled and barred with black and buff; lacks conspicuous black and white head markings.
Habitat. Open short-grass plains, sparse fallow fields, overgrazed and burnt grassland and pastures, bare or sparsely shrubby sandy or gravelly desert, salt-pans. Uncommon in pure sandy desert, such as Kalahari, where is localized on pans and exposed stony flats.
Food and Feeding. Insects, especially harvester termites (*Hodotermes mossambicus*). Takes prey on ground by running quickly, stopping and pecking; also digs for food with bill in soft windblown sand under bushes and grass tufts; may also eat seeds.
Breeding. Almost any month, but mostly Aug-Dec, in dry season just before rains; Feb in Namibia. Eggs laid on bare ground, sometimes among antelope droppings. Clutch 2 eggs; incubation and fledging periods unknown. Chick similar to that of *C. temminckii*.
Movements. Locally nomadic; no long distance migrations recorded. May occur in loose flocks of up to 10 birds.
Status and Conservation. Not globally threatened. Although fairly common in drier parts of range, numbers are declining in more southerly regions, probably as a result of poor grazing practices and disturbance by domestic stock. Conservation measures are needed in stock-farming areas of South Africa. Considerable decline reported in Orange Free State.
Bibliography. Anon. (1995h), Dixon (1975), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Ginn *et al.* (1989), Macdonald (1957), Mackworth-Praed & Grant (1962), Maclean (1967, 1993), Pinto (1983), du Plessis (1994), Snow (1978), Urban *et al.* (1986).

4. Temminck's Courser

Cursorius temminckii

French: Courvite de Temminck **German**: Temminckrennvogel **Spanish**: Corredor Etiópico
Taxonomy. *Cursorius Temminckii* Swainson, 1822, Senegal.
Forms superspecies with *C. cursor*, *C. rufus* and *C. coromandelicus*, although present species partly allopatric with the first two taxa, which may therefore represent a separate superspecies. Occasionally treated as a race of *C. coromandelicus*. Possible races *damarensis* from SW of range and *ruvanensis* from E of range poorly defined and not usually recognized, though slight differences in upperpart coloration and apparently different migration strategies may indicate their validity. Monotypic.
Distribution. Savannas of sub-Saharan Africa from S Mauritania and Senegal to Nigeria, discontinuously across Sahel to Ethiopia, and S through C Africa to N South Africa.



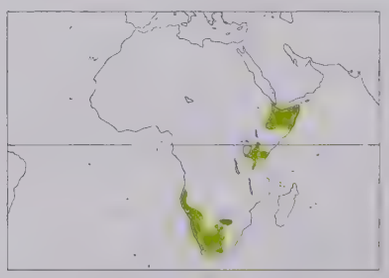
Descriptive notes. c. 20 cm; 64-80 g. Upperparts and breast light brown; crown bright rusty, black line through eye, white supercilia meet on nape; upper belly rufous, bordered below by large dark brown patch between legs; lower belly white; black flight-feathers above contrast with brown coverts, underwing all dark; bill dark, paler at base, legs whitish. Smaller and darker than *C. cursor* and *C. rufus*, with rufous crown and nape and all dark secondaries; latter feature also separates from *C. coromandelicus*. Juvenile has buff crown; dorsal feathers edged black giving mottled effect; breast pale rufous; belly blackish.
Habitat. Mostly in savanna on farmland, short-grass areas, especially on recently burnt ground and airfields; in Kenya 80% of population occurs in non-arid habitats, avoiding significant overlap with *C. cursor*. May appear on burnt grassland in savanna within hours of the fire. Where range overlaps with *C. rufus*, latter also occupies more arid areas. Nests up to 2000 m; on migration regularly occurs up to 3000 m.
Food and Feeding. Insects, harvester termites (*Hodotermes mossambicus*), molluscs and occasionally seeds. Feeds by running in bursts and stopping to peck at prey on ground.
Breeding. Mostly in dry season: all months except Sept and Oct in Senegal; nests Feb-Jul in Nigeria; Apr-Oct in Zaire; Jun-Oct in Zambia, with a peak in Aug-Sept; Jul-Nov in Zimbabwe; May-Jan in South Africa. No nest or just a shallow scrape, often among antelope droppings, usually on recently burnt ground. Clutch 2 eggs; incubation by both sexes, period unknown. Chick mottled black, buff and rufous above; chin and throat whitish, breast dull rufous; bill blackish, legs slaty grey. Young cared for by both parents; fledging period unknown.
Movements. Mostly nomadic, though some populations possibly intra-African migrants, depending on rainfall; southernmost populations in South Africa usually present only Feb-Aug; some birds from Sahel may migrate to S Africa Mar-Jul; in parts of Zaire, present only Mar-Jun, and in Malawi and Zambia Apr-Nov; departs from Zimbabwe at onset of rains in late Nov or early Dec, though remains in W of the country throughout rains, moving only very locally. Present in Cameroon savannas Nov-Mar, arriving at beginning of dry season to breed. Much local nomadism governed by burning of grassy understorey of savannas. On playing fields in Ghana, Jul-Nov, in flocks of up to 27 birds, moving to open burnt grassland Jan-Mar. In Gambia, 30-40 birds around Yundum Airport, Jan-Feb 1976. Vagrant to Sierra Leone.
Status and Conservation. Not globally threatened. Commonest and most widespread courser in sub-Saharan Africa; its wide habitat tolerance and generalized habits make it the most adaptable of the African coursers.
Bibliography. Bannerman (1931, 1951), Benson & Benson (1975), Britton, P. L. (1980), Clancey (1984), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Ginn (1991), Ginn *et al.* (1989), Gore (1990), Grimes (1987), Irwin (1981), Lewis & Pomeroy (1989), Lippens & Wille (1976), Louette (1981), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Maclean & Kemp (1973), Nuttall & de Swardt (1993), Pinto (1983), du Plessis (1994), Short *et al.* (1990), Snow (1978), Steyn (1965), Urban *et al.* (1986).

5. Indian Courser

Cursorius coromandelicus

French: Courvite de Coromandel **German**: Koromandelrennvogel **Spanish**: Corredor Indio
Taxonomy. *Charadrius coromandelicus* Gmelin, 1789, Coromandel Coast, India.
Forms superspecies with *C. cursor*, *C. rufus* and *C. temminckii*, although first two taxa may represent a separate superspecies. Occasionally considered to include *C. temminckii*. Monotypic.
Distribution. Pakistan and parts of Nepal through most of India to dry parts of NW Sri Lanka, from N of Puttalam to Jaffna Peninsula; no recent records in Bangladesh.

Descriptive notes. 23-26 cm. Above sandy greyish brown with white uppertail; crown bright rufous bordered below by white supercilia meeting in V on nape and black stripe through eye to bill; breast and upper belly cinnamon-chestnut, bordered below by blackish band on lower belly; undertail white; above black primaries and outer secondaries contrast with grey-brown coverts; underwing dark greyish brown, primaries black, narrow white trailing edge; bill black, legs white. Differs from other *Cursorius* by white uppertail and black lores. Juvenile strongly barred and blotched dark brown and buff above; crown dark brown, flecked buff.
Habitat. Dry stony plains, salty wastes, waste and fallow land with scattered scrub, ploughed fields, overgrazed areas and bare pastures around villages. Avoids areas of heavy rainfall.
Food and Feeding. Beetles and their larvae, especially tenebrionids; grasshoppers, crickets and other insects, such as ants; small molluscs. Catches insects by running in fast spurts, stopping and dipping forward to peck at ground.
Breeding. Mar-Aug; mainly May in Sri Lanka; in Lower Sind, peak egg-laying in third week of Apr. Nest is shallow unlined scrape on bare ground. Usually 2 eggs, sometimes 3; incubation mostly performed by female, period unknown. Chick mottled ginger, creamy white and black above; below creamy white with ginger breast; legs greyish. Chicks tended by both parents, but mostly by female; fledging period unrecorded.
Movements. Mainly resident, but locally nomadic. In Lower Sind overlaps with *C. cursor*. During Sept and Oct, after monsoon, gathers in small flocks of up to 10 birds; also c. 40 birds counted in Jul in bare fields near Delhi. No vagrancy outside Indian Subcontinent.
Status and Conservation. Not globally threatened. Apparently still fairly common; able to survive even in regions where grazing livestock, jackals, dogs and crows are plentiful, so unlikely to suffer severe decrease in numbers in short or medium term.
Bibliography. Ali (1953, 1979), Ali & Ripley (1982), Ganguli (1975), Harvey (1990), Henry (1971), Inskipp & Inskipp (1991), Kotagamana & Fernando (1994), Phillips (1942, 1978), Ripley (1982), Roberts, T. J. (1991), Whistler (1949), Wijesinghe (1994).



Genus *SMUTSORNIS* Roberts, 1922

6. Double-banded Courser

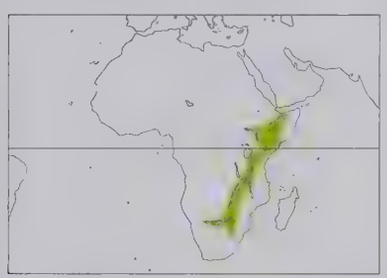
Smutsornis africanus

French: Courvite à double collier **Spanish**: Corredor Escamoso Chico
German: Doppelband-Rennvogel
Other common names: Two-banded Courser

Taxonomy. *Cursorius africanus* Temminck, 1807, Namaqualand. Often included in *Rhinoptilus*, sometimes in *Cursorius*, but probably merits its own monotypic genus. Alternatively, present species and *R. cinctus* have been placed in *Hemerodromus*. Birds from C Tanzania sometimes separated from *gracilis* as race *illustris*; race *sharpei sometimes* considered synonymous with nominate. Eight subspecies recognized.
Subspecies and Distribution.
S. a. raffertyi (Mearns, 1915) - E Ethiopia, Eritrea and Djibouti.
S. a. hartingi (Sharpe, 1893) - SE Ethiopia (Ogaden) and Somalia.
S. a. gracilis (Fischer & Reichenow, 1884) - Tanzania and Kenya.
S. a. bisignatus (Hartlaub, 1865) - SW Angola.
S. a. traylori (Irwin, 1963) - Etosha region of Namibia to Makgadikgadi system of Botswana.
S. a. sharpei (Erlanger, 1905) - C Namibia.
S. a. africanus (Temminck, 1807) - SW & C Kalahari, N Cape Province and S Namibia.
S. a. granti (W. L. Sclater, 1921) - W Cape Province and Karoo.

Descriptive notes. 20-24 cm; 69-104 g. Overall buff-brown; crown and back have boldly scaled appearance because of dark brown centres and broad pale fringes to all feathers; neck lightly streaked blackish; two well defined black breast bands round onto mantle; rest of underparts unstreaked, shading to whitish undertail; uppertail white; tail black; outer primaries black, inner primaries and all secondaries bright rusty cinnamon; short bill black; legs white. Plumage variable individually and seasonally. Differs from other coursers by double breast band, scaly upperparts and cinnamon flight-feathers. Juvenile similar to adult, but upperpart feathers have narrower fringes; lacks breastbands until 3 months old. Although basic coloration variable, races defined on basis of general darkness or paleness, with sandiest birds in N, through greyer, paler birds, to buffy brown birds in S of range; also slight size differences, central races smallest, southern largest.
Habitat. Stony and gravelly semi-desert with scattered low shrubs, overgrazed grassland and karoo, edges of dry clay-pans; patches of dry red sandy soils with low green vegetation and white grass tufts

c. 30 cm tall in Somalia; grassland and bushy grassland in E Africa, especially dry alkaline flats, sandy and short-grass plains. Generally uncommon or absent from sandy semi-desert, such as Kalahari, where confined to clay-pans and exposed stony ground. Occurs up to 1800 m in Tanzania and Kenya.
Food and Feeding. Insects, especially harvester termites (*Hodotermes mossambicus*). Feeds by pursuing prey during fast run, stopping and pecking at it on ground; does not dig. Largely nocturnal, also feeding at dawn and dusk.
Breeding. Feb-Jul in Somalia (mainly May-Jun); in E Africa, season varies with rainfall; all months in S Africa with peak in Oct-Nov; most nesting in dry months; usually 2-3 broods per year. No nest or just shallow scrape ringed with small stones, usually among antelope droppings, on bare ground in open semi-desert with good all-round visibility. Clutch 1 egg; incubation 26-27 days by both sexes. Chick mottled above with black and reddish brown, with pattern of white patches each bordered in black; below off-white, washed brownish in centre of breast; bill black; legs blue-grey. Young fed by both parents; fledging 5-6 weeks. Hatching success apparently high: in one study only 4 out of 56 eggs definitely failed to hatch.
Movements. Chiefly resident, but locally nomadic throughout range; movements governed by changes in vegetation: when ground cover too dense or too tall, or both, moves away to drier, more open areas.
Status and Conservation. Not globally threatened. Usually fairly common, but easily overlooked because of partly nocturnal habits; most populations probably stable. In South Africa, overgrazing by domestic stock may have allowed extension of range eastwards into grasslands; species adapts well to most livestock farming practices. Locally numerous in E Africa.
Bibliography. Archer & Godman (1937-1961), Beven & Chiazzari (1943), Britton, P. L. (1980), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Ginn *et al.* (1989), Lewis & Pomeroy (1989), Macdonald (1957), Mackworth-Praed & Grant (1957, 1962), Maclean (1967, 1970b, 1993), Pinto (1983), du Plessis (1994), Robertson, P. (1992), Short *et al.* (1990), Urban *et al.* (1986), Uys & Underhill (1977).



Genus *RHINOPTILUS* Strickland, 1852

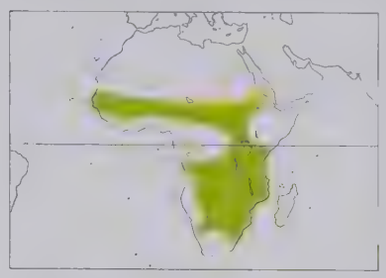
7. Three-banded Courser

Rhinoptilus cinctus

French: Courvite à triple collier **German**: Bindenrennvogel **Spanish**: Corredor Escamoso Grande
Other common names: Heuglin's/Seebohm's/Treble-banded Courser

Taxonomy. *Hemerodromus cinctus* Heuglin, 1863, near Gondokoro, White Nile.
Sometimes placed in *Cursorius*; alternatively, along with *Smutsornis africanus* in *Hemerodromus*. Race *emini* may be better merged with nominate *cinctus*. Three subspecies recognized.
Subspecies and Distribution.
R. c. cinctus (Heuglin, 1863) - SE Sudan, E Ethiopia, Somalia and N Kenya.
R. c. emini Zedlitz, 1914 - S Kenya, Tanzania and N Zambia.
R. c. seebohmi Sharpe, 1893 - extreme S Angola and N Namibia to S Zambia, Zimbabwe and extreme N South Africa; possibly also N Malawi.

Descriptive notes. 25-28 cm; 122-142 g. Above dark brown, boldly scaled rich buff; broad pale supercilia, buff in front of eye, white behind eye, meet as V on nape; ear-coverts rufous; uppertail white; tail dark brown, outer feathers white with darker bars; underwing largely white with black tip; underparts white with elaborate pattern of stripes and bands: chestnut band extends from ear-coverts to upper breast; lower breast pale rufous, boldly streaked with black and bordered with black, white and chestnut bands below; black stripe down sides of hindneck meets on top of broad rufous breast band; bill black at tip, yellow at base; eye-ring yellow to whitish; legs pale yellow. Complex face and neck pattern, with patterned upperparts, immediately separate from similar species. Juvenile similar to adult, but bands on breast fainter or absent. Racial separation on size, from largest in S to smallest in N, and richness of coloration, especially of upperpart feathers.
Habitat. Open sandy clearings in dry *Acacia* scrub in Somalia and S Sudan; thorn-scrub, bushland and bushy grassland in E Africa, including miombo (*Brachystegia*) woodland; sparse mopane (*Colophospermum mopane*) woodland with bare ground in S Africa.
Food and Feeding. Very poorly known. Probably feeds entirely on insects caught during ground pursuit. Largely nocturnal.
Breeding. Mar-Jul in Somalia; Jan-Aug in Ethiopia; variable according to rainfall in rest of E Africa, mostly in dry season; May-Aug in Zambia; Mar-Nov (mainly Aug-Oct) in Zimbabwe; at least sometimes double-brooded. Nest is a deep scrape filled with sandy soil in which eggs almost completely buried, even during incubation; usually placed under shady tree or bush. Clutch 2 eggs; incubation c. 25-27 days. Chick mottled tan and pale grey above with sparse black blotches; below whitish; bill blackish; legs and feet grey. Fledging period unknown.
Movements. Largely resident; may undertake local movements, but is probably not long distance migrant. Absent from Zimbabwe Dec-Mar. Small influx to E Botswana in 1993/94 following wet summer. Occasional sightings outside main range.
Status and Conservation. Not globally threatened. Widespread and common in Kenya and Tanzania; abundant in open areas of *Acacia* in Sabi valley, Zimbabwe. Range in S Africa restricted to mopane woodland and therefore potentially in need of protection, though several game reserves in mopane country appear to offer sufficient protection at present.
Bibliography. Archer & Godman (1937-1961), Benson & Irwin (1967), Benson & Pitman (1964), Brewster (1994), Britton, P. L. (1980), Cassidy *et al.* (1984), Cave & Macdonald (1955), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Dowsett *et al.* (1977), Érard *et al.* (1993), Ginn *et al.* (1989), Irwin (1981), Kemp & Maclean (1973), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957, 1962), Maclean (1993), Maclean & Kemp (1973), Medland (1989a), Pinto (1983), Short *et al.* (1990), Urban *et al.* (1986).



8. Bronze-winged Courser

Rhinoptilus chalcopterus

French: Courvite à ailes bronzées **German**: Amethystrennvogel **Spanish**: Corredor Patirrojo
Other common names: Violet-tipped Courser

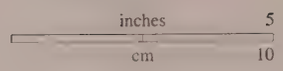
Taxonomy. *Cursorius chalcopterus* Temminck, 1824, Senegal. Sometimes included in *Cursorius*. Probably closest to *R. bitorquatus* of India with which may form superspecies; shares similar lightly wooded habitat. Birds from Tanzania S to South Africa sometimes racially separated as *albofasciatus*. Monotypic.

Distribution. Senegal across Sahelian region to S Sudan and W Ethiopia, thence S to Kenya, Tanzania, S Zaire and Angola, and to N & E parts of South Africa.

Descriptive notes. 25-29 cm; 117-172 g. Largest courser. Upper breast and upperparts dull greyish brown; white uppertail; tail dark brown fringed white; breast bordered below by black band; rest of underparts, forecrown, supercilium, line from behind eye, and sides of throat and upper neck cream or white; ear-coverts and lores dusky; primaries black, tipped iridescent purple to copper; underwing-coverts white, contrasting with black primaries and broad trailing edge to secondaries; bill black with purplish red base; large eye; eye-ring purplish red; legs dull red. Large size, plain dull upperparts, and distinctive head pattern separate from other coursers. Iridescent primary tips, visible only in flight, and hard to see; when flying away, superficially recalls lapwing (*Vanellus*). Juvenile duller; dorsal feathers tipped buff; black breast band narrower.
Habitat. Dry savanna woodland and thick bush, especially on recently burnt ground; occurs in less open situations than *R. cinctus*; more rarely in open grassland bordering wooded savanna. In Kenya, over 70% of records in rainfall range of dry sub-humid to semi-arid; mostly found at lower elevations.
Food and Feeding. Very little information available. Probably entirely insects, such as grasshoppers, caught on ground. Strictly nocturnal, feeding by night with plover-like action.
Breeding. Feb-Mar in Nigeria and Uganda; in E Africa variable according to rainfall; Jul-Dec, especially Sept-Oct, from Malawi to South Africa; mostly breeds in dry season. Usually makes no nest, but sometimes a bare scrape on ground. Clutch 2-3 eggs; incubation 25-27 days, by both sexes. Chick mottled black and rufous above with white nape; below white; bill black; legs dark grey. Chick cared for by both parents; fledging period unknown.
Movements. Probably an intra-African migrant that moves N after breeding. In Nigeria, undertakes seasonal movements, but not well understood; recorded in Ghana from Dec to mid-May; moves N in Sudan to breed before rainy season. In E Africa, movements not understood, but may include non-breeding visitors to Kenya from S tropics, mostly Dec-May; in Zaire, absent May-Jul in NE, present in S in dry season May-Nov, with marked passage in Apr and May. Present in Botswana Sept-Apr; influx to E Botswana Jan-Mar 1994, following wet summer. Influx to Zimbabwe between Apr and Jun after rains. Overwinters locally in South Africa. Sometimes in small parties, e.g. 10 together in Gambia in Dec 1975.
Status and Conservation. Not globally threatened. Nocturnal, so numbers often underestimated; probably fairly uncommon throughout range, but difficult to assess; most protection afforded by game and nature reserves in suitable habitat, because sensitive to human disturbance in farming areas. Often killed by traffic on dirt roads at night.
Bibliography. Bannerman (1931, 1951), Benson & Benson (1975), Brewster (1994), Britton, P. L. (1980), Crowe (1993), Dowsett & Dowsett-Lemaire (1980, 1993), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Freer (1981), Ginn *et al.* (1989), Gore (1990), Irwin (1981), Lewis & Pomeroy (1989), Lippens & Wille (1976), Macdonald (1957), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Pinto (1983), Pitman (1932a), Short *et al.* (1990), Snow (1978), Urban *et al.* (1986), Verschuren (1977), Wilson (1977).

9. Jerdon's Courser

Rhinoptilus bitorquatus



French: Courvite de Jerdon **German**: Godavarirennvogel **Spanish**: Corredor del Godavari
Other common names: Double-banded Courser(!)

Taxonomy. *Macrotarsius* [sic] *bitorquatus* Blyth, 1848, Eastern Ghats, Andhra Pradesh, India.
Sometimes included in *Cursorius*. Probably most closely related to *R. chalcopterus* of Africa, with which may form superspecies; shares similar lightly wooded habitat. Monotypic.
Distribution. Limited to Pennar and, formerly, Godavari Valleys in Andhra Pradesh, EC India.

Descriptive notes. c. 27 cm. Crown and hindneck dark brown with whitish crown stripe; broad white supercilia sometimes meet as V on nape, tinged cream in front of eyes; rest of upperparts and broad breast band pinkish sandy brown; brown breast bordered above and below by narrow dusky band; chin and throat white with broad rufous patch on foreneck; white band across lower breast bordered below by narrow dusky band; rest of underparts mainly white; upperwing-coverts edged white; flight-feathers black with white patches at wingtips on outermost 3-4 primaries; underwing-coverts mainly creamy white, with patch of black and rufous at bend of wing; tail black with white base; bill black with yellow base; legs yellowish white. Only courser with white in wing tips; head and neck pattern distinctive. Juvenile plumage undescribed.
Habitat. Rocky undulating land with thin forest and scrub jungle. Prefers bare, grassless patches of open ground amidst scrub bushes, in zone between denser forests and areas of human impact. Never in areas of cultivation or near artesian wells. Hides among thorny *Carissa* bushes, about 50 cm tall.
Food and Feeding. Virtually nothing known. Feeds at night, presumably on insects.
Breeding. No authentic information available. Supposed clutch of 2 eggs claimed to have been taken in 1895.
Movements. Rather rounded wing suggests species is sedentary. However, according to local *shikari*, seen mainly during rainy season in flocks of 7-8 birds. Only ever recorded in two river valleys c. 400 km apart.
Status and Conservation. ENDANGERED. Until very recently, considered Extinct. Rediscovered in Jan 1986 after a year-long survey by Bombay Natural History Society: two surveys earlier this century in Eastern Ghats had drawn a blank. Perhaps one of the world's rarest birds and distinctly in danger of extinction; until its rediscovery, had not been seen since 1900, and prior to that only in c. 1848 and 1871; three living birds rediscovered at Reddipalli, near Cuddapah, in scrub forests below Lankamalai Hills in valley of R Sagileru, Pennar Valley, S Andhra Pradesh. Recent records now from 6 sites in vicinity of Lankamalai ranges. Total area of suitable habitat within known range only 2000 km². Species rediscovered just in time, as planned irrigation scheme passing through site was then diverted, following conservation pressure. Considerable progress made in protection of habitat: forest near Cuddapah where bird rediscovered designated as Sri Lankamalleswara Wildlife Sanctuary, and local tribespeople employed to warden sanctuary; a further reserve of 500 km² has been designated further S, and another of 1300 km² to SE also planned. Habitat under grazing pressure, though some grazing or other habitat management may be necessary to maintain scrub patches. Also threat from needs of local villagers; species apparently extremely sensitive to human disturbance. May still occur in Godavari Valley, N Andhra Pradesh; conceivably also awaits discovery in Maharashtra, Madhya Pradesh and Tamil Nadu.
Bibliography. Ali & Ripley (1982), Anon. (1986), Bhushan (1985, 1986a, 1986b, 1990, 1992a, 1992b), Collar & Andrew (1988), Collar *et al.* (1994), Ripley (1982), Ripley & Beehler (1989), Shuker (1993).

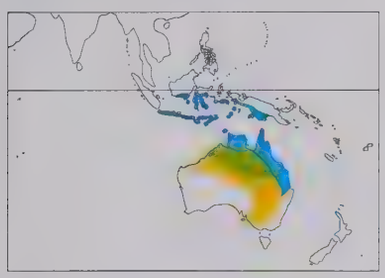
17

Subfamily GLAREOLINAE



Genus *STILTIA* G. R. Gray, 1855

10. **Australian Pratincole**

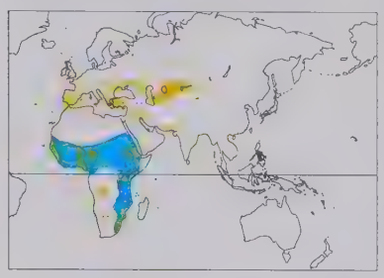
Stiltia isabella

French: Glaréole isabelle **German**: Stelzenbrachschwalbe **Spanish**: Canastera Patilarga
Other common names: Australian Courser, Long-legged/Isabelline Pratincole

Taxonomy. *Glareola isabella* Vieillot, 1816, "Australasie".
Forms apparent link between coursers and pratincoles. Sometimes included in genus *Glareola*, or at other extreme in its own subfamily Stiltiinae. Monotypic.
Distribution. Drier regions of N & E Australia, spreading further S in wetter years, but absent from SW; breeds sporadically throughout Australian range, but seldom N of 18° S; two breeding records in Trans-Fly, S New Guinea. Migrates to N Queensland and Northern Territory, New Guinea and E Indonesian archipelago as far NW as S Borneo.

Descriptive notes. 21-24 cm; c. 65 g. Above light cinnamon brown, with white rump; black lores, throat whitish shading to pinkish cinnamon breast and deep chestnut across belly; vent and undertail white; tail square, white with large black central patch; underwing black with silvery grey secondaries and inner primaries; wings extremely long, slender and pointed, with black primaries, outermost elongated, extending well beyond tail when standing; bill scarlet with black tip; long legs greyish brown, extend well beyond tail in flight. Long wings and legs and short tail make this pratincole unmistakable. Non-breeding adult duller; lacks dark lores, and chestnut of belly divided. Juvenile has bill duller red, mantle feathers edged buff, outer primary not elongated. First non-breeding plumage darker above, neck and breast streaked brown.
Habitat. Rather bare areas: blacksoil country of Queensland with sparse grass, scrubby redsoil ridges, gravel plains, gibbers, open plains with limestone or ironstone pebbles and scattered low shrubs, airfields, open shorelines of lakes, lagoons and rivers. Seldom far from water. Also occurs in harvested or fallow rice fields, when not breeding. In Papua New Guinea, recorded from sea-level up to 1740 m.
Food and Feeding. Grasshoppers, beetles, dragonflies, termites and other large insects; also centipedes, spiders and seeds. Obtains most of prey on ground, but also forages in flight; runs swiftly on ground after insects, sometimes stopping prey with outstretched wing and quick forward lunge with bill; aerial prey may be hawked from ground, birds leaping or flying up to catch single items before returning to ground; also hawks high in air. Needs to drink frequently.
Breeding. Dependent on weather; Aug-Jan, but most breed Sept-Nov. Nests in small, loose colonies, nests spread thinly over as much as 2 km² of open ground. Nest on bare, stony ground; rarely a shallow scrape, site often ringed with small stones and dry plant material, usually within 2 km of water. Usually 2 eggs, occasionally 1-3; incubation 18-21 days, by both sexes. Chick weighs c. 5 g; clay-buff above with pattern of sooty black; faint tan stripe in centre of forehead and tan patches on wings; below pale honey-coloured, shading to white on belly; bill black with pink on lower mandible; legs pinkish grey. After hatching, young may use a rabbit burrow as refuge from danger, or shelter under shrub or tussock; young fed and brooded by both parents; broken-wing display by adults at nest; fledging c. 3-4 weeks, up to 5. Main cause of nesting failure is predation by ravens, introduced foxes, snakes and lizards.
Movements. Movements influenced by rainfall patterns, with reports of greatly increased numbers arriving in S Australia to breed in unusually wet years, when range extends further SW. Occurs in southern half of Australia mostly in austral spring and summer; most numerous in New South Wales in Oct-Feb. Only two breeding reports N of Australia, from Trans-Fly region of New Guinea. Migrates N as far as New Guinea, and W to Sulawesi, Borneo, Bali and Java; arrives at Darwin, Northern Territory, between Apr and Jun, and departs in Nov and Dec; in Papua New Guinea, occurs Mar-Dec, mostly May-Nov.
Status and Conservation. Not globally threatened. Common to abundant, but sporadic in occurrence; probably not under threat in any part of range; total Australian, and therefore world, population estimated in 1993 at 60,000 birds; also a report of 50,000 birds on Timor, E Indonesia, in Nov. Flocks of 700-800 birds commonly seen outside breeding season; many thousands noted in late dry season in R Bensbach area, Papua New Guinea; more than 12,000 recorded immediately inland from Gulf of Carpentaria, Northern Territory, in mid-May. Throughout Sept, flocks of up to 50 birds at a time arrive to breed, totalling about 1000 birds per day; New South Wales population estimated at 5000 birds. Most birds in N Australia, where human population sparse, so no immediate threat. Species may be hunted in Indonesia.

(1985, 1988), Blakers *et al.* (1984), Bravery (1962), Bruce (1987), Campbell (1985), Chaffer (1949), Christian *et al.* (1992a), Coates (1985), Cumming (1981), Fergenbauer-Kimmel (1992), Hoogerwerf (1964), Hopkins (1976), Jaensch (1983a), Jesson & Maclean (1976), Judin (1981), Klapste (1977), Lane & Davies (1987), Liddy (1959), Macdonald (1988), MacGillivray (1924), MacKinnon & Phillipps (1993), Maclean (1973, 1976a), Marchant & Higgins (1996), North (1913-1914), Pringle (1987), Rand & Gilliard (1967), Smith, P. (1991), Smythies (1981), White & Bruce (1986).



Genus *GLAREOLA* Brisson, 1760

11. **Collared Pratincole**

Glareola pratincola

French: Glaréole à collier **German**: Rotflügel-Brachschwalbe **Spanish**: Canastera Común
Other common names: Red-winged/Common Pratincole, Swallow-plover

Taxonomy. *Hirundo Pratincola* Linnaeus, 1766, Austria.
Forms superspecies with *G. maldivarum* and *G. nordmanni*, although range overlap with latter leads some authorities to exclude that species from the superspecies. Formerly considered to include *G. maldivarum*, and even on occasion *G. nordmanni*, as races. Has hybridized with *G. nordmanni*. Possible race *boweni* of W Africa included in *fuelleborni*; form "*limbata*", described from Red Sea coasts, appears to be erroneous. Species has on occasion been regarded as monotypic. Three subspecies normally recognized.
Subspecies and Distribution.
G. p. pratincola (Linnaeus, 1766) - S Europe to Pakistan; winters in sub-Saharan Africa, N of 5° N.
G. p. erlangeri Neumann, 1920 - coastal plains of S Somalia and N Kenya.
G. p. fuelleborni Neumann, 1910 - Senegal E to S Kenya and S to Zaire, Namibia and E South Africa.

Descriptive notes. 22-25 cm; 60-95 g. Above brown, tinged olive, with white rump; long wingtips and deeply forked tail black; throat ochre yellow, bordered narrowly with black; breast brown shading to white belly; underwing-coverts and axillaries deep rich chestnut; narrow but distinct white trailing edge to secondaries; bill red with black tip, legs blackish. In non-breeding plumage black border to throat indistinct, lores paler and breast mottled grey-brown. Differs from *G. maldivarum* in longer tail, contrast from above between darker outer and paler inner wing, and white trailing edge; from *G. nordmanni* in last two features and also chestnut underwing. Juvenile mottled with black above and on breast; throat whitish without black collar. Races separated on small colour differences; African birds smaller and darker, not distinguishable in the field.
Habitat. Flat and open areas, fields, steppe plains in Eurasia, usually near water; in Africa open ground, often recently burned, overgrazed grassland, ploughed fields, alkaline flats or sandflats, usually near water, especially along larger rivers and estuaries. Feeds over water, rice fields or coastal scrub. On migration, occurs by water.
Food and Feeding. Locusts and grasshoppers, beetles, termites, flies and other, mainly large, insects; also some spiders and molluscs. Forages in flocks, chiefly on the wing, catching aerial insects in graceful flight, often at dawn and dusk, sometimes on moonlit nights; also chases prey with fast run on ground; leaps up to catch ephydrid flies along lake shoreline 10 cm above ground.
Breeding. May-Aug in Europe; May-Jun in Jordan; Apr-Jul Pakistan; in Africa, Mar-May in Sierra Leone, Apr-Jun in Nigeria, Apr-Sept (wet season) in Kenya, Uganda and NE Tanzania, Jun-Sept (dry season) elsewhere in Tanzania after floodplains have dried out, Apr-Jun in N Zaire, Jul-Nov in S Zaire and Zambia, Aug-Oct in Zimbabwe, Nov-Dec in Botswana, Aug-Dec in South Africa. Colonial nester in small groups of 10 or 20, up to 100 pairs, on dry mudflats or sandflats; sometimes forms mixed colonies with *G. nordmanni*. Nest is usually a shallow scrape or natural depression in ground, such as a hoofprint, in Africa often next to piece of driftwood or plant, sometimes lined with dry plant fragments; each pair defends small nesting territory within colony. Usually 3 eggs (2-4) in Eurasia, 1-2 eggs in Africa; incubation 17-19 days, by both sexes. Chick mottled above with charcoal and black; below white. Young leave nest at 2-3 days; fed by both parents by regurgitation or by presentation of food in bill tip, up to age of 7 days old; fledging 25-30 days. Comparison in Spain of breeding success in marshland and farmland found success much higher in former, despite equal amounts of insect food in both; however, egg losses during incubation much higher on farmland due to agricultural activities. Probably first breeding at one year old.
Movements. Nominate race migrates after breeding to savannas of Sahel, where probably overlaps with birds of race *fuelleborni* in N tropics. Southward passage migrant in Israel mainly in Aug and early Sept, moving N again in Apr and early May; common passage migrant through W Saudi Arabia, mainly around inland fresh waters; present in Pakistan Mar-Aug; some movement from Pakistan to W India, where species mingles with *G. maldivarum*; vagrancy recorded to most European countries N of breeding range. Many African populations nomadic, appearing and disappearing suddenly, often in response to changing water levels; may occur together with *G. nordmanni*; large numbers in Zambia in dry season, Apr-Nov. Flocks of 1000 or more birds regularly occur on migration; 30,000 birds noted moving N at Juba, S Sudan (4°52' N) in early Apr, 1983, though not clear whether these were all Palearctic breeders, as this race thought not to winter so far S.
Status and Conservation. Not globally threatened. Overall decline in range and numbers in Europe. Total of 6700-22,000 pairs breeding in Europe: largest populations are 1000-10,000 pairs in Russia, 500-1000 pairs in Greece, 500-5000 pairs in Turkey, c. 3800 pairs in Spain (fluctuating c. 3500-5000), and 250-1000 pairs in Portugal. As many as 10,000 pairs estimated in Guadalquivir Marshes, S Spain, as recently as early 1960's; use of insecticides and herbicides caused reduction in population to c. 2250 pairs in 1990, though this is still the most important site in Europe, current threats being changes in water levels and human disturbance. In SE Europe, many sites of former breeding colonies destroyed through ploughing of grasslands, artificial irrigation and fertilization, use of pesticides, change in traditional grazing regimes, and commercial collecting of eggs. In addition to habitat loss and degradation through agriculture and flood control measures, increasing urban encroachment is also a threat, especially through tourist pressure. Important colonies need protection, perhaps through establishment of reserves; measures also needed to reduce disturbance by agriculture and leisure activities. Decline in Ukraine from 3000 pairs in mid-1960's to 280-420 pairs in 1984; on N coast of Sea of Azov, Ukraine, colonization took place in 1950's, replacing *G. nordmanni*; numbers fell sharply in 1970's and early 1980's; breeding success very low owing to nests being trampled by cattle and preyed upon by Hooded Crows (*Corvus corone cornix*). Small numbers N of Caucasus; c. 500 pairs in Azerbaijan; range expansion further E in Chu Valley, Kyrgyzstan. Population of SW Asia numbers 10,000-100,000 pairs. Trends in E Palearctic not known. In N Africa, 200-300 pairs in Morocco, 200-250 pairs in Algeria, 1000-1500 pairs in Tunisia, and more than 1000 pairs in salt-marshes of Nile Delta, Egypt. Has become very uncommon in Israel, populations having declined by c. 90% since 1930's because of spraying with agricultural pesticides in species' nesting habitat of cultivated fields. Counts in sub-Saharan Africa include flocks of 3000 in Nigeria in Nov 1969; up to 100 together in S Somalia; 1500 in rice fields to N of L Maga, Cameroon, in 1991; 10,000 present along just 5 km (10%) of shore of L Ngami, NW Botswana, Nov 1989, some nesting; several thousand throughout Jun 1993 along R Chobe, Caprivi Strip, border of NE Namibia and N Botswana; up to 3000 wintering on R Baro, Sudan, along with *G. nordmanni*. Widespread decline of this and other insectivorous species through increased use of pesticides, both in Europe and in Sahelian wintering grounds; also, water management projects in Sahel are changing the habitat.

12. Oriental Pratincole

Glareola maldivarum

French: Glaréole orientale **German**: Orientbrachschwalbe **Spanish**: Canastera Oriental
Other common names: Eastern (Collared)/Large Indian Pratincole

Taxonomy. *Glareola (Pratincola) Maldivarum* J. R. Forster, 1795, open sea in the latitude of the Maldive Islands. Forms superspecies with *G. pratincola* and *G. nordmanni*, although some authorities exclude latter from the superspecies. Formerly included in *G. pratincola*. Monotypic.

Distribution. Extreme S Siberia, NE Mongolia and S Manchuria, S to N India, Sri Lanka, Thailand and SE Asia; also locally in W Japan and Ryukyu Is; has bred in Pakistan, Philippines and Borneo. Winters from India and SE Asia through Indonesia and New Guinea to Australia.

Descriptive notes. 23-24 cm; 87 g. Above olive brown, with white rump; throat ochre yellow, edged with narrow black collar; upper breast brown, shading to rufous and then white on belly and undertail; flight-feathers black, underwing chestnut; forked tail black, white at base; bill black with red gape; legs blackish. Collar indistinct in non-breeding plumage. Differs from *G. pratincola* in shorter tail, uniform upperwing lacking contrast between inner and outer wing, and lack of white trailing edge; from *G. nordmanni* by shorter tail and chestnut underwing-coverts. Juvenile mottled black and buff above.

Habitat. In Asia inhabits steppes, open grassland, dry floodplains, tidal mudflats, rice stubble, ploughed and fallow fields and open pastures, usually near water. In Australia, open grassy plains, clay-pans, muddy wetlands and airfields; occasionally found on beaches and intertidal mudflats.

Food and Feeding. Insects and other terrestrial arthropods, especially grasshoppers, crickets and beetles; also, in non-breeding quarters, winged termites which may emerge in large numbers before rain. Prey caught mainly in flight but some also on ground, e.g. shore-flies (Ephydridae); attracted to bush fires. Often crepuscular.

Breeding. Apr-Jun. Nests in colonies on open plains, often after recent grass fire; also on grassy islands in rivers with River Terns (*Sterna aurantia*). Nest is a shallow scrape or dried hoofprint. Clutch 2-3 eggs; incubation and fledging periods unknown, but probably similar to those of *G. pratincola*.

Movements. NE populations are long distance migrants S to winter Oct-Apr mainly in SE Asia, Indonesia and Australia; birds return N to breed in E Asia from May to about Aug. Most of Indian breeding population resident, locally nomadic, or short distance migrants. Rare but annual, Oct to late Mar, in New Guinea; birds overfly to N Australia Dec-Feb, when absent to N, therefore large portion of migratory population may be in Australia at this time. Late arrival in Australia: from Nov in Darwin area after local wet season starts; nomadic in Australian summer, following insect populations; departs from Darwin and NW Australia by first week in Apr. Common on migration in C & NE China, especially during S migration, Jul-Sept; passage Hong Kong Sept-Oct and again Mar-May. Up to 1500 birds recorded together, Malay Peninsula, on migration; arrives Thailand in Feb, most birds departing Aug-Sept, with few overwintering perhaps irregularly. Generally uncommon migrant to Japan, mostly in Aug-Sept, with maximum of 306 birds in 1984; now also breeds locally in W Japan. Uncommon visitor to W Micronesia. Vagrant to New Zealand, Seychelles and Mauritius, Arabian Peninsula, England, Cyprus and Attu I (Aleutians).

Status and Conservation. Not globally threatened. Numbers in winter in Indian Subcontinent in broad range of 25,000-1,000,000 birds; in rest of winter distribution, from SE Asia to Australia, population probably in range 100,000-1,000,000. Large numbers reported in Java; 300 in Bali, Nov-Dec 1983. Total of 50,000 winter in Australia, with several high counts from Western Australia including: 10,000 at Port Hedland Saltworks; 4000 on Pilbara Coast; flock N of De Grey River in Mar 1980, stretched for c. 300 km, at density of 10-50 birds/km along road at night. Largely crepuscular, sluggish by day, so numbers can be underestimated. Favours open grassy plains away from coast in N Australia so rarely counted; however, there is no immediate threat to this habitat. Appears to survive well even in areas of fairly heavy overgrazing by domestic stock, so unlikely to be threatened, though any intensive agricultural development over a wide area may have an impact. Probably declining in some areas; in NC Java large numbers are killed each year by hunters.

13. Black-winged Pratincole

Glareola nordmanni

French: Glaréole à ailes noires **Spanish**: Canastera Alinegra
German: Schwarzflügel-Brachschwalbe

Taxonomy. *Glareola Nordmanni* Fischer, 1842, steppes of southern Russia.
Forms superspecies with *G. maldivarum* and *G. pratincola*, though range overlap with latter causes some authorities to exclude present species from the superspecies. At one time erroneously regarded as colour morph of *G. pratincola*, with which has been known to hybridize; also, on occasion, considered a race of *G. pratincola*. Monotypic.

Distribution. Romania, E through Ukraine to SW Russia and N Kazakhstan. Winters in S Africa and, more irregularly, in W Africa.

Descriptive notes. 23-26 cm; 84-105 g. Above brown with olive tinge, and white rump; flight-feathers and deeply forked tail black; throat ochre yellow with narrow black border; breast brown, shading to white belly; bill black with red at base, legs blackish. Black border to throat indistinct in non-breeding plumage. Separated from *G. pratincola* by black underwing-coverts, lack of white trailing edge to wing, darker, more uniform upperwing, and less red on bill; from *G. maldivarum* by black underwing-coverts, and longer tail. Juvenile mottled blackish above and on breast; throat dull whitish without black collar; may show few chestnut tips to underwing-coverts.

Habitat. In Eurasian breeding areas inhabits saline and alkaline steppes, grassland, ploughed and arable land, in river valleys and along shorelines of lakes or seas. Prefers saline soil with sparse vegetation; always with water or wet meadows nearby; tolerates taller and denser vegetation than *G. pratincola*. Non-breeding birds frequent open high altitude grassland or low-lying mudflats.

Food and Feeding. Locusts, grasshoppers, crickets and beetles, also flying ants, termites, wasps, bees, dragonflies, flies and other insects. Forages mainly on the wing, often in flocks of hundreds or even thousands of birds, especially when locusts are swarming; also feeds on ground by running swiftly after prey; usually hunts in early morning and late evening, often after dusk.

Breeding. May-Jul in Black Sea region. Nests in loose colonies of several tens or hundreds of pairs on open ground, usually near water, often with other Charadrii; occasionally several thousand in colony; sites may move from year to year, even when still apparently suitable. Nest is a simple scrape, sparsely lined with dry plant pieces. Clutch 3-4 eggs; incubation by both sexes, period unrecorded. Chick similar to that of *G. pratincola*, but somewhat darker. Young independent at 5-6 weeks. Breeding success has decreased with predation by Rooks (*Corvus frugilegus*) attracted by plantation of shelter-belts in steppe; in one study, grazing pressure resulted in destruction of 50% of chicks and 30% of nestlings; heavy rain and drought may also affect breeding success.

Movements. Long distance migrant from Eurasia to W & S Africa, chiefly South Africa, Namibia and Botswana, Sept-Apr; nomadic in winter range following swarming insect prey. On passage in Sudan, W Kenya, W Uganda, Zaire, Angola, W Zambia, but seldom in Malawi and Zimbabwe; thousands of birds pass southward through Zaire in Oct, and northward again in Mar. In W Africa, flocks of up to 200 birds in Nigeria, Sept and Dec-Apr. Arrival in breeding areas usually Apr-May, departure in Sept. Much migration at high altitude, so passage often not observed from ground. Rare passage migrant through Saudi Arabia, which species probably overflies; uncommon passage migrant through Israel along coastal plain, southward in Sept and Oct; also regular through Iran. Vagrant N and W to many European countries.

Status and Conservation. Not globally threatened. Has declined markedly and now considered near-threatened, requiring close monitoring of trends and numbers. Total world population now estimated at only 10,000-25,000 birds, and declining. Although non-breeding flocks may number hundreds of birds in S Africa, occurrence of large flocks in recent years sporadic: c. 10,000, with similar numbers of *G. pratincola*, at L Ngami, NW Botswana, in Nov 1989, along just 5 km of lake shoreline, largest recent documented count. On migration, flocks of 5000-10,000 noted in W Zambia in Oct-Nov 1966, and again in Mar 1967; up to 5000 birds with *G. pratincola* in 1970's in Dec and Jan on R Baro, Sudan; 400 Cyprus, Sept 1961; 230 in E Turkey, Sept 1968. In European breeding range population 6500-11,000 pairs, almost all now in European Russia, though still 40-100 pairs in Ukraine. In early 20th century flocks still numbered hundreds of thousands in Russian steppes. Sharp decline in numbers from 19th century in Romania and Ukraine. Has bred in Germany, occasionally in Hungary, and in Azerbaijan. Partial irrigation of dry steppes in Russia N of Caucasus may have allowed increased breeding numbers during second half of 20th century, reaching 5000-7000 pairs in mid-1980's, though by 1993 population had stabilized or started to decline. Population to E of R Volga appears to be fairly stable. Cause of overall decline appears to be cultivation of steppes in breeding areas; species may also be adversely affected by use of pesticides in Africa. Threatened not only by loss of steppe grassland, but also by agricultural operations such as harrowing and intensification of grazing, and predation by increasing numbers of corvids.

Bibliography. Ash (1977), Aspinwall (1977), Beaman (1994), Becker & Kollibay (1976), Belik, V. (1994a), Benson *et al.* (1971), van den Berg (1985), Britton, P. L. 14. Madagascar Pratincole

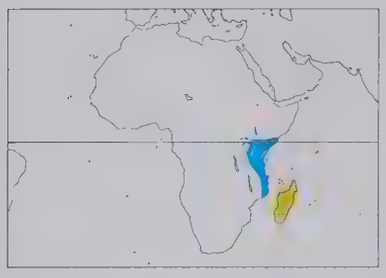
Glareola ocularis



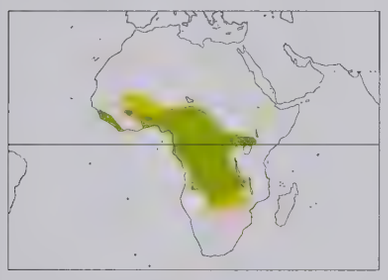
French: Glaréole malgache **German**: Madagaskarbrachschwalbe **Spanish**: Canastera Malgache

Taxonomy. *Glareola ocularis* J. Verreaux, 1833, Madagascar.
Monotypic.

Distribution. Madagascar, except extreme S & SW. Non-breeding visitor to E Africa from S Somalia to N Mozambique, mainly in coastal Kenya (dunes N of Malindi) and Tanzania.

Descriptive notes. 23-25 cm; 82-103 g. Above dark olive brown; forecrown dark chocolate brown; rump white; lores and ear-coverts blackish; short white line below and back from eye contrasts with dark crown; throat and breast brown, shading to dark rufous on upper belly and white on lower belly; flight-feathers black; shallowly forked tail mostly black with white sides; underwing-coverts pale chestnut with white spot near bend of wing; bill black with red base, legs greyish black. Differs from superficially similar *G. nuchalis* by much larger size, chestnut belly and underwing; darker than *G. pratincola*, especially on head, and shorter-tailed. Juvenile lightly scaled rufous above; paler below than adult, streaked rufous on breast; line under eye rufous.

Habitat. In Madagascar, breeds on rocky islets in permanent rivers and coastal waters. When not breeding, on African mainland, mainly coastal, on shores of lakes, sandbars in rivers and estuaries, short grasslands, estuarine flats, coastal dunes; forages over almost any habitat; often rests on offshore rocks or on open ground, including airfields.



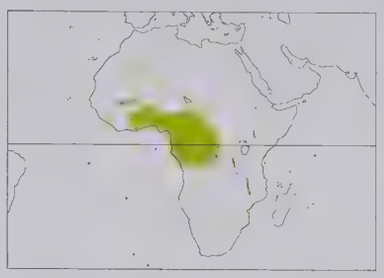
Food and Feeding. Mostly insects, including Hymenoptera, Neuroptera and beetles. Forages mostly in flight, in flocks, over grassland, beach, water or woodland; usually in late evening, but on overcast days, also during day.
Breeding. Poorly known. Early Nov. Small loose colonies on rocky islets in coastal waters and rivers. Nest is a hollow on the rock, sometimes lined with regurgitated insect exoskeletons. Clutch 2 eggs. No further information available.
Movements. After breeding, birds migrate to spend period Mar-Sept on E coast of Africa, from Mozambique N of R Zambezi to S Somalia; less often inland to L Victoria; S passage in Kenya most marked Aug-Sept; probably spends start of non-breeding season in Somalia before moving S along Kenya coast. Present in Madagascar mostly from Sept to Apr/May. Vagrant or scarce migrant to Mauritius, Reunion, Comores in Oct.
Status and Conservation. Not globally threatened. Fairly common, but poorly known. Non-breeding flocks on coast of Africa may number several hundred birds, but also flocks of 9000-10,000 birds on Kenya coast in Aug 1978, and 3000 S Somalia in May 1979 and Jul 1981. In Madagascar, flocks usually only of 10-50 birds, less often as many as 150 birds. Only apparently protected breeding sites are on granitic rocks off Special Reserve of Nosy Mangabe in NE Madagascar; other populations unprotected by legislation, but some security afforded by offshore inaccessibility.
Bibliography. Appert (1971), Ash (1977), Ash & Miskell (1989), Benson (1960, 1978), Benson *et al.* (1976-1977), Britton, P. L. (1977, 1980), Dee (1986), Dhondt (1975), Dowsett & Forbes-Watson (1993), Langrand (1990), Lewis & Pomeroy (1989), Louette (1981, 1988), Mackworth-Praed & Grant (1957, 1962), Milon *et al.* (1973), Nicoll & Langrand (1989), Short *et al.* (1990), Urban *et al.* (1986).

15. Rock Pratincole

Glareola nuchalis

French: Glaréole auréolée **German**: Halsband-Brachschwalbe **Spanish**: Canastera Sombría
Other common names: Collared Pratincole(!); Chestnut-collared/Rufous-collared Pratincole (*liberiae*); White-collared Pratincole (*nuchalis*)

Taxonomy. *Glareola nuchalis* G. R. Gray, 1849, Fifth Cataract of the Nile near Berber, Sudan.
Sometimes placed in *Galachrysia* with *G. cinerea* and *G. lactea*. Race *liberiae* sometimes considered a megasubspecies. Two subspecies recognized.
Subspecies and Distribution.
G. n. liberiae Schlegel, 1881 - Sierra Leone to W Cameroon.
G. n. nuchalis G. R. Gray, 1849 - Chad E to Uganda, extreme W Kenya and Ethiopia, and S to R Zambezi in Zambia, NE Namibia, Zimbabwe and Mozambique.



Descriptive notes. 18-19 cm; 43-52 g. Above dark brownish grey; white lines from behind each eye join to form white collar across nape; rump and base of tail white; below ash grey, shading to white on lower belly and undertail; underwing dark grey with white bar on inner wing; bill black, red at base; legs bright red. Differs from *G. ocularis* by much smaller size, collar, white underwing bar and red legs; much darker than *G. cinerea*, which also has striking wing pattern. Juvenile lacks pale collar and eyestripe; flecked buff above and below; legs more orangey. Race *liberiae* differs in having chestnut, not white, across nape; darker overall; intermediates occur in W Cameroon.
Habitat. Exposed rocks in larger rivers and streams, especially for breeding; may rest on sandbars; when rivers in flood moves to coastal localities or to other inland waters.
Food and Feeding. Flies, including tsetse flies (*Glossina*), ants, beetles and other insects. Strongly gregarious; forages mainly on the wing at dawn and dusk, catching insects over water or far from water 15-50 m above ground, sometimes very much higher; may enter towns at dusk to catch insects attracted to street lights.
Breeding. Feb-Apr in Sierra Leone, Apr-Jun in Nigeria at low water, Jul-Oct in Zaire, Sept-Oct in Zambia, Sept-Nov in Zimbabwe; breeding starts earlier where risk of flooding earlier, such as in narrow gorges with deep water. Breeding colonies usually small, up to c. 26 pairs. No nest; eggs laid on bare rock in river or lake, in depression or crack, or on ledge or under overhang. Usually 2 eggs (1-3); incubation 20 days, by both sexes. Chick mottled brownish grey and black above; smoky grey below. Chick fed by both parents on regurgitated insects; fledging c. 20-30 days. About 14% of young survive to fledging annually in Gabon; most losses of eggs and young result from predation, flooding and exposure.
Movements. May be resident at nesting sites in Nigeria, Cameroon, Zaire, Uganda and W Kenya, but much post-breeding dispersal during wet season to rivers further afield. On R Niger found only Mar-Sept; on Zambezi usually present only from about Jul/Aug to Jan/Feb during breeding season, migrating northward to more equatorial regions after breeding. Migrant *nuchalis* seen in Oct in Togo, in range of *liberiae*.
Status and Conservation. Not globally threatened. Nominate *nuchalis* quite common on suitable rivers where exposed rocks available; on R Zambezi c. 1·5 birds/km², but distribution patchy and confined to suitable habitat, usually near rapids; up to 300 birds may occur together; estimated total of more than 1000 birds in Victoria Falls area, including 700 birds in Batoka Gorge, over 105-km stretch of R Zambezi, in 1981. Not uncommon in Ghana in colonies of 20-30 birds, though L Volta has flooded some sites where species formerly common. In Sierra Leone, abundant in dry season on most rocky stretches of large rivers, e.g. 100 pairs on stretch of c. 3·2 km of R Moa, and 75 birds sitting on 3 small rocks on R Sewa close to women washing clothes. Species is vulnerable to unpredictable fluctuations in water levels of rivers on which dams have been built, especially where rivers are deep and narrow, and some sites lost permanently to dams; further dam building likely to be detrimental. Species is now only vagrant or rare visitor to Sudan, where first described.

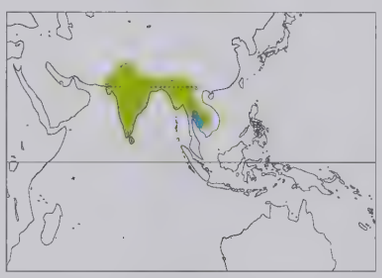
(1987), Lippens & Wille (1976), Louette (1981), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Penry (1979), Pinto (1983), Pollard (1982), Rand (1951a), Short *et al.* (1990), Urban *et al.* (1986), Williams, Coppinger & Maclean (1989).

16. Grey Pratincole

Glareola cinerea

French: Glaréole grise **German**: Graubrachschwalbe **Spanish**: Canastera Gris
Other common names: Cream-coloured Pratincole

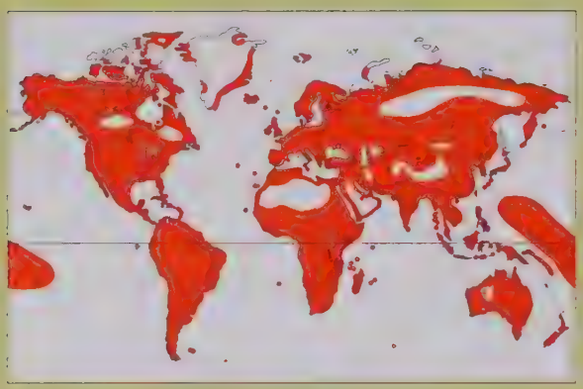
Taxonomy. *Glareola cinerea* Fraser, 1843, mouth of River Niger. Sometimes placed in genus *Galachrysia* with *G. nuchalis* and *G. lactea*. Forms superspecies with *G. lactea*. Birds from upper R Niger, with more cinnamon on nape and breast, may merit subspecific separation as race *colorata*. Monotypic.
Distribution. Large rivers and coasts: Mali and Niger to Ghana, Cameroon, W Zaire and NW Angola.



Descriptive notes. 18-20 cm. Above pale grey with pale chestnut nape and white rump; narrow black eyestripe curving down behind eye, and narrow white supercilium; tail black, with white sides and base, slightly forked; primaries black with white patch, secondaries white with black trailing edge; below white, washed buff on breast and upper belly; underwing largely white with black and white pattern on primaries; bill black, red at base; legs red. Differs from *G. lactea* by head pattern and largely white underwing. Juvenile scaled black and buff on upperparts; no black markings on face; tip of tail mottled black and buff.
Habitat. Sandbanks of larger slow-flowing rivers; during flood or high water also uses local reservoirs and coastal habitats, occasionally mangroves.
Food and Feeding. Flies, beetles, small grasshoppers and spiders. Catches prey mostly on the wing over water, mainly in evening; feeds socially.
Breeding. Mar-May in Niger, Mar-Jun in Nigeria, Feb in Gabon, Jun-Jul in Zaire when rivers at their lowest. Breeds in loose colonies, with nests a few metres apart. Nest is a shallow unlined scrape in sand of sandbar or on shingle, usually near water. Clutch 1-2 eggs; roles of parents, incubation and fledging periods unknown. Chick pale sandy grey above with fine black markings; below white.
Movements. Post-breeding dispersal in Nigeria and elsewhere, when rivers in flood, moving Jul-Sept to L Chad, and to smaller rivers and coastal localities.
Status and Conservation. Not globally threatened. Locally abundant and not under any immediate threat, except perhaps where relatively uncommon. In Nigeria, over 500 at L Chad in Sept, when rivers in spate; up to 300 on coast at Lagos, Jul-Nov. Not recorded since 1956 in Ghana, where creation of L Volta has removed much suitable habitat. Subject to human disturbance.
Bibliography. Bannerman (1931, 1951, 1953), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Grimes (1987), Lippens & Wille (1976), Louette (1981), Mackworth-Praed & Grant (1970), Pinto (1983), Snow (1978), Urban *et al.* (1986).

17. Small Pratincole

Glareola lactea



French: Glaréole lactée **German**: Sandbrachschwalbe **Spanish**: Canastera Chica
Other common names: Little/Small Indian/Milky Pratincole, Swallow-plover

Taxonomy. *Glareola lactea* Temminck, 1820, Bengal. Sometimes placed in *Galachrysia* with *G. cinerea* and *G. nuchalis*. Forms superspecies with *G. cinerea*. Monotypic.
Distribution. E Afghanistan and Pakistan, through India, Sri Lanka and Bangladesh to SC China (S Yunnan), and thence S & SE through Myanmar to Thailand, Laos and Cambodia.

Descriptive notes. c. 17 cm; 37-38 g. Above pale sandy grey; forehead brownish; lores black; rump and base of tail white, with black subterminal band; primaries black, contrasting with pale coverts, secondaries white with black trailing edge; below pale rufous buff, shading to white on lower belly and undertail; underwing black with white bar across secondaries and inner primaries; bill black with small amount of red at base; legs dusky to black. Adult non-breeding duller, loses black lores. Differs from *G. cinerea* by plain head and darker underwing. Juvenile scaled and spotted buff above; spotted pale brown below.
Habitat. Large rivers and streams with exposed sandbars and shingle banks, up to c. 1800 m in Himalayas; also coastal marshes, estuaries; also large inland lakes when not breeding.
Food and Feeding. Beetles, bugs, termites, flies and other insects. Crepuscular; forages in large flocks on the wing, either high in air or low over water or ground; may also catch insects by running on ground like plover. When feeding may recall pipistrelle bat (*Pipistrellus*) with which often flies in twilight.
Breeding. Feb-Apr in India and Sri Lanka; from Mar in Pakistan; young in Jun in E Afghanistan. Nests colonially, often dozens of nests together, sometimes with River Terns (*Sterna aurantia*), Black-bellied Terns (*S. acuticauda*), or Indian Skimmers (*Rynchops albicollis*). Nest is a shallow scrape, or no nest at all; on sandbank in river, even up to water's edge. Clutch 2-3 eggs (2-4); incubation 17-18 days, by both sexes; during hot hours of day, attentive periods 25-35 minutes long; incoming parent often wets belly plumage before return to nest, to cool eggs. Chick finely mottled greyish white, pale buff and dusky above; narrow black line behind eye; below white. Chick fed by regurgitation; when threatened, mock-incubation and broken-wing distraction displays frequently performed by adults; fledging period not recorded. Unseasonal rains or snow melt may cause flooding of early clutches, but birds lay again soon after, even as late as Jun.
Movements. Locally migratory, depending on water levels of rivers. Present in many breeding areas only Apr-Aug; moves to lower levels in winter. Mainly summer breeding visitor to Pakistan, but up to 350 birds recorded in Jan; disappears from R Indus in mid-winter, though over 500 birds seen together on Indus in Mar. Vagrant W to Arabian Gulf and Oman, Nov-Mar; also S to Malay Peninsula in Nov and Jan.
Status and Conservation. Not globally threatened. Total population estimated to be in range 10,000-100,000 birds. Species seems able to survive adequately in large numbers throughout range. Flock of 2000 recorded at Chitwan, Nepal, Jan 1983; flocks of a few hundred birds often seen in S Nepal.

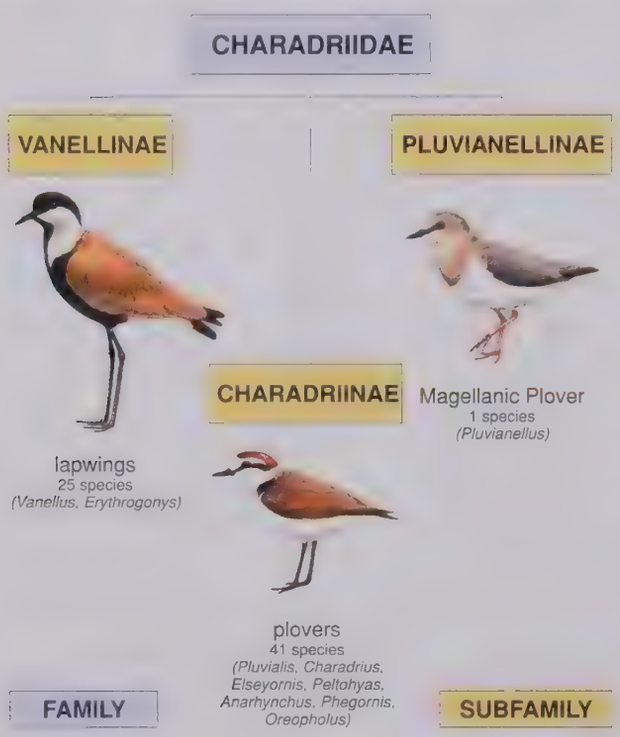
Class AVES
Order CHARADRIIFORMES
Suborder CHARADRII
Family CHARADRIIDAE (PLOVERS)

- Small to medium-sized upright shorebirds, with round head, large eyes and short, pointed bill.
- 12-38 cm.

- All regions except Antarctic; almost all areas support several species.
- Open habitats, both wet and dry, including great variety of wetlands, coastal shoreline, grassland, tundra, steppe and semi-desert.
- 10 genera, 67 species, 106 taxa.
- 10 species threatened; 1 of these almost certainly extinct since 1600.



Systematics

Plovers are normally encountered in open wetlands, grassland and tundra and along seashores, habitats which they share with the sandpipers and their allies (Scolopacidae). The two families together comprise the great majority of the guild of shorebirds, or waders. The strong ecological congruence between plovers and sandpipers, and their overall morphological similarity has lead many scientists and most laypersons to infer a close evolutionary relationship between the Charadriidae and Scolopacidae. H. Gadow in the nineteenth century, and E. Mayr, D. Amadon, A. Wetmore and P. A. Johnsgard in the twentieth, regarded plovers and sandpipers as sister groups within the Charadriiformes. In contrast to this is the suggestion that plovers are more closely related to gulls (Laridae) and terns (Sternidae) than to sandpipers, a conclusion arising from several recent comparative studies of shorebirds and their allies using: morphology of bones, chromosomes, sperm and downy young; behaviour, for instance whether head-scratching is direct or, as in plovers, indirect; and biochemistry, of allozymes, DNA and some metabolic products. The same studies indicate that avocets and stilts (Recurvirostridae) and oystercatchers (Haematopodidae) may have evolved from plover-like ancestors. The intriguing proposal of A. Feduccia was that all of these families, and indeed most other avian taxa, are the result of a fantastic adaptive radiation emanating from a "transitional shorebird" that survived the wave of extinctions at the end of the Cretaceous, about 65 million years ago. During this episode the dinosaurs were wiped out completely, along with most bird species then alive. The "transitional shorebird" might well have looked like a plover, and might have behaved like one.

The modern plovers may have originated in the late Eocene, about 40 million years ago, but there are no known generally accepted fossil plover remains from that era. The first fossils assignable to two modern genera within the Charadriidae, a *Charadrius* species from Colorado and a *Vanellus* species from Belgian deposits, were retrieved from the middle Oligocene, dating back to 30 million years ago, the time when the first grasses appeared.

With the exception of the enigmatic Magellanic Plover (*Pluvianellus socialis*), biochemical evidence suggests the plover family to be holophyletic, in other words that all modern plovers, and no other taxa, share the same common ancestor. The morphological studies of skeletons by J. G. Strauch, corroborated by P. C. Chu and M. Björklund, confirm the idea of a common ancestor for the Charadriidae, but suggest that oystercatchers, avocets, stilts and the Ibisbill (*Ibidorhyncha struthersii*) have all evolved from early members of the plover family. Although the family is commonly divided into two subfamilies, the lapwings (Vanellinae) and the true plovers (Charadriinae), both the DNA-DNA hybridization studies of C. G. Sibley and J. E. Ahlquist and the protein electrophoretic studies by Canadian and Australian teams indicate that the four plovers of the genus *Pluvialis* may be an outgroup to the other two, having derived from a common ancestor early on. Perhaps, *Pluvialis* should not be included in the subfamily Charadriinae, but rather be awarded a subfamily of its own.

On several occasions it has been suggested that the plovers are a family that originated at low latitudes in the Southern Hemisphere, the region where most species are to be found today. The

Subdivision of the Charadriidae .

[Figure: Àngels Jutglar & Etel Vilaró]

The Magellanic Plover of southern South America diverges notably from other plovers in terms of both morphology and behaviour; indeed, it may not actually belong in the plover family at all. Whereas other plovers feed by pecking at surface-dwelling prey, it uses its thick legs to dig in the sand for food; it possesses a crop; unlike the precocial young of all other waders, its two chicks are rather weak, and one normally dies of starvation. These and many other peculiarities suggest that it may merit a family of its own, Pluvianellidae.

[*Pluvianellus socialis*, Chile. Photo: R. Seitre/Bios]

family would appear to have evolved under rather arid, semi-desertic conditions, specializing on small prey that are most active at night. Only the genus *Pluvialis*, of which all four species breed in tundra areas around the Arctic Ocean, may have its origin in the Northern Hemisphere. Nocturnal feeding on small invertebrates could have been the critical characteristic that allowed the similarly styled "transitional shorebird" to survive the period of relative cold and darkness at the end of the Cretaceous that wiped out most of the bigger beasts.

The lapwings, with 25 extant species in two genera, form a fairly close-knit group that would seem to be monophyletic on the basis of several morphological and biochemical studies, the latter including research on allozymes, DNA and the wax produced by the preen glands. Africa has the most species of lapwing, while North America has none. The tradition to split the lapwings into as many as 19 different genera, most of which contained only a single species, has generally been abandoned since the review of W. J. Bock in 1958. On the basis of morphological characteristics, two South American lapwings, the Southern Lapwing (*Vanellus chilensis*) and the Andean Lapwing (*Vanellus resplendens*) appear more closely related to one another than to any other lapwing species. They may descend from relatives of the Blacksmith Lapwing (*Vanellus armatus*) or the Spur-winged Lapwing (*Vanellus spinosus*). The Red-kneed Dotterel (*Erythrogonys cinctus*) was commonly placed in the genus *Charadrius* until allozyme studies of Australian plovers and lapwings by P. D. Christian and co-workers in 1992 showed that it is probably more appropropriately considered a lapwing.

The subfamily Charadriinae with 37 species and seven genera, is somewhat more diverse than the Vanellinae. As well as *Charadrius* itself, it includes the distinctive genus *Pluvialis*, to which the Red-breasted Plover (*Charadrius obscurus*), endemic to New Zealand, was previously assigned. It also includes an aberrant plover with a side-ways curved bill from New Zealand, the Wrybill (*Anarhynchus frontalis*). Wrybills are *Charadrius*-like in all respects and would certainly have been placed in that genus were it not for their highly peculiar bill. Recently, it has been argued, on the basis of allozymes and behavioural characteristics, that two *Charadrius* species, the Hooded Plover (*Charadrius rubricollis*) of Australia and the Shore Plover (*Charadrius novaeseelandiae*) of New Zealand, should be placed in a distinct genus, *Thinornis*, although, with the limits of *Thinornis* still under discussion, for the time being it seems most prudent to retain these species in the genus *Charadrius*. This species pair may be most closely related to the Black-fronted Dotterel (*Elseyornis melanops*), also an endemic of Australia and New Zealand. The desert-adapted Inland Dotterel (*Peltohyas australis*) was previously classified as a courser (Glareolidae), on the basis of overall resemblance and the colour pattern of its downy young. However, recent morphological studies and biochemical studies have suggested it to be a *Charadrius*, with which it shares an alternation of breeding and non-breeding plumages. Perhaps, instead of an ancient endemic, the Inland Dotterel is a quite newly arrived descendent from north-south migrant *Charadrius*-stock that has effectively adapted to the arid conditions of inland Australia.

In accordance with most recent authors, the genus *Eudromias* has been dropped herein and the Eurasian Dotterel (*Charadrius*

The Diademed Plover is another strange South American species of uncertain taxonomic affinities, a situation not helped by the fact that the species is so poorly known. Its bill is quite different from the typical stubby plover bill, instead recalling those of Calidris *sandpipers, but, while it too is used for probing in soft substrates, nobody yet knows for certain whether or not the tip is similarly sensitive. This species is a rather solitary and inconspicuous denizen of the high altitude* puna *zone in the Andes.*

[*Phegornis mitchellii*. Photo: R. & N. Bowers/ VIREO]

morinellus) assigned to the genus *Charadrius*, despite marked idiosyncrasies in both sexual dimorphism and breeding strategy (see Morphological Aspects, Breeding). Another species that was previously also assigned to *Eudromias* is the superficially similar Tawny-throated Dotterel (*Oreopholus ruficollis*) of the Andes and the arid coastal zones of South America; DNA-DNA hybridization studies place it firmly at the root of the plover lineage. Due to its relatively long and slightly down-curved bill, the Diademed Plover (*Phegornis mitchellii*), another Andean species, was sometimes thought to be a sandpiper, perhaps closely related to the peculiar Tuamotu Sandpiper (*Prosobonia cancellata*) of the Pacific islands. Studies of skeletal morphology confirm it to belong to the Charadriidae, however, and even suggest a closer relationship with the lapwings than with the true plovers. Modern studies of functional morphology and molecular genetics would surely help to elucidate the systematic position of this confusing wader species.

The Magellanic Plover is an unusual, grey-plumaged plover with turnstone-like morphological and behavioural features. It breeds around upland lakes in Tierra del Fuego and spends the non-breeding season several hundred kilometres away to the north in coastal Patagonia. For many reasons it is very doubtful whether this species really belongs in the Charadriidae, where it is often retained for convenience. Unlike the rest of the plover family, it has the habit of turning seaweed and stones to look for hidden prey, and it will dig into sand with its short legs to uncover buried prey items. Magellanic Plovers carry food to their chicks in the crop, a pouch which can also be distended in display. The osteological studies of J. G. Strauch, recently supported by P. C. Chu, place *Pluvianellus* in a single lineage with the sheathbills (*Chionis*), completely outside the plover family, and, consequently, many recent texts include the Magellanic Plover either in the Chionidae, or in a family of its own, Pluvianellidae.

At the species level, there has been rather little excitement over taxonomic issues regarding plovers in recent years. One development was the recognition of three species of golden plovers, where previously only two were accepted. In 1983, a thorough morphometric study by P. G. Connors confirmed the recognition of the Asian and the North American forms as full species: in an area of sympatry in western Alaska, Pacific Golden Plovers (*Pluvialis fulva*) and American Golden Plovers (*Pluvialis dominica*) had distinct plumages and showed body size differences, while there was no evidence of interbreeding. Since then, field studies in western Alaska have demonstrated clear differences in nesting habitat and breeding vocalizations between the two plover species, and found that they mate strictly assortatively, thus confirming the biological importance of the differences in plumage and morphometrics.

Other cases are rather less clearly defined. For example, the St Helena Plover (*Charadrius sanctaehelenae*), restricted to a remote island in the South Atlantic, is clearly a close relative of Kittlitz's Plover (*Charadrius pecuarius*) of Africa and Madagascar, but whether or not it really merits separate species status is debatable; as the two are most unlikely to come into contact in the wild, the question is liable to remain academic. In contrast, another closely related species, the Black-banded Plover (*Charadrius thoracicus*), endemic to Madagascar, behaves as a separate species when in contact with Kittlitz's, although the phylogenetic proximity of the two species could prove to be the downfall of the threatened Black-banded (see Status and Conservation). Even more complicated is the case of the Kentish Plover (*Charadrius alexandrinus*) and its closest allies. At one extreme, the Javan Plover (*Charadrius javanicus*), the Red-capped Plover (*Charadrius ruficapillus*) and even the White-fronted Plover (*Charadrius marginatus*) have been considered conspecific with it, while, at the other, its races *nivosus* and *occidentalis* have been proposed to constitute two additional species. Once again, the treatment adopted is essentially a matter of personal preference.

One of the most recent taxonomic developments in the family came in 1994, when J. E. Dowding concluded that the allopatric populations of the Red-breasted Plover on Stewart Island and North Island were sufficiently distinct in respect of body size, plumage, eggs, ecology and habitat preference to warrant subspecific recognition.

Morphological Aspects

Although Charadriidae is a species-rich family, this does not go together with a proliferation of body forms, as in the other large shorebird family, the Scolopacidae. Plovers are rather uniform

The Eurasian Dotterel differs from all other plover species in that the female is the more brightly coloured sex, a phenomenon that is closely linked with the fact that the sex roles are reversed in this species. Here we see a rather drab-looking male sitting on the nest. Depending on local sex-ratios, females may have two or even three males incubating and raising young, although the males that receive the later clutches may receive some assistance from her. In breeding areas, when females are in excess males may mate with two or three, and some nests may contain the two to three clutches simultaneously.

[*Charadrius morinellus*, Cape Sterlikowa, Taymyr Peninsula, Siberia. Photo: Jan van de Kam]

Plovers form smaller, less compact flocks than do sandpipers, with each bird generally keeping its distance. Within this flock of roosting Lesser Sandplovers the different colour patterns show there to be adult males and females, as well as juveniles which lack all traces of red in their plumage. The bulky, rotund figure, the medium-length legs, the short, stubby bill, and large eyes are typical features of the plover family.

[*Charadrius mongolus*, Australia. Photo: Ad Trounson/ Nature Focus]

in size, the largest species being only three times as long as the smallest; they have legs which are never very long nor very short, very small or vestigial hind toes, and a rather short, blunt bill that is swollen at the tip and narrower centrally. Perhaps most characteristically, they have relatively large eyes in a rounded head carried on a short, thick neck. The bill is usually straight, and no longer than the distance from the base of the bill itself to the back of the eye. The few exceptions are the Wrybill, with a sideways turned bill, and the Diademed Plover, with a rather long, decurved, sandpiper-like bill. The Magellanic Plover shares with the true plovers a rounded head and a short, stout bill, but otherwise reminds field observers of a turnstone rather than a plover. Its greyish coloration, relatively small eyes, hunched-back posture and flat-footed waddling gait are reminiscent of a small ground dove.

Now consider a mixed flock of Northern Lapwings (*Vanellus vanellus*) and Eurasian Golden Plovers (*Pluvialis apricaria*) foraging on a Western European field in winter. The feeding style and prey choice of the two plovers is similar; their foraging is typical for all Charadriidae. Then a raptor appears over the hedge. The plover flock flies up and splits into a loose, almost "dancing", group of rather slow-flying lapwings with broad wings, and a much denser group of straight- and fast-flying golden plovers with pointed wings. There, in the air, the two basic body forms and flight styles within the Charadriidae strike the eye.

All plovers are obligate visual foragers that catch their prey at boundary layers, usually picking small invertebrates from the surfaces of dry or wet substrates, or from low vegetation cover. Coming as close to probing as true plovers can, birds of the genus *Pluvialis* may sometimes pull invertebrates out of shallow holes. Plovers forage by making repeated runs, of up to a few metres at a time, interrupted by standstills, when the head is held high. Such pauses may also result in a peck, in order to capture a prey item detected on the surface. It is thought that these pauses allow plovers to detect prey at quite large distances, using a particularly acute form of monocular vision, and perhaps an auditory detection system as well. Whilst engaged in a run, a plover may be able to see and hear less acutely, but during the direct approach towards a detected prey item the plover may use binocular vision to judge the remaining distance. Field observations show that the bigger the plover species, the larger the distances run and the larger the prey items captured.

Not surprisingly perhaps, in the Magellanic Plover the archetypical run, stop and peck behaviour of plovers is absent. This bird waddles along the shore in a stoop-shouldered stance, head low and eyes constantly peering at the ground. Except when disturbed, it rarely raises the head above the level of its back. Also unlike typical plovers, it does not peck perpendicularly to the ground but uses a slight twisting motion, so that the bill hits the ground at a sideways angle, resulting in a distinctive cock-headed feeding posture.

Plovers must also possess great visual acuity under poor light conditions, as they routinely feed at night as well as in daylight. This is made possible by specialized visual receptors. Compared with scolopacid waders, plovers have a higher retinal density of rods (useful for detection under poor light conditions), and also a greater ratio of rods and cones (the latter are for visual acuity in daylight and for colour discrimination). The bills of plovers

The Wrybill's extraordinary bill is well adapted for probing for insects underneath stones. This species breeds on sand and shingle beds in the braided rivers of central South Island, New Zealand, a biotope in which the odd, right-curved bill can be fully exploited. After the breeding season Wrybills move from the inland river habitats to coastal mudflats, where the curved bill is probably of no adaptive significance, since the species usually feeds on small prey in muddy substrates amidst other small waders.

[*Anarhynchus frontalis*, New Zealand. Photo: Geoff Moon/FLPA]

The differences between the two large subfamilies in the Charadriidae are amply illustrated by flying birds: the lapwings are larger, broad-winged species, generally with more attractive plumage and rather slower flight; the "true" plovers tend to be smaller, with longer and more pointed wings, duller, more uniform plumage and a swifter, more darting flight. The Pied Lapwing undoubtedly belongs to the first group, but it shows several similarities with Charadrius *in details of plumage and physiology, and may perhaps form some sort of a link.*

[*Vanellus cayanus*, Hato el Frío, Apure, Venezuela. Photo: Benjamín Busto]

are simple in their gross morphology: they do not have movable parts, apart from the Magellanic Plover, which can move the frontal part of the upper mandible independently, as can most sandpipers. The head anatomy aids rapid alignment towards a position indicated by a short-term cue, and appears tolerant of strong impacts on hard substrates. The jaw muscles of typical plovers are well developed but are unspecialized. Although plover-bills show quite high densities of touch-receptors, known as Herbst's Corpuscles, on both the inside and outside of the upper and the lower mandibles, these receptors are not arranged in the complicated ways known from probe-feeding scolopacid waders. It is likely that the touch-receptors are used for the inspection of captured prey items rather than for prey detection. The visual hunting style of plovers is correlated with the structure of the brain. The relative size of the optic lobe of plovers is almost twice that of probe-feeding sandpipers.

The Diademed Plover, an inhabitant of gravelly and grassy areas near freshwater lakes and streams in the high Andes, has a long and slender bill, only slightly swollen at the tip. Atypical of plovers, it uses its bill to make vertical probes, although it also commonly pecks at prey items on the surface. Nothing is known about the details of its bill structure and the arrangement of touch-receptors in the bill tip. The unique bill of the Wrybill, of which the distal quarter is laterally deflected to the right, has been subject to much more research. The Wrybill also breeds in highlands, in this case along the braided rivers of New Zealand's South Island, while it winters on intertidal mudflats on North Island. According to R. J. Pierce, the sideways curved bill is useful in capturing mayfly larvae typically clinging to the undersurface of stones. A Wrybill feeding in shallow water in shingle riverbeds tilts its head to the left, and pushes its bill under a stone so that the bill curvature fits closely. The bill is then moved forward and to the right. With a shorter, straight bill a plover would not be able to catch insects under stones; and with an upturned bill it would be impossible to open the mandibles between the undersurface of a stone and the stone beneath. On intertidal mudflats, Wrybills also feed by tilting the head to the left. They then make sideways sweeps with the bill, mostly from right to left, against the curvature of the bill, to sieve animals from water and the upper layer of mud. It is interesting that the Magellanic Plover of Patagonia preferentially pecks slightly sideways, with its head tilted in one direction. This is correlated with a slight lateral deflection of the tip of the horny covering of the bill, but not the bone; in 80% of examined specimens the twist was to the right.

Captured food items are processed in the gut. As in other birds, the digestive tract of plovers consists, from mouth to cloaca, of the oesophagus, the glandular stomach, the gizzard (muscular stomach), the small intestine and the large intestine. In all examined plovers, the glandular stomach is rather small compared to the gizzard, comprising about 10% of the total stomach mass. This means that plovers are not able to store much ingested food, nor can they achieve much digestion before the food has entered the gizzard. An exception is again provided by the Magellanic Plover, which has a well developed extensible crop, a strong-walled pouch that opens into the oesophagus on the right side of the neck. This crop serves as a storage organ and is also used for transporting food to the young, a form of behaviour otherwise unreported in the Charadriidae; the young are then fed by regurgitation. A crop may be particularly important for Magellanic Plovers in view of their reliance on clumped and small prey items, such as buried fly and chironomid larvae, that are only briefly available and must be gathered as the opportunity arises.

Plovers have gizzards of similar size, relative to body mass, to those of sandpipers, but species such as the Grey Plover (*Pluvialis squatarola*), which regularly ingest hard-shelled prey, have heavier, more muscular gizzards than those that feed on softer prey items, for instance the Eurasian Golden Plover. In contrast, the intestinal lengths of north temperate plovers is greater than that of co-occurring sandpipers with comparable diets. The caeca, a paired extension of the lower intestine that may have a function in the bacterial digestion of plant material, are also larger in plovers than in sandpipers; large caeca being typical of "primitive" birds, this has historically been interpreted to indicate that plovers are more primitive than sandpipers.

In the earlier morphological treatments of the Charadriidae, the width of bone between the eyes was used as a critical taxonomic character. In all plovers, and in many other avian taxa, this area on the forehead is also where the paired salt glands are found. When it turned out that plovers with larger salt glands had narrower bony rims between the eyes, and that the size of the salt gland was associated with the salinity of the chosen habitat within and between species, degree of ossification was discarded as a useful character in taxonomy. Salt glands are small, but powerful, glands that excrete excess salt directly from the blood plasma into the nasal cavity. Plovers of freshwater habitats, such as the lapwings, have rather small salt glands, whereas those frequenting estuarine and marine habitats have rather large salt glands. A careful allocation of energetically expensive tissue and a premium on being as lightly built as possible may prevent sea-

An African Wattled Lapwing on the look-out. The flat, open country that this species inhabits gives it little opportunity to survey its surroundings for rivals and predators, and consequently birds have been found to associate with termite mounds. In normal conditions, plovers are most unlikely to take up a position any higher than this. If at any stage they take advantage of the presence of trees, bushes or fence posts, it is almost always simply in order to stand in their shade during the hottest part of the day. In contrast to this, members of the Scolopacidae are more frequently observed making use of an elevated perch.

[*Vanellus senegallus lateralis*, KwaZulu-Natal, South Africa. Photo: Heinrich van den Berg/Bruce Coleman]

Tawny-throated Dotterels live on overgrazed grasslands or otherwise essentially bare surfaces. Some populations of the nominate race live at altitudes of up to 4600 m in the Andes, and only during migration can they be found on grassy fields and meadows in the lowlands. Others, including members of the race pallidus, *inhabit bare coastal plains. Interestingly, when disturbed, this species may turn its striped back to the observer, offering a highly effective disruptive camouflage in stony habitats.*

[*Oreopholus ruficollis ruficollis*, Salar de Surire, Chile. Photo: X. Ferrer & A. de Sostoa]

shore plovers from having strongly ossified skullcaps. The strong, heavy membranes surrounding the salt glands provide a suitable replacement for the bone.

The ratio of leg to body length is relatively uniform in most plovers, although some of the Afrotropical and one Asian species of lapwing have rather long legs. Among these, the Long-toed Lapwing (*Vanellus crassirostris*) is the extreme. With its long legs and long toes it easily negotiates the floating vegetation in east African freshwater marshes. Long-toed Lapwings live like jacanas, show territorial interactions with jacanas and look like them as well, not only with respect to leg and toe length. The white head and foreneck in combination with a dark hindneck and back, and the rather uniformly coloured upperwing, provide a pattern that is more jacana-like than lapwing-like.

Lapwings have other features that set them apart from the remaining plovers. Of the 24 *Vanellus* species, 16 carry a crest or show facial wattles or sport wing-spurs, or have a combination of two of these features; no species has all three. In all lapwing species these showy characteristics are more prominent in males than in females, and their presence correlates with the aggressive nature of the genus, especially of the males. Wing-spurs are used in combat, and even in species that have no actual spur on the carpal joint, a bony knob is present beneath the skin, which makes blows with the leading edge of the wing more effective. Lapwings, and the Diademed Plover, are also characterized by their rounded wings. This is taken to an extreme by the Northern Lapwing, where the unfolded primaries almost form a semicircle. In this species, males have a spectacular flight display, during which they show much twisting and turning with great speed and agility. This display is even detectable at night by the quiet creaking of the wings with their large surface area. Although the Northern Lapwing is the most migratory species among the Vanellinae, it does not cover very long distances in single flights. Indeed, it does not have to, since suitable habitat is found along most of the routes between its breeding and wintering grounds, unbroken by large ecological barriers. Then again, it would not be able to anyway, since long distance flights require a different flight apparatus: long and pointed wings.

Most *Charadrius* and *Pluvialis* plovers have such slender wings, in which the outermost primary is the longest. Only sedentary species, such as the Black-banded Plover of south-west Madagascar, Kittlitz's Plover from much of Africa south of the Sahara, the St Helena Plover from the tiny island of St Helena, and the Shore Plover from one of the Chatham Islands of New Zealand, have more rounded wings. Birds with long, pointed wings are not the most manoeuvrable, but their flight is both rapid and energetically relatively cheap. Of course, such long distance flights need to be powered by strong pectoral muscles and must be fueled by large fat stores. The pectoral muscles of *Pluvialis* plovers form an even greater proportion (7-8%) of the total lean mass than those of sandpipers (5-6%), highly migratory birds too. The absolute size of these muscles in relation to the skeletal area of attachment is also larger in plovers than in sandpipers. At least in mid-winter, the fat stores that can be deposited by plovers is higher than that of most sandpipers. The genus *Pluvialis* and many *Charadrius* species thus seem particularly well equipped for undertaking long distance flights.

The plumage of plovers differs from that commonly found in the Scolopacidae in that it shows bold colour patterns in olive, brown, grey, black and white, but that it is nevertheless rather cryptic, owing to the disruptive effects of bands on the head, breast and tail. Species that nest on discontinuously coloured substrates tend to have breast bands. Species such as the Piping (*Charadrius melodus*), White-fronted, Kentish and Malaysian Plovers (*Charadrius peronii*) all nest in uniform beach habitats and have incomplete or no breast bands. A few large lapwing species do not show much crypsis. Due to their size, habits and nest-sites they can not hide effectively, and so they might as well advertise their presence. Although sexual differences in plumage are only slight in plovers, in many species males have a more intensely coloured plumage than females. Only in the Eurasian Dotterel is the breeding plumage of the females much more colourful than that of the males, a feature correlated with reversed sexual size dimorphism and also breeding role reversal, the female being the larger, competitive sex and the male caring for the eggs and chicks. The total mass of the contour feathers varies in direct proportion to body mass, accounting for about 7% of it. It is slightly higher in plovers wintering in cold temperate zones than in those in the tropics.

The facial markings and breast bands of many *Charadrius* species may have adaptive value for reasons of crypsis, but the counter-effect, conspicuousness, may also be important for reasons of display. In territorial aggressive interactions between the more brightly coloured males, threat displays are important. During such interactions the two contestants stand face to face and present the bold facial markings to each other. For this reason it may not be fortuitous that the black crown of 21 *Charadrius* species is restricted to the front edge of the crown and thereby maximally visible for a threatening opponent. Moreover, the black markings are most conspicuous during the courtship period. In Magellanic Plovers, it is iris coloration that features prominently in the complicated courtship and territorial displays. During these

displays, the eye is opened widely and the pupil contracted, thus giving added prominence and brightness to an expanded coral iris; at these times the inner rim of the iris is yellow, which intensifies the contrast between eye and head.

Moult of the head feathers begins as soon as incubation has started. Yet, in rather few plover species is the seasonal change in plumage very pronounced. Several *Charadrius* plovers, however, especially those with rufous areas on the head, breast or belly, are more intensely coloured during the breeding season than during winter. The highly migratory *Pluvialis* plovers, seasonally commuting between Arctic or sub-Arctic and temperate to tropical habitats, show black underparts during the breeding period while these are whitish or grey during the rest of the year. That the black bellies, bordered by contrasting white edges, also combine the two functions of highly visible quality signals to attract mates and to impress competitors, without loosing the benefits of disruptive coloration, is suggested by the partial summer moult documented in Eurasian Golden Plovers. During the breeding season these plovers have part of their black breast and belly feathers replaced by much more cryptically coloured striped feathers. This makes the breeding plumage much less contrasting by the time that the pair-bond and territory are firmly established, and when most of the snow has melted, taking the starkest contrasts out of the landscape.

The juvenile plumage of plovers is not strikingly different from that of adults. All juveniles, and the freshly moulted adults of some species, show buff to rusty fringes on the contour feathers of the upperparts. Over the non-breeding season, as the contour feathers wear, the colour of these fringes fades, and after a few months young birds are generally indistinguishable from adults. Just before the breeding season, most plovers carry out a partial moult of the contour feathers only, especially with regard to the body parts that play a role in signalling. Depending on whether or not they make a breeding attempt as one year olds, young birds may or may not acquire this distinct breeding plumage. The Eurasian Golden Plover is an example of a species that breeds in its second calendar year after having acquired a full breeding plumage when only 9-10 months old.

In most plover species the complete moult takes place after the birds have arrived in their non-breeding quarters, and at this time the wing and tail feathers are renewed too. In some cases moult is started on the breeding grounds, or on staging areas during the post-breeding migration. During the moult of the flight-feathers, plovers start off by replacing some primaries. They start moulting the secondaries, the tertials and the tail feathers when the primaries are half completed. The primaries are moulted outwards from the "wrist", and the secondaries inwards. Wing moult is usually completed over a period of 3-5 months, but there are many cases in which wing moult is suspended and finished at a later date. An example is provided by the Grey Plover, a species that breeds in the high Arctic. The relatively long time that it takes these plovers to hatch a clutch and raise their chicks means that they only arrive late in the year in their temperate staging and wintering areas. As a consequence they often suspend wing moult after having completed the growth of 6-8 of the 10 primaries. Usually, primary moult is resumed when environmental conditions improve after the mid-winter. Regular yearly replacement is not the rule for the moult of secondaries in the genus *Pluvialis*, and perhaps in other plovers too. Each year only some of the secondaries are replaced, and the order in which this happens is rather chaotic. It may take 2-3 successive moulting seasons to replace them all. This contrasts with the annual and orderly replacement of all primaries, a difference that can be explained by the much heavier wear and tear to which primaries are exposed. Plovers that forego breeding in their second calendar year and which do not migrate to the breeding areas, capitalize on this free time by using the breeding period for a complete moult.

The plovers show an intriguing lack of size dimorphism between the sexes. Within a sample of Palearctic plovers, 10-20% of the species show some degree of dimorphy in wing, bill or tarsus length. This contrasts with scolopacid waders, of which more than 50% show dimorphism, often to a degree that is more extreme than in plovers. In many lapwing species the males tend to be slightly larger than the females. In the rest of the plover family, a few species show the opposite pattern, and in the Eurasian and Tawny-throated Dotterels and the Diademed Plover, the female is larger than the male. In the Eurasian Dotterel this is known to be correlated with a reproductive sex role reversal.

Habitat

A foraging style during which prey is detected by visual means and captured afoot provides adaptations for a life in open terrain

Most lapwing species are found at low latitudes with warm, dry climates. They inhabit a variety of open habitats, ranging from the edges of inland to coastal waters, and from dry savannas or steppes to cultivated land. Lapwings are not strongly migratory but may move erratically, following rain or fire or avoiding cold spells. The River Lapwing is largely confined to the margins of running water all year round, and is only rarely found near still or stagnant water. It breeds on shingle and sand banks where its contrasting plumage provides splendid camouflage. It sometimes feeds on cultivated land adjacent to the river.

[*Vanellus duvaucelii*, India. Photo: Getrud & Helmut Denzau]

Intraspecific territorial disputes are usually settled by means of threats in an upright posture, with the neck stretched out. On occasion, confrontations intensify and the carpal spurs, which are well developed in many lapwing species, may be used as effective weapons; in most cases, the spurs are brightly coloured red or yellow, and they tend to be longer in males. Like many of its congeners, the Southern Lapwing defends its territory with loud, persistent calls, and this has led to its employment as a sentinel on many ranches.

[*Vanellus chilensis lampronotus*, Pantanal, Brazil. Photo: Günter Ziesler]

with short vegetation or with completely barren ground. Plovers use inland habitats, including river and lake shores, marshes, dry plains and savannas, as much as the typical shorebird habitats along the coast. Most plover species avoid rocky shores, but the Shore Plover, an endemic of New Zealand's Chatham Islands, does not. Several other *Charadrius* species are beach dwellers in both breeding and non-breeding seasons. Only some of the highly migratory *Pluvialis* and *Charadrius* species show substantial habitat change in the course of the year, from tundra to coastal mudflats and inland grasslands.

Although the general features of plover habitats are easy to summarize, the details of habitats used by different plover species vary greatly and are finely tuned to their biology. To gain a feeling of what the habitats of a plover may look like in the course of a year, seasonal habitat use of a few will be examined in more detail. At one climatic extreme, Inland Dotterels occur year round on arid and sparsely vegetated plains and semi-desert in the tropical heat of Australia. At the other end of this spectrum, Eurasian Dotterels breed on cold and misty moorland and tundra in northern Europe and Asia, where they typically favour sparsely vegetated open flats with plenty of bare rock. During migration they are found on fallow and freshly ploughed fields and areas with short, heavily grazed or saline, vegetation. In North Africa and the Middle East, where Eurasian Dotterels spend the winter, they frequent stony steppe, semi-desert and marginal farmland.

The four *Pluvialis* species all breed in similar boreal and Arctic habitats to Eurasian Dotterels, but prefer the slightly more vegetated parts of upland moors and tundra. During migration and in winter the three golden plovers mainly occur on open fields and grassland. Eurasian Golden Plovers may feed on intertidal flats but most use cultivated fields and, especially, grassland. Within Europe, regional and seasonal differences in the use of these habitat types have been documented. This is unlike Grey Plovers that always and only feed on intertidal flats during migration, and wherever they spend the winter: from the north of Scotland to the deep south of South Africa or Tierra del Fuego. However, Grey Plovers wintering in Britain indicate a behavioural fine-tuning to habitat characteristics by establishing feeding territories only in intertidal areas with deep gullies, whereas they feed in loose flocks in other parts of the estuaries.

Common Ringed Plovers (*Charadrius hiaticula*), Semipalmated Plovers (*Charadrius semipalmatus*) and Long-billed Plovers (*Charadrius placidus*) are typical shoreline birds, usually occurring in areas where their distinct blotched plumage pattern has a disruptive effect. Ranging from north temperate to high Arctic latitudes, these species breed in well drained, gravelly and sparsely vegetated areas near a seashore, stream or pool. During the migration and winter periods they occur predominantly on wide sandy and shingle intertidal beaches. Similar shifts from inland to seaside shorelines is made by other species such as the Wrybill of New Zealand and the Magellanic Plover of Patagonia. The first moves from the upland braided riverbeds where it breeds to the estuarine intertidal areas where it winters. The second breeds along the open shorelines of pools and lakes on the south Patagonian steppe and winters further north on the wide beaches along the Atlantic coast of southern Argentina.

There are several *Charadrius* species that spend both the breeding and non-breeding seasons in salty beach-like habitats, a category that includes salt-lakes and salt-pans. Such habitats are the rule for south temperate resident species such as the Red-breasted, Red-capped and Hooded Plovers, north temperate migratory species such as Kentish and Piping Plovers, and tropical residents such as Wilson's (*Charadrius wilsonia*), White-fronted and Malaysian Plovers. Kentish Plovers not only breed along seashores, but also have an extensive inland distribution. They share the steppes and semi-deserts of Eurasia with the Greater Sandplover (*Charadrius leschenaultii*), a species also wintering along tropical seashores, and Caspian (*Charadrius asiaticus*) and Oriental Plovers (*Charadrius veredus*). The latter two species winter inland on the short dry grasslands of tropical Africa and Australia respectively. Greater Sandplovers spend the non-breeding season along the shores of the Indian Ocean, and are joined there by Lesser Sandplovers (*Charadrius mongolus*), a closely related species that breeds above the tree-line on elevated tundra and sparsely vegetated mountain steppes, thus showing many ecological similarities to Eurasian Dotterels.

The grassy Eurasian steppes are home to Sociable (*Vanellus gregarius*) and White-tailed Lapwings (*Vanellus leucurus*). The latter long-legged species usually nests close to water bodies, where it forages on the shallow margins. Both species are migratory, and winter in the region from north-east Africa to Pakistan, using habitats quite similar to those on the breeding grounds. Faithfulness to one habitat type is, in fact, typical of all lapwings, including the only two other north-south migrants, the Northern and Grey-headed Lapwings (*Vanellus cinereus*). The first is a grassland specialist, the second, with much longer legs than the first, an Asian marshland dweller.

Among the waders wintering on intertidal flats, plovers tend to forage at higher tidal levels than probing sandpiper-like shorebirds. Visual prey detection may allow plovers to feed prof-

itably on the rather low densities of active and surface-living prey typical of high-lying and compact substrates. At the same time, plovers thus avoid areas with high densities of probing sandpipers which disturb their prey, since sandpipers usually concentrate foraging on lower and looser sediments.

Also in contrast to many scolopacid waders, plovers show relatively little tendency to make special movements between feeding and alternative roosting habitats. Many plovers simply roost on their feeding grounds. Some species, such as Eurasian Golden Plovers and Northern Lapwings, may regularly commute between grassland feeding areas and nearby arable fields or shore habitats to preen and roost. Such habitat shifts are the routine of American Golden Plovers and Tawny-throated Dotterels on Argentinian *pampas*. The two species come together in flocks in wetlands, to bathe and preen in the daytime and to roost at night. Plovers living on the coast are forced off the intertidal flats by the rising tide, and then coalesce into flocks on high-lying sandbanks, bare sandy patches between mangroves, or fields behind a dyke. However, in such cases plovers habitually keep their distance, roosting spread out and quite far away from the large, compact roosts of scolopacid waders, or at the most remaining along the fringes of such roosts.

Plovers rarely sit or stand on branches of shrubs or trees in tall vegetation. This is essentially a consequence of the hind toe being very short or vestigial, which means that they are unable to grasp a branch. In tropical coastal areas, the odd flock of Grey Plovers may spend the high water periods perched in a mangrove tree, but as a rule plovers do this less frequently than most of the co-occurring sandpiper species. Yet, plovers in the tropics do routinely use the sunshade of mangroves, or other stands of trees, to reduce the heat load at midday. Inland Dotterels in Australia roost in the shade of fenceposts, shrubs and tussocks when air temperatures reach over 45°C. In breeding areas, unlike the case with many scolopacid waders, one never encounters plovers that are vigilant or displaying in the top of a small tree or any other vertical structure. In wet grassland areas of Western Europe, where breeding waders reach high densities, one of the more typical sights is a shank, a snipe or a godwit on a fencepost, but never a Northern Lapwing.

General Habits

For most of the year the great majority of plovers operate in small flocks. These flocks are never very tightly packed and may comprise any number of birds up to a few thousand individuals. Plovers are rarely counted by the ten thousands, as can happen with several scolopacid waders. During peaks of southward migration in the Netherlands, a steady stream of flocks of Northern Lapwings, each containing several hundred to a few thousand individuals, may pass by. Even more spectacular sightings must have been made along the Gulf coast of Louisiana, USA, early in the last century. On a single day an estimated 48,000 American Golden Plovers were shot in one small area, indicating the simultaneous northward passage of even greater numbers.

During migration, plovers fly alone or in flocks comprising two to several hundred individuals. Grey Plovers migrate in flocks averaging about 30 birds. Especially upon departure on long distance flights, such as those between West Africa and the European Wadden Sea, such flocks are highly structured. They have the appearance of an echelon or a V. Migratory flocks are usually monospecific, but when flockmates are in short supply, outside the peak of the migration season for example, plovers may fly with like-minded shorebird species. When travelling to and from their Siberian breeding grounds, mixed flocks of Grey Plovers and Bar-tailed Godwits (*Limosa lapponica*), or Grey Plovers and Red Knots (*Calidris canutus*) occur regularly. In the last century, American Golden Plovers and Eskimo Curlews (*Numenius borealis*) often migrated together in flocks. During the breeding season most plover species are not gregarious, but split up in pairs or other small reproductive units, each of which usually defends a patch of ground, the breeding territory.

Territoriality is not limited to the breeding season, since many plover species also defend small feeding areas during migratory stopovers and on the wintering grounds. Such patches may be defended continuously for several months over an entire non-breeding season, or temporarily, for a few days at a suitable stopover site, or even for less than an hour when a clumped resource is monopolized by a bird in a feeding flock. Grey Plovers show long-term defence of feeding territories on intertidal mudflats in

Plovers usually roost in flocks. There is a good reason for this: a single bird roosting alone has to keep an eye on its surroundings constantly, in order to spot any approaching predator; with a roosting flock, however, the alarm can be given for the entire flock by a single bird detecting the predator, so each bird is able to repose more deeply. During the non-breeding season some Grey Plovers will defend a feeding territory to which they may return annually. Within such territories, birds often have a favoured loafing site, but even territorial birds tend to roost with the flock.

The Killdeer is a characteristic species of agricultural land in North America. It is well known for the distinctive rufous rump and uppertail-coverts which it uses to stunning effect in several displays, most notably its distraction display. The other well known feature of this species is its distinctive call, "kill-dee", which is the source of its vernacular name, and more indirectly of its scientific name.

[*Charadrius vociferus vociferus*, southern USA. Photo: François Gohier/ Ardea]

many parts of their wintering range, at least from northern England to southern Africa. In fact, the same individual may return year after year to the same patch of mud once it has established itself as a young bird. Grey and Common Ringed Plovers feeding on polychaete worms in Moroccan estuaries during northward migration defend feeding territories over periods of up to several weeks. These territories show complete overlap between the two species and are only defended against conspecifics. Individual Eurasian Golden Plovers feeding in flocks on grassland, may occasionally and temporarily defend little patches of space against conspecifics. Territorial defence is much more outspoken in American Golden Plovers wintering on the *pampas* of Argentina. Most of these birds defend long-term territories during daytime in short-grass uplands and along streams, but come together at communal night-time roosts.

The behavioural components involved in territorial encounters in the non-breeding season are highly ritualized and are quite similar among different plover species. Normally the aggressor runs up to an encroaching neighbour in a head-down, tail-fanned posture. The two then walk parallel to each other virtually along the territory boundary, up to a metre apart, each with wings drooped towards the opponent, back feathers slightly raised and tail fanned. They may march repeatedly back and forth along the territory boundary in this posture. Contestants frequently show displacement feeding, and parallel walking is occasionally interrupted by bouts of posturing, during which the bird fans the tail and tilts it slightly, so that its upper surface projects towards the opponent. Simultaneously, the bird keeps the wing on the side of the opponent drooped and ready for a strike; it may crouch low or sit on the ground. Nevertheless, the behavioural repertoire involved in territory establishment and defence in non-breeding situations is impoverished relative to that used on the breeding grounds, where there is a larger aerial component to territorial displays, correlated with the fact that breeding territories are about an order of magnitude larger than the territories used exclusively for feeding.

Plovers may feed throughout day and night, but daily rhythms show marked variations depending on feeding conditions and the presence of predators. Northern Lapwings tend to feed by day and roost by night during most moon phases, but carry out all feeding by night for a few days around full moon. According to T. P. Milsom and co-workers, this lunar rhythm is clearest in mid-winter, except when the ground is frozen or covered in snow. During moonlit, but cloudy, nights the incidence of night feeding is also smaller, suggesting that light conditions play an important role. It is still unclear whether nocturnal foraging around full moon is a response to enhanced night-time feeding conditions, to decreased daytime feeding conditions, to changes in the relative predation risk for lapwings during day and night, or a combination of these factors. A good example of enhanced feeding conditions at night is provided by Grey Plovers in an English estuary that were studied by D. J. Townshend and colleagues. These plovers obtained high intake rates by eating large polychaete worms in an area that was not visited by day. A contrasting example of a diurnal pattern in a closely related species is provided by J. P. Myers' studies on American Golden Plovers on the *pampas* in northern Argentina. After feeding during the day, they assembled at communal roosts in shallow water during the night. Another contrast is provided by Wilson's Plovers in a mangrove area in Venezuela. These plovers roost in small flocks during much of the daylight period, while feeding solitarily at night, almost uniquely on small fiddler crabs. Because fiddler crabs are most available during the day, M. Thibault and R. McNeil interpret the nocturnal foraging habits of Wilson's Plovers as a strategy to avoid diurnal predation.

To avoid the claws of hunting raptors or the jaws of roaming jackals and foxes, plovers possess remarkable cognitive abilities and subtle behavioural adaptations. In a study of the Southern Lapwing in Venezuela and Long-toed and Blacksmith Lapwings in Kenya, J. R. Walters showed that the discriminative ability of these plovers of open savannas is quite sophisticated. Southern Lapwings have a specific call for reptiles that causes small chicks to move away. The lapwings' responses indicate that pigs, which are potential egg predators, are not classified with cows and horses. Vehicles are classified with hoofed herbivores, which is most appropriate since cars, cattle and horses pose the same threat of trampling the eggs upon close approach. Southern Lapwings ignore fish-eating raptors, but respond strongly to other large hawks. The African lapwing species have a similar ability to tell a dangerous raptor species, the Tawny Eagle (*Aquila rapax*), apart from the extremely similar looking vultures with which it often soars high in the air. In general, these lapwings appear to discriminate between various kinds of predators and non-predators, and give responses that reflect the type and degree of danger that each of them represents.

In breeding situations, plovers may show a great variety of behavioural responses, depending on the kind of threat and the stage of reproduction. For example, studies by I. Byrkjedal have shown that during incubation, Eurasian Golden Plovers either sneak away from the nest when a predator is still far off, or sit

The bulk of plovers' diets is always made up of invertebrates, although within this category a fair range of food types can be taken. The Blacksmith Lapwing inhabits southern Africa, where over the years the volume of ornithological activity has been considerable, but surprisingly little seems to be known about its food preferences. It is recorded as taking small molluscs, crustaceans, worms and insects, but, as this photo demonstrates, it will also take amphibians, or at least capture them!

[*Vanellus armatus*, Hwange National Park, Zimbabwe. Photo: M. P. Kahl/DRK]

tight, and leave the nest at the last moment to perform a distraction display, either in the air by showing impeded flight, or on the ground by walking away as if injured. Once the chicks hatch, the adults approach potential predators when they are still far away from chicks, and dog them whilst continuously giving loud alarm calls. The great wariness of lapwings and *Pluvialis* plovers may be capitalized on by other shorebird species that come to breed and feed in close association with these plovers and use them as sentinels. When a mammalian predator has been detected in a field where several lapwing pairs are breeding, the lapwings will assemble in a large mobbing flock over the intruder and try to scare it off with dive-bombing attacks. In non-breeding situations where a predator has been detected, behaviour may vary between flying up in flocks to move away, and crouching flat on the ground or in the water to get out of sight.

Diurnal feeding and roosting rhythms, the presence or absence of special communal roosts and the behavioural responses to potential threats will all be shaped by the energy and time demands of the plovers in combination with predation risks and feeding opportunities: a plover on its breeding grounds will find its movements constrained by the time for which it must incubate the eggs or tend the chicks; a plover in heavy wing moult will be constrained by high flight costs and low manoeuvrability; a plover in harsh winter weather will need much food per day to balance its energy budget; and a plover in the tropics will have to make behavioural adjustments to avoid overheating. All these demands will subtly affect the details of the habits that have been discussed here, and offer endless scope for future studies.

Voice

The melodious but mournful whistling songs of *Pluvialis* plovers, uttered most frequently in late spring and summer, but as briefer versions in other seasons too, provide very evocative sounds for the human ear. They are strong reminders of days spent in lonely moorland or tundra. Most *Charadrius* plovers have rather softer voices, and vocalize mainly on the breeding grounds. They have relatively low-pitched display calls and rather higher-pitched alarm calls. Lapwings, and their ecological equivalent in North America, the Killdeer (*Charadrius vociferus*), are characterized by louder and harsher sounds, especially when the birds are on their breeding territories. Magellanic Plovers have an unusually wide variety of calls by plover standards; many of them are quite similar, and some appear to be used in more than one context. Overall, vocalizations of plovers have been rather poorly documented, with descriptions only being available for about 20 of the 67 species. For example, regarding the Vanellinae, detailed studies are available only for the Northern Lapwing, which in many respects is an atypical member of its genus.

Detailed studies of the communication behaviour of *Vanellus*, *Pluvialis* and *Charadrius* species usually come up with about 10 different vocalizations. These calls are categorized according to their sound and appearance on the sonagraph, and according to the behavioural context in which they appear. The tendency that the best studied species have the largest vocabularies underlines how rudimentary our present knowledge is. In the communication between adult plovers the following call types are usually recognized. The commonest call type heard when a human observer disturbs a plover on its territory is usually the general contact and alarm call, or "Warning-call". There may be up to eight distinct types in any one species, and these are given year round, but most commonly at the breeding grounds. The next category are the "Alarm-threat Calls", which are given during the breeding season in contexts where birds show ambiguity between approach and withdrawl. They usually sound somewhat harsher than the contact and alarm calls, and show a gradient in harshness towards real threat calls, which are given when birds in the reproductive phase are particularly excited, and sometimes during fights over feeding territories as well. Then there are a few vocal categories that are mainly used in sexual contexts, the most important of which is the "song", a conspicuous long-range signal that may be produced during highly choreographed song flights; especially in *Pluvialis* and *Vanellus*, quite complicated vocalizations (songs) may be produced. During advanced courtship and when making shifts during incubation, mates may approach each other with calls denominated as "Pair-contact Calls" (or "Tenderness Calls" and "Mating Calls"), which are much softer, short-range vocalizations. When making a nest scrape in a ritualized way, males, and rarely females, of some species may produce soft "Scraping Calls". The "Copulation-call" is usually attributed to the female and is given just before she is mounted by a male. A Eurasian Golden Plover settling on the nest for an incubation shift may produce a soft "Settling-call".

The final group of vocalizations given by adult birds are those that have a role in ensuring nest and chick survival. "Distraction Calls" are given when parents try to lure potential predators away from the nest and chicks, for instance by a "Broken-wing Display". The calls made towards chicks comprise those that warn

the chicks of various kinds of threats, the sophistication of which we have only the faintest idea; those that summon the chicks out of a hiding place or a crouched position, the "All-clear" signals; and those signals that invite chicks to follow or to be brooded. The chicks themselves produce a graded series of vocalizations, starting with the soft peeps from a pipped egg that develop into the "Location Call", the juvenile version of adult contact call. Small chicks that have a decreased body temperature and need to be brooded to return to normal temperatures, make repeated series of this call. In some species, warm and contented chicks brooded by one of the parents convey this by a long, sustained and melodious "Contentment Call". Distress calls are made by older chicks, especially when they are frightened, for example when picked up by man.

One of the more spectacular and vocally accompanied behavioural displays given by any member of the Charadriidae is the song flight of male Northern Lapwings, a phenomenon studied in detail by T. Dabelsteen. Song flights may be made spontaneously, during interactions with other males, with females or with a predator, and sometimes when a male returns to an empty territory. More than half of all song flights are made during male-male interactions and are clearly meant to establish a territory. They are most commonly performed in the early morning, but otherwise continue throughout day and night during the breeding season, except in bad weather. They consist of fixed sequences of about eight different flight modes. The song phrases themselves are made when the bird makes a steep ascent or a vertical dive, thus accentuating his proficiency in flying. During the so-called "Alternating flight" phase of the song flight, during which the lapwing rolls from side to side, the bird does not vocalize but makes a thrumming sound with his wings: a strong and impressive signal. A quite similar phenomenon is shown by the Double-banded Plover (*Charadrius bicinctus*) when breeding in New Zealand. Males of this species produce loud "Wing-clicks", audible 100 m away; these are made at each beat of the wings during territorial flight displays that can be sustained for several minutes.

A Lesser Sandplover feeding at a coastal site during the non-breeding season. This polychaete worm was surprised when surfacing and is now being pulled out of its burrow. Swallowing such elongated prey needs some elaborate handling, and the risk that it will be snatched by neighbouring birds, either conspecifics or other kleptoparasitic species such as gulls, may be high. Migrant plovers appearing outside the breeding season in coastal habitats feed mainly on crustaceans, polycheates and molluscs, while insects are sometimes eaten. In the breeding areas the diet usually consists merely of insects.

[*Charadrius mongolus*, Changi Beach, Singapore. Photo: Morten Strange]

Food and Feeding

Plovers eat small invertebrate prey species that live close to the ground. Creepy and crawling arthropods and worms provide most of the diet of all plovers, always and everywhere. In terrestrial habitats, birds feed on earthworms, spiders and especially the larvae and adults of different insect groups, including flies, beetles, ants, chironomids and tipulids; these are sometimes supplemented with small berries, for instance of heather, and seeds. In riverine freshwater habitats, aquatic insects and small crustaceans make up the diet. In intertidal areas, plovers live on small crustaceans, including crabs, slow types of shrimp, amphipods and isopods, and also on worms, especially large polychaetes. In freshwater and marine habitats, small molluscs are sometimes preyed upon, but they never provide the bulk of the diet.

All members of the Charadriidae, except the Wrybill and the Magellanic Plover, forage by waiting for prey to reveal itself, either by coming to the surface of the ground, or, if already on the surface, by moving. The bird then runs rapidly to catch and swallow a detected prey item, before resuming a waiting position. It will move on to new waiting positions if no prey is detected. During the downward movement of the head, a further pause may occur, during which the bill is held close to the substrate before the plover finally grabs its prey. In such cases the prey is usually large and is captured by a relatively deep peck. Unsuccessful and aborted pecks are likely to result from misidentification of the prey rather than its escape. As the rate of prey detection increases, the pause rate increases too, and the average distance moved between pauses decreases. On rare occasions, plovers may wade in shallow water, making regular pecks on the water surface to capture small floating prey items.

The foraging style of typical plovers is thus highly stereotyped. It is well adapted for feeding on surface prey in flat compacted substrates that may be hard to penetrate with a long and sensitive bill. If prey is indeed detected mainly visually, as most authors assume, then everything else being equal, feeding rates of plovers at night, relative to daylight performance, should be lower than those of tactile feeding sandpipers. Longer pause times, shorter sighting distances and lower peck rates in darkness have indeed been reported in several species. That plovers have a more southerly non-breeding distribution than sandpipers has thus been explained by the shorter daylight periods and the limited profitable feeding time available to plovers wintering further north. However, in several cases, prey reveals itself so much more at night by increases in surface activity, that a decreased detection efficiency during darkness is more than compensated for. In fact, intake rates may sometimes be higher at night than during the day. Several authors, with G. Lange as the strongest advocate, have argued that during prey detection plovers use auditory cues in addition to visual stimuli. In dry terrestrial habitats, plovers would be able to hear quite large invertebrates moving underground, thus enabling them to decipher the right location for a strike, but auditory detection is otherwise likely to be little used, even at night.

A recurring theme in studies of foraging plovers is the strong influence of prey activity and visibility on the plovers' feeding success and intake rate. For example, in a hayfield in Iceland, Eurasian Golden Plovers almost uniquely fed on lumbricid earthworms, but selected the more conspicuously coloured species over the cryptic one. The detailed research by M. W. Pienkowski and other scientists has shown that in intertidal areas Common Ringed and Grey Plovers have their highest intake rates during periods when prey is most active or visible, for example during incoming tides, with calm weather, at relatively high temperatures, and also on moonlit nights. At many of the intertidal sites where the diet and foraging of Grey Plovers has been studied, they indeed feed only on the active prey types, polychaete worms and surface-living crustaceans, even though such prey may comprise only a small fraction of the benthic communities at these sites. Bivalves are buried too deeply and snails may behave too sluggishly to be available for a group of birds that have specialized on actively moving prey. In terms of foraging, the most ex-

ceptional true plover is undoubtedly the Wrybill. Amazingly, it has adapted to catch invisible and static invertebrate prey under stones, in the braided rivers of New Zealand's South Island.

As a way of enhancing the availability of their active prey, most lapwing and plover species occasionally make tapping or trembling movements with one of their feet, usually alternating both legs. The movements disturb the invertebrates living on the surface, which then make themselves visible by moving away. To buried invertebrates, such as earthworms, the sounds or pressure ripples in the substrate produced by trembling of tapping plovers may signal "mole". As a consequence these animals creep towards the surface to escape from the putative mole, only to be captured by the plover waiting overhead. Foot-trembling is often shown by lapwings and smaller plovers feeding in grassland, but similar behaviour is displayed on intertidal mudflats, for example by Common Ringed Plovers and Lesser Sandplovers; it is rarely used by Grey Plovers. During foot-trembling one leg is lifted up slightly, while the toes vibrate the upper layer of sediment. Rather than stirring up the substrate, the trembling toes may elicit movements in small worms, such as nematodes, living close to the surface. It is likely that plovers are able to detect worms that are forced to move in this way much more easily than untriggered, stationary ones.

Typical plovers use foot-trembling to increase their capture success and intake rate, but Magellanic Plovers are unique in making prey items available by digging in sandy substrates with their strong feet. They dig by rapid backwards and sideways kicks, alternating the feet at a fast rate of about seven kicks per second, while small quantities of sand fly around; in this process, the birds look like tiny dogs digging up bones! At the same time, they pirouette rapidly over the shallow holes and peck rapidly, rather like a phalarope that picks tiny items from the water surface. According to J. R. Jehl, digging for food would be derived from nest building behaviour such as clearing a scrape, rather than from foot-trembling.

During the breeding season, plovers tend to forage individually, in the neighbourhood of the nest or young, within the breeding territory or slightly beyond. Non-breeding plovers do not usually forage alone, but nor do they do so in very tight aggregations. Plovers tend to feed dispersed. Foraging in groups is beneficial by reducing the chance for an individual plover to fall victim to birds of prey. This might be so for purely statistical reasons, such as finding safety in numbers by being one possible target among many others, or because in larger groups with an increased overall vigilance potential predators are detected earlier, or both. Birds can also benefit from each other's experiences to find the best feeding locations. On the negative side, birds in tight flocks disturb each other's prey. Especially in plovers, birds that hunt for active prey crawling along the surface, the presence of other predators will disturb prey and depress its activity, hence lowering individual feeding success.

Interference during foraging is probably the reason that plovers usually spread themselves thinly over the feeding areas. An additional drawback of feeding in flocks is that high densities invite the stealing of prey, especially when food items are large and require long handling times. Such kleptoparasitism can be inflicted by conspecifics or by other species. An example of the latter is provided by Common Black-headed Gulls (*Larus ridibundus*) which steal earthworms from Northern Lapwings and Eurasian Golden Plovers in European grasslands. The presence of these gulls in a flock reduces the tendency of plovers to take large earthworms, and thus see their intake rate reduced. Common Black-headed Gulls are, however, highly vigilant, and this may partly compensate the cost of their kleptoparasitic behaviour. A contrasting observation from southern Africa is of Spur-winged Lapwings interfering with the courtship feeding of Grey-headed Gulls (*Larus cirrocephalus*). The lapwing chases away the female gull just when she has incited her male to regurgitate the content of his crop: delivery being under way, there is little that the excited male can do, thus presenting the lapwing with his offering!

A clear case of feeding dispersion and the avoidance of interference and prey depletion is the defence of feeding territories, areas exclusively exploited by a territory owner. Such birds may tolerate shorebirds of a different kind, though, and there are cases where Grey and Common Ringed Plovers, feeding on the same stock of polychaete worms, occupy completely overlapping territories. A feeding territory can be a small area of grassland defended during successive daytime periods, or an area of intertidal mudflat defended during successive low tide periods. Although territorial plovers spend 5-10% of the potential feeding time on the defence of their territories, the observations of J. K. Turpie on Grey Plovers in southern Africa show that their higher intake rates, when compared to nearby non-territorial birds, more than compensate for this time loss. Nevertheless, both territorial and non-territorial Grey Plovers have to feed during daytime and night-time low water periods in order to satisfy their daily energy requirements, a condition that has also been noted for north temperate feeding areas.

Most shorebirds, plovers as well as sandpipers, live in habitats where they are fully exposed to wind and rain. In the tropics,

Crabs can form a large proportion of the Grey Plover's diet. Only the soft parts are swallowed. First the crab is shaken vigorously in order to dismember it, after which the carapace is removed, revealing the digestable parts of the prey. The reward may be relatively high, but handling a crab is a tiresome task and foraging on soft-bodied prey, such as polycheate worms, may be more profitable. In order to assure their food supply, Pluvialis *plovers often hold feeding territories on their wintering grounds.*

[*Pluvialis squatarola*, Ceará, north-east Brazil. Photo: Luiz Claudio Marigo]

Plovers are frequently observed trembling with one foot, or tapping the ground alternately with each foot. In this way prey hidden just below the surface or taking shelter in the vegetation may be provoked into revealing itself. The Three-banded Plover is thought to feed by night, as well as by day. Nocturnally feeding waders have been shown to possess relatively more rods in the retina, thus gaining enhanced night-time vision. Nevertheless, the food intake rate is usually lower during the night.

[*Charadrius tricollaris tricollaris*.

air temperatures are such that no extra energy is required to maintain a high body temperature of 41°C, even in strong winds. In all other parts of the world, plovers face considerable heat loss and have a high energy requirement in order to keep up body temperature. High rates of energy expenditure not only require these plovers to eat relatively large quantities of food per day, but also force them to maintain a digestive system that is capable of processing so much food. In turn, sizeable processing machinery leads to a further increase in energy requirements, since the metabolically active tissue of which it consists needs to be maintained. For this reason plovers from the tropics that need to process less food, expend energy at lower rates than those from further north or south, even when both are asleep under thermoneutral conditions.

A low metabolism in the tropics has an additional advantage. The high solar radiation in combination with high air temperatures can load plovers with so much heat that they need to evaporate body water so as to maintain a core temperature of 41°C. In marine environments this is particularly problematic, since all ingested water, even the body water of prey, is saline. Birds need to get rid of the salt by way of their nasal salt glands, in order to produce osmotically free water for evapo-transpiration. Salt excretion is an intense metabolic process, during which yet more heat is produced, all of which leads to a chain of events that can easily result in overheating and death. Plovers in tropical environments often have relatively large salt glands, but they may additionally seek shade in the middle of the day, and preferentially feed on prey with low salt loads.

In general, however, plovers do not drink much. In most circumstances, they probably obtain sufficient water from the body fluids of their invertebrate prey. A plover drinks by inserting its bill horizontally in the water, then lifting its head and bill to swallow the water in the bill. An exception to this drinking style is, yet again, provided by Magellanic Plovers, which appear to drink by making sucking motions, just like doves and pigeons. In this way they may ingest a much higher quantity of water per unit time than typical plovers.

Apart from eating nutrient rich food items, at times plovers also ingest apparently indigestible items, such as little stones and pieces of shell. Grit and shells can be retrieved from gizzards of plovers, and are probably used to grind ingested nutritious food items. Common Ringed Plovers studied in Norway over an entire reproductive cycle by A. Moksnes, ate the valves of freshwater bivalves during the egg-laying phase only. In this case the plovers appeared to compensate a calcium deficit during egg-shell production by the selective ingestion of calcareous material.

Reproduction affects food and feeding in other ways too. Plover chicks, which find food on their own and decide their movements quite independently from their parents, often have a different diet. For example, Northern Lapwing chicks feed on small surface-living beetles and fly larvae living in cow dung, at a time when the chief prey type of the parents is earthworms. The latter are partly obtained by foot-trampling, a technique that is not available to small, light-weight chicks. Probably typical of most boreal and Arctic breeding plovers, Eurasian Dotterel chicks ingest proportionally more soft-bodied types of insects than adults, while the adults may also feed on berries and seeds. Only during mass emergences of tipulids, when the parents and their young feed almost exclusively on this bumper crop, do the two age groups have perfectly similar diets.

Breeding

As in all birds, plovers breed during the time of the year when they are most likely to hatch eggs and raise chicks successfully. This usually means that plovers breed when arthropod food resources reach their peak: during summer in temperate, boreal and Arctic climates, and some time after the rains in the tropics. Latitudinal variations in seasonality also imply that the further north a plover breeds, the later in the year it starts, a relationship that holds good both within and between species. Species with a wide latitudinal breeding range, such as the Common Ringed Plover, delay laying the first egg by 1·6 days per degree of latitude. This means that southerly breeding populations at 56° N in north-east England are raising their first clutch before the Arctic breeders at 72° N in east Greenland have even started breeding. Although most species are single-brooded, plovers can produce additional clutches if the first fails. At higher latitudes the breeding season can be so short that there is little point in producing a replacement clutch if the first has been lost at a late stage of incubation.

In tropical lapwings and plovers, the timing of breeding is strongly influenced by the timing of the rainy and dry seasons, critical determinants of the abundance of insects available for parents and young. It is striking that most African lapwings breed in the dry season, whereas Australian plovers of arid environments breed immediately after the rains. If breeding grounds are otherwise available and open for settlement by competitors, for

Plovers feed mainly on small animals, especially arthropods and worms. One of the striking differences between them and the sandpipers and snipes of the family Scolopacidae is that the plovers essentially forage visually, taking their prey from or near the surface, as opposed to the tactile feeding typically used by members of Scolopacidae. In conjunction with this, almost all plovers have rather short, fairly stubby bills. Another consequence of their visual foraging is that they tend to feed some distance apart, as the close proximity of another feeding bird may disturb prey and drive it into hiding, or, quite simply, the prey item may be caught by the neighbouring bird. The Blacksmith Lapwing tends to forage along margins of water, or in ploughed fields or areas with short grass. It uses the typical plover technique of running along in swift bursts, pausing and perhaps pecking at a food item, and then following this with another quick run.

[*Vanellus armatus*. Photo: Heinrich van den Berg/Bruce Coleman]

example containing sufficient food and not covered by snow, plovers may establish their territory long before starting to breed. For example, male Northern Lapwings may defend their territories more than a month before clutches are laid. G. Högstedt showed that in southern Sweden the time between territory establishment and laying was a function of food availability; the higher the densities of earthworms, the shorter the interval. In the Netherlands, A. J. Beintema and associates have shown that between 1910 and 1970 Northern Lapwings started to breed about three weeks earlier. This represents a response to an advance in the seasonality of their earthworm prey, as a consequence of changed farming practices, such as increased gifts of fertilizer and reduced water tables, that stimulate an earlier growth of grass in spring.

The vast majority of plovers have a socially monogamous mating system, but as intensive studies on individually recognizable birds are tending to uncover more variability than initially reported, plovers may have some interesting surprises in store. For example, Northern Lapwings have long been thought of as monogamous birds. Yet, as a rule, a male Northern Lapwing will try to establish bonds with more than one female, even though most males remain monogamous in the end. Good percentages of bigynous and even trigynous males are now reported for some regions, and polygyny is also suspected in Eurasian Golden and Caspian Plovers. As another example, the Kentish Plover was long considered a monogamous species, but a recent flurry of detailed observational studies of individually colour-marked birds, initiated by C. M. Lessells, has revealed that sequential polyandry, whereby a female gains access to more than one male in the course of one season, and polygyny also occur quite regularly when females or males desert their partners soon after hatching, and turn up somewhere else with new partners. That mate change is not documented more frequently in Kentish Plovers may reflect the high degree of dispersal after desertion, rather than any rarity of the phenomenon. The considerable distances moved between breeding attempts can be illustrated by a pair of Kentish Plovers, which started a clutch in southern Sweden but left the area when the clutch was lost. In the meantime, the male had mated with a second female, but he deserted her with a full four-egg clutch to nest again with his first female 280 km to the south-west in Schleswig-Holstein, northern Germany; here the pair successfully hatched a brood, and returned a year later.

With respect to mating system, Kentish Plovers actually occupy an intermediate position. Mountain Plovers (*Charadrius montanus*), and perhaps Lesser Sandplovers too, have a rapid multiple-clutch system that may be accompanied by sequential polyandry, whereby the female leaves her first mate soon after the completion of "his" clutch, to start another by herself. In the Eurasian Dotterel, female reproductive investment usually ceases completely once a clutch is complete. The male is in charge of all parental care, during incubation as well as after hatching, so once a clutch is complete the female starts to search for a new male. In the Scottish Highlands, Eurasian Dotterel females, the larger and more colourful sex, compete for males on mating arenas. A female gains exclusive access to a male by isolating him from the rest of the flock, having to deter attacks from other females during courtship. In Norway, Eurasian Dotterels arrive back from their wintering areas already paired, so courtship must have taken place earlier in the season, perhaps at staging areas during northward migration. Males of this species try to ensure paternity of the clutch in which they invest so much, by controlling the copulations during the few days that they are accompanied by a female. In monogamous systems, incubation is usually shared fairly equally by the two sexes, but in general female plovers have a tendency to leave the chicks before fledging, while males continue to give parental care until, and even after, the young can fly. In an experimental study of Killdeers, D. H. Brunton showed that two adults were needed for successful breeding; lone males were able to hatch chicks while females were not, but no individual managed to raise offspring alone.

Although most plover species defend exclusive territories during the breeding season, there are several in which these territories are quite small and are clumped together. Especially when breeding territories are small, most feeding takes place outside the territory. Northern Lapwings and Kentish Plovers quite often breed "semi-colonially", although this pattern is most striking in Sociable Lapwings. These small lapwings live up to their name by nesting in scattered "neigbourhood groups" of up to 20 pairs, with several such aggregations of nests within an area of a few hectares. Aggregation allows birds to defend the area jointly against aerial and terrestrial predators. This benefit may explain why other wader species are attracted to breed close to concentrations of nesting Northern Lapwings.

Although both sexes may help in the defence of a breeding territory, males usually take on the larger share or indeed the

The "Broken-wing Display" is commonly performed by several ground-nesting species. In an attempt to distract attention from its nest, this Black-fronted Dotterel is fluttering its wings and fanning its tail, while moving away from the nest. Overall, eggs appear to have a better chance of survival than chicks. Eggs usually fail through predation, trampling or other dramatic events, such as flooding. During the chick phase factors such as weather and feeding conditions can become more critical.

[*Elseyornis melanops*, Australia.

A Banded Lapwing displays near its nest, showing off its highly conspicuous white underwing. As an inhabitant of arid regions with irregular rainfall, this species reacts quickly to the rains. Pairs may select a territory only two weeks after the first rains have fallen. At such times, the birds can be more or less assured of enjoying good feeding conditions around the moment when the chicks hatch.

[*Vanellus tricolor*, Australia. Photo: T. & P. Gardner/ FLPA]

whole task on their own. In the Magellanic Plover territorial defence is peculiar, since it is often performed by both members of the pair acting together as a unit. In this respect its territorial behaviour differs notably from the territorial displays of typical plovers. It reminded J. R. Jehl of the piping displays of oystercatchers. When an intruder appears on a defended beach, the residents immediately run towards it, side by side with their heads held low and their bills pointed forward, calling aggressively.

Plovers do not build impressive nests. Although marsh-breeding lapwing species may pull together heaps of plant material to establish a nest on top of the mound, plover nests usually consist of a shallow scrape only. This scrape may be lined with small pebbles or shell fragments on the shore, with grass leaves in a meadow, or with pieces of lichen or moss on moorland and tundra. Several beach-breeding *Charadrius* species lay their eggs in a shallow depression in the sand.

Plovers lay their eggs at one or two day intervals. During actual egg-laying, a female stands on her "heels" in quite an upright manner, gaining additional support from slightly opened wings pressed firmly on the rim of the nest. Plover eggs have a pale ground colour that varies between whitish, beige and green, and are covered with dark spots and scribbles that vary in size and density. Clutch size varies between two and four eggs. Sometimes more than four eggs are encountered in a nest, but this always indicates that two females have laid there. Since the variation in colour and pattern of eggs, at least in Eurasian Dotterels, is more uniform within than between individual female plovers, eggs can often be told apart as issuing from different females.

Although four is the commonest modal clutch size in plovers, many species lay fewer eggs, usually three. Reviews by G. L. Maclean and J. R. Walters show that in northerly breeding species a clutch of four is commonest, while in the tropical and southern regions three eggs appear to be the rule. Also the Vanellinae tend to have larger clutches than the Charadriinae. Why restrict clutch size to three or four eggs? Does it represent a phylogenetic constraint, or has it functional significance today? The traditional explanation that food available to the laying female limits the clutch size is not well supported by the available data; Northern Lapwings can easily be induced to lay more than four eggs if the initial eggs are removed, and there are no indications that foraging time is at a premium when eggs are being formed. The number of eggs that can be incubated successfully may be limited by the size of the brood patch; and the typical pear shape of plover eggs may allow an economically tight arrangement under a brooding plover, but only when there are three or four eggs. Small clutches may also be an adaptation to high rates of nest predation since larger clutches are exposed to the risk of predation for longer periods, and small clutches are replaced more easily if lost. Finally, there may be a limit to the number of chicks that can be successfully tended by the parent or parents. For the moment, the worldwide data set is too fragmentary to tell which of these functional hypotheses carries most of the truth.

Once the clutch is complete, plovers incubate for 21-30 days before the eggs hatch; small plovers require a shorter period than

Plovers defend their territories vigorously against conspecifics. If vocal and visual displays are insufficient, a chase can develop, or even an aerial pursuit-flight. Disputes with other species are less common, but when a breeding bird feels its territory to be threatened, it may take similarly violent action, as amply demonstrated by this Eurasian Golden Plover, in the process of "bombing" a Eurasian Curlew (Numenius arquata).

[*Pluvialis apricaria*. Photo: Michael Callan/ FLPA]

Calling loudly and continuously, making a sound like a blacksmith's hammer hitting an anvil, a Blacksmith Lapwing shows itself to be quite undaunted by a sizeable warthog (Phacochoerus aethiopicus) *that is wandering too close to the lapwing's nest for comfort. Since many species of lapwings breed on open grassy fields where herds of cattle or wild ungulates commonly graze, a large proportion of clutches may be trampled.*

[*Vanellus armatus*. Photo: Philip Perry/FLPA]

the large species. Compared to similarly-sized shorebirds of other families, these incubation periods are rather long. Long incubation times may have evolved to ensure that chicks hatch fully mature with respect to neural function, so that they are capable of detecting and capturing highly mobile insects from the start. For plovers breeding in temperate to Arctic climatic regions, the challenge is to keep the eggs warm. This is best achieved by incubating for a maximum of time, an activity shared by both parents in most species. Single incubators, such as male Eurasian Dotterels, indeed face difficulties in completing this task, even though they care for a three- rather than a four-egg clutch. Plovers in tropical and arid environments face the reverse problem, at least during the day: they have to ensure that the eggs do not become too warm. Again, the best way is to provide the eggs with a good thermal insulator or a shading device, such as the body of a living plover, during such stressful periods. If this does not suffice, or if the incubating birds become overheated themselves, lapwings breeding in hot environments may soak their belly feathers, and return to the nest to wet the eggs and the nest. Alternatively, the eggs can be buried under a layer of sand, a solution used by White-fronted Plovers. Egg-covering serves the dual function of concealment from predators and protection from the sun. In Wilson's Plover, also breeding on tropical shores, the eggs are incubated continuously: males incubate mainly at night and females during the day; relief takes place at low light intensities at dusk and dawn, perhaps to reduce the danger of nest predation.

Although disputes over territory ownership can lead to vigourous confrontations, like this one between two male Northern Lapwings, physical contact is rare. Once a male has established a territory he remains in permanent residence to fight off intruders and guard his mate, and he attempts to expand it at the expense of neighbouring lapwings. The female will help to defend the borders after she has laid the eggs. Territorial defence becomes increasingly directed towards potential predators rather than conspecifics.

[*Vanellus vanellus*, Warwickshire, England. Photo: M. C. Wilkes/ Aquila]

After three or four weeks of incubation the eggs pip, and after another day the chick works its way out of the egg by cutting the shell open with the small egg tooth on the tip of its bill. As soon as the eggshell is free of the wet chick, it is carried away by the parent on duty. O. Moedt photographed Northern Lapwings flying off with eggshells that were then buried in the mud of a nearby ditch. The white insides of empty shells might attract the attention overflying predators, such as corvids, to the nest-site. As soon as all the eggs have hatched, usually within one or two days, both chicks and adults leave the immediate vicinity of the nest. Broods may wander over large areas, each day covering several 100 m or more. In arid regions, several families may come together in loose flocks at moist places. Due to confusion of nests, mixed broods of Common Ringed and Little Ringed Plovers (*Charadrius dubius*) occur in which the foreign young are apparently adopted and raised successfully.

The downy chicks of plovers, studied in detail by J. R. Jehl and J. Fjeldså, have proportionally large rounded heads, very short bills and strikingly large and strong legs and feet. The down is dense, woolly and short, with a pebbly colour pattern composed of finely stippled upperparts and a prominent black band bordering the white underparts. Some species have light coloured terminal "puffs" attached to the downy feathers, which gives them

Plover nests are usually no more than simple shallow scrapes in the ground. They are not lined with insulating material as in many other birds. As plovers breed in open habitats, without shelter close by, the nests would be very conspicuous if lined with plant material. Instead, some material from the immediate vicinity may be added to the nest to improve the camouflage, for example, in the case of coastal nesters, some shells or pebbles. This beach-nesting Red-capped Plover relies heavily on the camouflage of its eggs and of its own plumage.

[*Charadrius ruficapillus*, Australia. Photo: Darran Leal/Auscape]

a densely stippled moss-like appearance. The dorsal markings are usually irregular and faint, but may form two parallel central dark bands, or one broader one, changing to an irregular row of U-shaped marks toward the rump. With few exceptions, the nape is white, heavily bordered by dark feathers from the crown, and this contrasting collar stands out when the chicks are active and move about with their necks erect. Independently and actively foraging plover chicks at a distance are best discovered by the collar, and signal their whereabouts to their vigilant parents in this way. When a chick crouches as a response to the alarm calls of its parents, it withdraws its neck tightly against the body so that the collar is hidden. The downy chicks of Magellanic Plovers have a colour and pattern unique among all waders (Charadrii). The head, face, back and upperwings are greenish grey, tinged with gold; the neck is greyish and the underparts white except for a golden patch on the breast. There is no dorsal pattern except for a short dark line on the head, and the upperparts show a sparse scattering of white-tipped feathers that are longer than average.

Plover chicks are precocial and feed for themselves, but parental care consumes considerable time. This time can be partitioned in three components. First, the chicks have to learn the dangers of their world, including raptorial birds, humans, other predatory mammals, cars and so on; plovers show a high level of vigilance and communication with their chicks which is maintained until they can fly. A substantial amount of time is also devoted to active parental behaviour, such as leading, following and gathering young. The gathering of chicks is usually the preamble to the third time cost activity, brooding. In open, sun-baked habitats, young birds run the risk of overheating, and parents may provide shade and a cooler thermal environment by brooding the chicks. In very cold weather, plover chicks need to be brooded at regular intervals so as to heat them up to normal body temperatures of about 40°C. This is because plover chicks are thermolabile. Over the first two to three weeks of their life they are not able to keep up their body temperature fully when foraging alone in the cold. In the course of the breeding season this may lead to bizarre scenes when three or four large chicks that have survived to almost three weeks of age and are close to fledging, want to be brooded by one of their parents. In such cases the adult is almost lifted off the ground! Although still competent and active at body temperatures as low as 30°C, at a few degrees less the chicks become lethargic. The younger the chicks and the colder the weather, the longer they have to be brooded by a parent, and the less time there is for feeding. When young Northern Lapwings are not able to feed for periods longer than five hours per day, they can not sustain growth and eventually die from starvation.

Compared to those of sandpipers, plover chicks show an extended period of thermolability, combined with slow growth rates. Their lower metabolism has the benefit of considerably reducing the energy costs for growth, and it increases the capacity of chicks to survive temporary food shortages or inclement weather. It has the distinct disadvantage that chicks are dependent on parental care for such a long time, a factor that operates most severely in cold environments. If the plover family has indeed a tropical origin so that breeding at Arctic latitudes is a derived strategy, then relative growth rates may be "phylogenetically inert", that is not able to evolve into a pattern that is better suited to colder climatic conditions.

In the aberrant Magellanic Plover, clutch size is usually two eggs. Each egg comprises about 15% of the adult body mass, which is rather less than the 20-30% that is usual for typical plover eggs. The most striking characteristic of the small chicks is their general weakness; they are far less agile than chicks of typical plovers of the same age. The parents also feed the chicks, carrying the food in the extensible crop, a feature otherwise unknown in the Charadriidae. The growth rate of Magellanic Plovers is even slower than in other plovers and they can not fly until they are four weeks old. Even then the chicks remain associated with the parents, and may still be fed until they are 40 days old. Also unlike typical plovers, Magellanic Plovers show no distraction displays, either during incubation or when caring for chicks of any age.

In the nest, the daily survival rates of eggs are usually close to 99%. Over incubation periods of 25-30 days this yields overall nest survival rates of 70-75%. The daily survival rates of chicks are usually somewhat lower than those of eggs, an average of 96% per day leading to a chick survival of 25-30% over the 35 days from hatching to fledging. These values are just sufficient for Northern Lapwings in Western Europe to sustain their population sizes. It is interesting that in temperate as well as Arctic

Birds from the tropics have to cope with problems caused by high temperatures. Moreover, the open habitats where plovers live do not offer any protection from the blazing midday sun. Incubating the eggs or leaving them in such circumstances put the fertility of the eggs at risk, so, instead, the eggs must be protected from the sun's radiation by casting some shade on them, as demonstrated by this Yellow-wattled Lapwing. Some species may even wet the eggs by moistening their breast feathers, thereby enhancing heat loss through evaporation.

[*Vanellus malabaricus*. Photo: Vivek Sinha/ Survival Anglia/ Oxford Scientific Films]

regions, the population cycles exhibited by voles and lemmings influence breeding success of plovers. In years when vole and lemming populations reach a peak, potential mammalian predators such as ermines and foxes have high reproductive success, and show little interest in searching for plover eggs. During the subsequent breeding season, when voles or lemmings are almost absent, the then abundant mammalian predators are forced to switch to alternative prey types, and few shorebird eggs survive. This may be the reason why in the Netherlands egg survival of Northern Lapwings cycles in concert with vole populations, while in South Africa the years when large numbers of juvenile Grey Plovers arrive from the Siberian hatching grounds correspond with the years that the lemmings peak in Arctic Siberia.

Although small plovers may live for 10 years or more and large plovers for 20 years or more, most individual plovers that have survived to fledging do not reach such ages. The few studies of survival rates in plovers indicate considerable variability, partly due to methodological differences, with estimates ranging between 70% and 91%. During the first year, survival is always lower than later in life. A detailed study of Northern Lapwings by W. J. Peach and colleagues has shown that survival over the first year is 59·5%, whereas later in life 70·5% of the birds survive each year. In juveniles, as well as adults, survival is closely correlated with winter temperatures and rainfall: the warmer and wetter the winter, the higher the survival. Since 1960 adult survival rate has increased to 75·2% per year, a result of reduced hunting pressure in Europe. For this reason the average life expectancy of a Northern Lapwing has improved from 2·4 years during the first half of this century to 3·5 years in the second half. Recent declines in the British population must thus be due to poor breeding success, as a consequence of increasingly unfavourable agricultural practices. In the Netherlands, where lapwing populations appear stable, the increased survival apparently compensated for reduced reproductive rates.

The degree to which adult and juvenile plovers will return to the same breeding and wintering areas in successive years has attracted few comprehensive studies. Site-faithfulness will be a function of the environmental variability of the breeding and wintering areas, and the costs involved in making a move. Costs and benefits may differ between the sexes, territory-holding males usually being more site-faithful than females. Resident plovers, almost by definition, will tend to be more site-faithful than migratory ones. But some highly migratory species, such as Grey and Pacific Golden Plovers, are known to be very faithful to both breeding and wintering sites, in the latter case especially those birds that are territorial. Individual Grey Plovers on the Wash in eastern England may use the same high tide roost for several successive winters. Northern Lapwings mostly return to the previous breeding areas, and their natal sites too, but plover species in which there is less of a premium on meeting up with old partners in familiar areas are likely to show relaxed philopatry. Eurasian Dotterels may provide an example. In this species, large shifts in breeding area are the rule, and an individual has even been found changing from Norway to Scotland. In a population of Common Ringed Plovers on the Western Isles of Scotland, D. B. Jackson showed that adult site-fidelity is positively correlated with breeding success, and that birds nesting on unstable habitats show a tendency to move to habitats of equal or better quality in subsequent years.

Movements

The seasonal appearance of golden plovers on oceanic islands, at distances of 4000 km or more from the nearest landmass, provides excellent evidence that such plovers migrate over thousands of kilometres. In 1910, H. W. Henshaw published such observations for Pacific Golden Plovers on Hawaii. This was later followed by reports suggesting that even longer flights were made over the west Atlantic by American Golden Plovers migrating from North to South America. Golden plovers thus became celebrated cases in the literature on bird migration. In the early 1960's, E. G. F. Sauer made innovative tests on hand-raised Pacific Golden Plovers to show their orientation ability in the presence of different orientational cues, such as the sun and the stars. This intriguing research direction has not been followed up with plovers. A 1967 study by D. W. Johnston and R. W. MacFarlane on the fat content and metabolic rate of Pacific Golden Plovers on Wake Island, a lonely spot in the Pacific between the Hawaiian Archipelago and the Philippines, was one of the first that came up with estimates of the energy costs of transoceanic flights. This research was continued by O. W.

Johnson and co-workers who published detailed accounts on the ecology and physiology of Pacific Golden Plovers migrating between Hawaii and nearby Pacific islands and Alaska.

All these, and many other studies on different plover species, have confirmed the impression that the species belonging to the genus *Pluvialis* are the migratory champions among the Charadriidae. However, some smaller *Charadrius* species, such as Common Ringed Plovers, which also commute between tropical shorelines and high Arctic breeding areas, follow quite closely on their heels. At the opposite end of the spectrum are most members of the subfamily Vanellinae and some smaller plovers that live rather sedentary lives, often in the tropics and in isolated island habitats, or that carry out short altitudinal migrations. Most non-migratory plovers demonstrate this life history feature by the rounded shape of their wings: long, slender wings being favoured for cheap, fast forward flight. The round-winged Northern Lapwing provides something of an exception, as the northernmost breeders migrate quite far, although they cover the distance in short hops.

The long distance migrants within the Charadriidae all make seasonal north-south movements, radiating away from the extensive temperate, boreal and Arctic breeding areas in the Northern Hemisphere. With respect to the distances travelled, they are followed by several species in the Southern Hemisphere. Double-banded, Two-banded (*Charadrius falklandicus*) and Rufous-chested Plovers (*Charadrius modestus*), Tawny-throated Dotterels and Wrybills, for example, all migrate north of their breeding grounds in the austral winter, some birds moving up to several thousand kilometres; in the process, Double-banded Plovers cross the 1600-2000 km wide Tasman Sea between New Zealand and Australia.

Then there are the movements of equatorial and subtropical species of lapwings and plovers in South America, Africa and Australasia, migrations about which very little is known. In arid regions, these movements are probably mediated by the occurrence of regular or irregular cycles of rainfall and fires influencing plant growth, and thereby insect food abundance and nesting habitat. Recent studies in Australia, carried out by a large network of volunteers, have shown that only two of the four resident inland plover species studied, the Red-kneed Dotterel and the Red-capped Plover, make large-scale movements to and from regions with heavy rainfall. The other two, the Masked Lapwing (*Vanellus miles*) and the Black-fronted Dotterel, mostly appear to live sedentary lives in the more permanent wetland areas in eastern and central Australia, and are not affected by heavy rains elsewhere.

For some bird species, specific parts of the breeding grounds are connected with specific wintering areas, via the flight routes of individual birds. Grey and Pacific Golden Plovers have very extensive breeding and wintering ranges, but up to now the ringing efforts have failed to show much substructuring in the populations of these plovers. Grey Plovers breeding in Arctic Canada move southwards, to winter along the coastlines of Central and South America. These birds are separate from the Grey Plovers wintering along the shores of the east Atlantic, from Scotland to South Africa, which all appear to breed in Arctic Siberia, many of them on Taymyr Peninsula. Common Ringed Plovers wintering in West Africa share breeding origins as far apart as Greenland, Scandinavia and Siberia, whereas British breeding birds remain in Britain, migrating over short distances only. In Western Europe, Northern Lapwings and Eurasian Golden Plovers winter as far north as they possibly can, only moving south when pushed by the frost-line. Of the two, the somewhat smaller Eurasian Golden Plover is more sensitive to cold weather and departs southwards earlier.

In preparation for the flights to cover the long distances between suitable staging areas, along the route between the southern wintering and the Arctic breeding grounds, plovers must store considerable amounts of fuel before take-off, sometimes doubling in mass over a period of one to two months. Although a large proportion of the mass increase is fat, which contains eight times as much energy as proteinaceous muscle and organ tissue, there are changes in the size of the organs as well. During the refuelling phase, the digestive tract increases in size, and before take-off for long distance flights the breast muscles show hypertrophy. A detailed study of the compositional changes in Eurasian Golden Plovers, comparing the mass gains before the winter and the spring peaks in weight, indicated that most extra winter mass consists of fat, but that most of the mass gain in spring consists of fat-free tissue. Most of the fat is stored in a fairly homogeneous layer directly under the skin, as if wrapped around the body. Even in winter, such subcutaneous fat is unlikely to

The eggs require about three to four weeks of incubation before they hatch. Once the chick has left its egg, the remains of the shell are conspicuous with the white lining, a stark contrast with the well camouflaged outside of the shell. Therefore, the parent bird promptly removes the eggshells from the nest before they attract predators. There is even evidence of Northern Lapwings (Vanellus vanellus) *burying the shells in mud.*

[*Vanellus indicus aigneri*, Hafeet, Oman. Photo: Hanne & Jens Eriksen/Aquila]

Early on in life, chicks of precocial birds develop homoiothermia, the ability to keep the body temperature at a constant level. Nevertheless, as they still lack an insulating plumage, for a long period they remain dependent on their parents in order to maintain a high enough body temperature, and frequent solicit brooding by burrowing under an adult in the manner of these Eurasian Golden plover chicks. Young hatched at Arctic or temperate latitudes have to find good balance between the time spent being brooded by their parents and the time dedicated to feeding. During cold or wet spells brooding time may increase to a level that does not leave enough feeding time for the chicks to survive. In temperate regions this can be a crucial factor determining fledging success.

[*Pluvialis apricaria apricaria*.
Photo: John Hawkins/FLPA]

fulfill an insulatory function, since in air the insulative capacity of plumage is an order of magnitude larger than that of fat.

A successful migration, one that is survived by its participants, can lead to a successful reproductive season. Especially for high Arctic breeding plovers that experience a short summer season, a proper timing of different migratory activities such as fuelling, refuelling and flying, is of critical importance. The further the wintering areas are from the breeding grounds, the more difficult it may be to achieve an optimal timing of migration, but some individuals will have an easier time than others. In the case of Grey Plovers wintering in southern Africa, about 14,000 km away from their Siberian breeding grounds, territorial individuals preparing the northward flight achieve higher intake rates than non-territorial birds. For this reason, territorial Grey Plovers fuel faster and are the first to depart from South Africa, thereby building in some spare time for setbacks further along the route. Grey Plovers that defended a territory in South Africa are probably the earliest to arrive on the breeding grounds. However, non-territorial birds are quick to gain advantage of the departure of territory-holders, moving onto the vacated high quality feeding areas, and partially making up their time deficit regarding fuel storage.

Relationship with Man

The attitude of mankind towards plovers has mostly been of the exploitational kind. Only in the late twentieth century does a rather appreciative and even respectful attitude seem to be developing towards breeding shorebirds in general, and species like the Northern Lapwing in particular, in segments of the human population of some European countries. This respect is fed by the realization that these large bird populations are negatively affected by a growing pressure on natural environments in this part of the world, but provide something unique that is well worth preserving for future enjoyment.

In the agricultural province of Friesland in the northern Netherlands, the abundant Northern Lapwing, locally known as the "Ljip", is something of a regional symbol. Its flight displays are celebrated in Frisian folk songs, poems and expressions. Northern Lapwings have achieved this status after many centuries of regulated egg-collecting in early spring. The first egg of the season was traditionally presented to the Queen of the Netherlands, a ceremony now abandoned. Although the eggs are no longer brought onto the market either, the collection of lapwing eggs for local consumption is still allowed by law, on

Many plover species return to the same breeding grounds every year. The young, however, more often disperse to sites other than their natal breeding grounds. Of the many open habitats that members of the Charadriidae patronize, beaches are amongst the most typical. The Piping Plover of North America breeds on bare flats, on lake shores and on beaches along the Atlantic coast. The species is classed as Vulnerable, with only some 2000 breeding pairs remaining.

[*Charadrius melodus*, Silgo Beach, Long Island, New York. Photo: Arthur Morris]

the grounds that egg-collecting fosters another tradition, that of protecting wader nests from agricultural onslaughts, such as trampling by high densities of cattle and destruction by grass-harvesting machines. Nests are searched out and firm iron structures are put over them. This effectively prevents trampling by cattle and horses, and warns the mowing farmer of a nest. Breeding success of Northern Lapwings has been shown to improve markedly as a result. In 1994, volunteers protected breeding lapwings and other waders on 1220 km² of grassland, 860 km² of which were in Friesland, where this practice originated 40 years ago.

All lapwing species are exceptionally vigilant. They spot potential predators from distances of 100 m and more. This characteristic has been recognized by farmers in southern Argentina, who in the past kept tethered or wing-clipped Southern Lapwings as sentinels in their farmyards. These lapwings call "tero tero tero" in a loud barking way, as a response to approaches from large animals, humans included. Not surprisingly, a lapwing is onomatopoeically called "Tero" in much of Latin America.

Humans have a long tradition of exploiting plover populations. This varies from the sport hunting of Wrybills by the European settlers of New Zealand, the use of the colourful scapulars and back feathers of shot female Eurasian Dotterels for angling in Britain, and the collection and sale of over 100,000 lapwing eggs per spring season in the Netherlands, to the widespread hunting of the large plover species for fun and for the pot, which continues today in several parts of the world. The intense hunting of shorebirds and other waterfowl in eastern North America in the late nineteenth century almost exterminated the American Golden Plover. It was once very abundant, but by the early 1900's most authors were lamenting the disappearance or drastic decline in numbers of the species at all localities. According to A. C. Bent, the population reached a low point at about 1900, when large flights occurred no more and golden plovers were rarely seen in places where they once abounded. But changes in game laws occurred just in time, and American Golden Plovers showed a strong population increase when the artificially high mortality rate became reduced. Although hunted to a lesser extent, the Pacific Golden Plover did not entirely escape the onslaught. Having been taken as food for centuries by Pacific island natives, heavy sport gunning occurred in Hawaii well into the twentieth century.

In their attempts to shoot as many golden plovers as possible, the market hunters of eastern North America employed techniques that had been in use in Europe for centuries. They used little groups of decoys set out on a field, and tried to imitate the plovers' whistles to attract them close to their hides. Both of these aspects represent basic ingredients of a netting technique that has been used for catching Eurasian Golden Plovers in the Low Countries of Europe since the Middle Ages. This method, called "wilsternetting", is found on paintings of Dutch masters from the sixteenth century and has not been modified since. It involves a large net that, after an initial pull with a rope, is pushed by the wind towards flocks of plovers that have been tempted to land just behind the lying net. The temptation consists of a flock of realistic decoys in combination with one or two captive plovers that flap their wings. The captive birds sit on soft pads attached to a hook with a rope. If this rope is pulled by the catcher the birds are lifted from the ground and start to flap their wings. Flocks of golden plovers are called in from afar with loud imitations of their melodious whistle, made by the catchers on special flutes. The Eurasian Golden Plovers thus caught in the northern Netherlands in the first half of this century were sold to the big cities, notably Paris and London, for consumption. In late autumn and winter this hunt provided the income for a small but dedicated group of people that laboured on farms during the rest of the year. In contrast to the history of American Golden Plovers, neither wilsternetting, nor the shooting that still goes on in Denmark, France and Spain, have ever brought the Eurasian Golden Plover close to extinction; the southernmost breeding populations are now in sharp decline, but there may be other causes.

Market hunting of plovers and many other waterbirds is still an important economic activity, and hence a threat, in parts of the Middle East and Asia. The best information available is from Egypt, where surveys of the bird markets of Port Said and Damietta by P. L. Meininger, W. C. Mullié and their associates have documented the numbers of waterbirds killed each year at the Nile Delta. Plovers comprised only 2-3% of the 260,000-375,000 waterbirds taken annually between 1979 and 1986. However, an annual harvest of about 2000 Kentish Plovers, the plover species taken most, must surely represent a significant mortality factor. In addition, hunters cause much disturbance and thereby lower the carrying capacity of wetlands in subtle ways.

Al over the world man has been, and continues to be, responsible for the destruction or radical alteration of the habitats so often irreplaceable to particular plants and animals. Sometimes his modifications can actually provide new habitat for some other species. Few species may actually respond to these temporary opportunities, but those that do are often extremely successful. Common Ringed Plovers, for example, have adapted with a certain amount of success to breeding at artificial sites, such as gravel pits, reservoirs and playing fields.

Status and Conservation

The one recognized plover species that will fairly certainly not make it into the twenty-first century is the Javanese Wattled Lapwing (*Vanellus macropterus*), historically an endemic of the Indonesian Archipelago. It was last observed on the south-east coast of Java in 1939. Javanese Wattled Lapwings probably succumbed under the combined pressures of degradation of breeding habitat by intensified agricultural practices and hunting.

Other island populations of plovers are threatened with extinction too. The two populations of Red-breasted Plovers, living on Stewart Island and North Island, New Zealand, have shown drastic declines in numbers and range over the past 150 years, with some 65 birds surviving on the former and 1400 on the latter; as a result of predation by introduced rats and cats, the effective breeding population on Stewart Island is now reduced to 12 pairs. Another New Zealand endemic, the Shore Plover, living on a small island of only 2 km² in the Chatham group, is doing slightly better, with 40-50 breeding pairs. The total population remained stable between 1969 and 1993, and has probably been constrained by the availability of suitable habitat ever since Shore Plovers became extinct on North and South Islands more than 100 years ago. Habitat also seems the limiting factor for the third plover species classified as Endangered, the St Helena Plover, of which about 300 birds were counted during the last survey in 1993. An island dweller that is considered Vulnerable is the Black-banded Plover, a rare species limited to a small region of dry saline lowlands in southern Madagascar. It may be genetically swamped or outcompeted by its closest relative, the common Kittlitz's Plover.

Although plover populations living on islands may run the greatest risk of extinction due to their restricted distribution, there are several continental and more widespread plover species that give cause for concern as well. Sociable Lapwings once lived quite widespread on the steppes in southern Russia and Kazakhstan. They are now in sharp decline due to changes in land use for agricultural reasons, and, perhaps, desertification, and the species is considered Vulnerable. In North America, two Vulnerable plover species are the Piping Plover, a bird of open, often saline, lowland habitats, and the Mountain Plover, which breeds and winters in short-grass prairies. In the last century both species were still very widespread, but they are now in steep decline, as a consequence of changes in land use and, perhaps, hunting. Also Vulnerable is the Hooded Plover, a southern Australian endemic shoreline species that is threatened by increased human use of beaches and nest predation by gulls and introduced mammals. The other Vulnerable plover is the Wrybill of New Zealand. Hunted until the 1940's for sport, the population of Wrybills subsequently expanded until the 1960's, when it stabilized at 5000-6000 birds. However, the entire population might be at risk if the breeding sites on braided rivers in the Canterbury and Mackenzie Basins of South Island were to be modified by the development of hydro-electric schemes.

There are a few widespread inland east Asian plover species about which precious little is known, but which might well be in the danger zone. One is the Grey-headed Lapwing of Manchuria and neighbouring areas of China and the Russian Far East. There are indications that the population of less than 20,000 birds is decreasing; land use changes and the application of pesticides and herbicides on the tropical south-east Asian wintering grounds could pose a serious threat for this species. The Long-billed Plover has a slightly larger but overlapping range, perhaps an even smaller world population of less than 10,000 birds, and very similar problems. In both species, the resident populations in Japan are of unknown but surely small size, but may be relatively safe. Grey-headed Lapwings and Long-billed Plovers require urgent attention, as does another resident species from south-east Asia, the coast-living Malaysian Plover. Its total population size is also under 10,000 birds, but only 410 individuals were counted during the most recent international Asian Waterfowl Census.

In South America, the Diademed Plover, a species restricted to the Andes, has an unknown but probably small population. It lives in areas of difficult access, and its status needs clarifica-

tion. The Magellanic Plover, endemic to Patagonia, may have suffered badly from the introduction of sheep to Tierra del Fuego 100 years ago. Magellanic Plovers make no attempts to distract potential predators or herbivorous intruders from their nests or chicks. Since the shores of pools where they breed are paths for hordes of sheep, trampling is still an important cause of egg loss. With a total population of under 1500 individuals, this is a potentially vulnerable species. Certain management practices, for instance keeping sheep away from breeding sites during the nesting season, may be practical, and even critical, to safeguard this weird and wonderful species.

Some plover species are quite numerous. There are more than 250,000 Common Ringed Plovers and 168,000 Grey Plovers wintering along the east Atlantic. In Western Europe, Grey Plovers are on the increase. In Britain numbers have quadrupled over the last 25 years to more than 40,000 birds. Across the Atlantic, along the eastern seaboard of Canada and the USA, Grey Plovers have shown serious declines over the same period. In Europe, Eurasian Golden Plovers and Northern Lapwings are even more numerous than Grey Plovers, approaching a million birds or more each. During the last decades, Northern Lapwings have greatly increased their breeding range in Eurasia towards the north and east, apparently in response to climatic amelioration.

In spite of the fact that some species are very abundant, specific populations or races of the same species may not do so well. The nominate southern race *apricaria* of the Eurasian Golden Plover has become extinct in the southern part of its range, and is declining in Scotland and parts of southern Scandinavia; it may now be seriously threatened. On the basis of systematic interviews with old practitioners of wilsternetting, J. Jukema showed that a sizeable population of Pacific Golden Plovers must have wintered in Western Europe during the first half of the present century. Despite much better coverage than before, Pacific Golden Plovers have only very rarely been captured or sighted since 1950. The original population, probably breeding in western Siberia, may have gone extinct unnoticed.

Man-induced habitat modifications can also present plovers with opportunities. For example, the large populations of Northern Lapwings inhabiting parts of Europe and northern Asia owe their presence to the disappearance of forests and their conversion to cultivated land, a process that still goes on in Siberia. Also in Europe, the Little Ringed Plover has benefited from the many newly exacavated sand and shingle quarries that provide excellent breeding habitat.

That even an abundant species may be open to extinction is shown by the recent history of the American Golden Plover. A reduced annual survival rate due to intense seasonal hunting certainly brought this long distance migrant to the brink of extinction at the turn of the century. In Europe, hunting has been shown to decrease the annual survival rate of Northern Lapwings by 5% or more, to the extent that agriculture-induced declines in breeding success can not be compensated for. Large-scale changes in land use and agricultural practices will continue to pose threats to many plover species, including the presently abundant or widespread ones. Major declines are reported for coastal and inland breeding populations of Kentish Plovers over much of Europe between 1985 and 1995. Coastal species and those which depend on intertidal areas for part of the year, may be jeopardized by land reclamation, human disturbance of breeding sites, hunting, and the predicted fast rise in the water level of the oceans. Plovers need habitat, but so does man. It can only be hoped that an increased appreciation for members of the avian family that characterizes the only birds to survive the crash of a large meteorite at the end of the Cretaceous, the one that wiped out the dinosaurs, may help us to help them survive this time.

The St Helena Plover, endemic to the small, remote Atlantic island of the same name, is Endangered. In 1993, some 315 birds still remained, but numbers seemed to be declining, probably as a result of habitat loss due to housing development. Although the species would appear to be safe from extinction in the long run owing to some of its habitat appearing useless to people, caution is required. With such a small population, the species could be wiped off the map at one fell swoop, for instance by the unintentional introduction of an effective predator.

[*Charadrius sanctaehelenae*, Deadwood Plain, St Helena. Photo: Simon Bannister/ Aquila]

The world's coasts are increasingly being developed by money-makers for intensive human use. Many beach-living plover species, among them the Hooded Plover, have thus lost extensive tracts of potential breeding habitat. Its nests often fall victim to 4-wheel-drive vehicles using beaches as racing tracks, and chicks are sometimes killed while hiding in wheel ruts; the rate of predation of eggs and chicks also increases due to the expansion of scavengers, attracted by the humans.

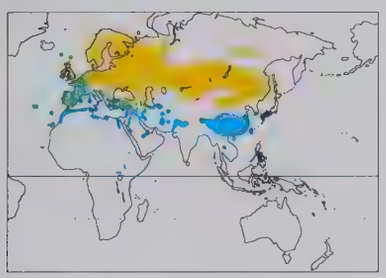
Subfamily VANELLINAE



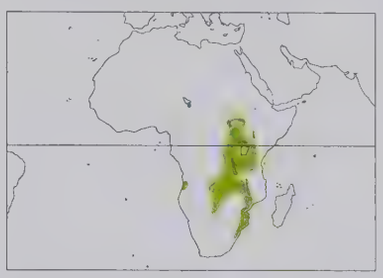
Genus *VANELLUS* Brisson, 1760

1. Northern Lapwing

Vanellus vanellus

French: Vanneau huppé **German**: Kiebitz **Spanish**: Avefría Europea
Other common names: Eurasian Lapwing, Peewit, Green Plover

Taxonomy. *Tringa Vanellus* Linnaeus, 1758, Europe, Africa; restricted to Sweden.
In past, genus *Vanellus* commonly considered to contain present species only. Monotypic.
Distribution. Europe, C Turkey and NW Iran through W Russia and Kazakhstan to S & E Siberia, Mongolia and N China. Winters from W Europe, E Atlantic islands and N Africa through Mediterranean, Middle East and Iraq across N India to SE China and S Japan.



Descriptive notes. 28-31 cm; 128-330 g; wingspan 82-87 cm. Metallic glossy green upperparts, blackish crest and bronze scapulars; very broad wings, especially in breeding males. Female has less distinctive head pattern and white flecks on throat. Non-breeding adult has buff face, and white chin and throat; upperwing-coverts and scapulars have buff fringes. Juvenile similar to non-breeding adult, but has more extensive buff feather fringes, and narrower and browner breast band.
Habitat. Breeds in variety of wide open habitats with short vegetation or bare ground, including various wetlands, heaths, moors, arable fields, meadows and hay fields; in Europe mainly a farmland breeder. Outside breeding season also appears on harvested stubble and ploughed fields. Roosting flocks prefer spacious, old pastures and sometimes appear on mudflats.
Food and Feeding. Feeds on invertebrate prey, primarily earthworms and insects, including larvae and adults of beetles, ants, Diptera flies, moths and crickets; also spiders and snails. On arable fields, adults and chicks take mainly cranefly larvae and earthworms, but evidently not selectively. Sometimes feeds by foot-trembling. Diurnal and nocturnal; sometimes even primarily nocturnal on bright, moonlit nights.
Breeding. Laying late Mar to early Jun. Mostly seasonally monogamous, but sometimes polygamous. Territorial during incubation; solitary breeder, with average densities 0·6-1·8 pairs/ha, maximum 9 pairs/ha. High degree of site-faithfulness in males, and high degree of natal philopatry, usually nesting within 60 km of hatching site. Males perform dazzling aerial song flight display (see page 396), during which wingtips produce droning sound. Nest is shallow scrape, lined with some vegetation, situated in short grassy vegetation. Clutch 4 eggs, occasionally 3 or 2; clutch completed in 5 days; incubation 21-28 days, starting once last egg laid; downy chick pale brown or cinnamon, with black streaks and blotches and white nape; chicks tended by both parents, although brooding primarily by female; fledging 5-6 weeks. Agricultural activities may cause 36% of broods to fail, plus another 32% partial losses of clutches; rainy and cold weather can have deleterious effects during chick phase; other causes of failure are predation, especially by crows, trampling by cattle and flooding. Highest mortality of hatchlings during first 10 days. Fledging success varies with year and habitat, but averages 0·2-2·8 fledglings per pair. Age of first breeding mostly 1 year; annual mortality of adults c. 25-30%, first-year birds c. 35-40%. Oldest ringed bird 18 years, 11 months.
Movements. Migratory and resident. After breeding season gathers in flocks. Breeding areas left as early as beginning of summer, movements starting already in early Jun. Movements during summer are mainly westward. British and southernmost breeders partly sedentary; many British birds winter in Ireland. Migration towards SW takes place in Sept-Oct, and starts with cold spells. Wintering area bordered by 3°C isotherm, but exact S and W distribution depends on weather. Spring migration at peak in early Mar, but can start as early as Jan; males precede females.
Status and Conservation. Not globally threatened. Estimated 7,000,000 birds in Europe, with 1,000,000-1,200,000 breeding pairs in Europe (excluding Russia), of which 226,000-278,000 in Netherlands, 200,000-250,000 in Britain, 150,000 in Finland (1986), 120,000 in Sweden (1984), and high numbers in Norway, Germany, Denmark and Ireland. More than 25,000 birds winter in SW Asia, c. 20,000 birds winter in Iran, 10,000-25,000 birds winter in SC Asia; more than 25,000 birds in E & SE Asia, and this population on increase. Marked decreases in last decades in S Sweden, and in large areas of Britain, Netherlands, Germany and Czech Republic. In winter (Nov), 1,000,000-1,500,000 birds present in Netherlands and 100,000-200,000 in Denmark; in Jan, 275,000 in Britain. Breeding area expanding northwards throughout range, mainly following extensive, man-made water meadows. European population decreased in 19th and early 20th centuries, probably as result of intensification of land use, drainage and egg-collecting, and same now happening in many E parts of range; due to habitat shift to agricultural land, numbers thereafter increased, until last decades, when population of W Europe in decline again, apparently caused by intensifying and changing agricultural practices, resulting in reduced breeding productivity; on arable fields, clutch destruction during cultivation and poor chick survival can result in insufficient productivity to maintain a stable population.

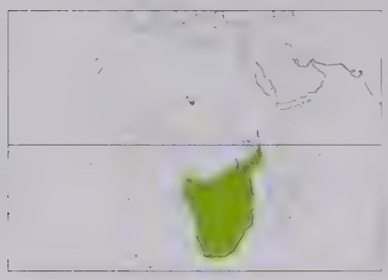
2. Long-toed Lapwing

Vanellus crassirostris

French: Vanneau à ailes blanches **German**: Langzehenkiebitz **Spanish**: Avefría Palustre
Other common names: White-faced Lapwing, Long-toed/White-winged Plover

Taxonomy. *Chettusia crassirostris* Hartlaub, 1855, Nubia.
In past, commonly placed in monospecific genus *Hemiparra*. Races intergrade in Tanzania, SE Zaire and N Malawi, and these intermediate birds formerly separated as race *hybrida*. Two subspecies recognized.
Subspecies and distribution.
V. c. crassirostris (Hartlaub, 1855) - S Sudan through Uganda, E Zaire, W Kenya and Tanzania to N Malawi; W Angola; also NE Nigeria, where may not breed.
V. c. leucopterus Reichenow, 1889 - Tanzania, SE Zaire, Zambia and Malawi to E Angola, N Botswana and NE South Africa.

Descriptive notes. c. 31 cm; 162-225 g. Long-legged and unusually long-toed lapwing; nape, hindneck and breast black with bluish gloss, face and throat white; upperparts dark greyish brown; eye-ring red, heavy bill red with black tips; short wing-spurs; legs deep red. Sexes alike. No seasonal variation. Juvenile has black parts browner, with buff tips to feathers; upperparts mottled with brown and buff. Races differ in wing coloration: nominate has all flight-feathers black, while in *leucopterus* only outer primaries black, rest of primaries and secondaries white; some birds intermediate.
Habitat. Forages on surface of floating vegetation in stagnant water, e.g. lakes, pools and marshes; also occurs in swamps, rivers and floodplains. In dry season, feeds at muddy edges of pools and small waterways; in wet season, on inundated grassland and in flooded rice fields.
Food and Feeding. Feeds on aquatic insects, larvae, dragonfly nymphs, beetles, ants and small snails. Unlike any other *Vanellus* species, feeds mainly on surface of floating vegetation, like jacanas (Jacanidae), supported by its long toes. Associates with Spur-winged Goose (*Plectropterus gambensis*), profiting from the goose turning over dead vegetation.
Breeding. Laying probably mainly Dec-Mar in C Africa, Jun-Nov in S Africa, but breeding occurs year round throughout range. Monogamous. Rather small territory, aggressively defended against neighbouring conspecifics by attacking from the air; after chicks hatch, adults very aggressive against intruding birds of many other species, e.g. African Fish-eagle (*Haliaeetus vocifer*). Nest is shallow scrape lined with plant material on grassland or mud, up to 100 from water's edge; or cup made from plant material on floating vegetation; or 5-10 cm high platform of mosses, weeds and debris in swampy areas. Clutch 2-4 eggs; incubation c. 30 days; downy chick buff above with irregular black markings, white below with dark brown breast; fledging c. 2 months.
Movements. Mainly sedentary, unless habitat dries up. Some movements between habitats have been observed in Rwanda. Status uncertain in NE Nigeria on S shore of L Chad, where species occurs, but may not breed. Non-breeders occur seasonally in Upemba National Park, Zaire.
Status and Conservation. Not globally threatened. No population estimates available; frequent to common, with local aggregations due to restrictive habitat requirements. A concentration of nearly 100 birds noted on Kafue Flats, SW Zambia; fairly common in Malawi.
Bibliography. Benson & Benson (1975), Britton, P.L. (1980), Brown & Britton (1980), Dean (1986), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Ginn *et al.* (1989), Henderson & Harper (1992), Lippens & Wille (1976), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Nikolaus (1987), van Perlo (1995), Pinto (1983), Saunders (1970), Short *et al.* (1990), Snow (1978), Tree (1978), Urban *et al.* (1986), Walters, J.R. (1979).



3. Blacksmith Lapwing

Vanellus armatus

French: Vanneau armé **German**: Schmiedekiebitz **Spanish**: Avefría Armada
Other common names: Blacksmith Plover

Taxonomy. *Charadrius armatus* Burchell, 1822, Klaarwater (= Griquatown), South Africa.
Formerly placed in monospecific genus *Anitibyx*; sometimes included in *Hoplopterus*. Monotypic.
Distribution. Angola to C Tanzania and CS Kenya, and S to South Africa, except W coast of Namibia.
Descriptive notes. 28-31 cm; 114-213 g. Medium-sized lapwing with contrasting plumage colours; glossy black face, foreneck and back, white crown and hindneck, grey upperwing-coverts; black carpal spurs. Metallic alarm call "tink-tink" recalls blacksmith's hammer on anvil. Sexes alike; female has shorter wing-spurs. No seasonal variation. Juvenile has brownish crown, white chin and throat; black feathers between grey scapulars and upperwing-coverts and all black feathers with buff fringes.
Habitat. Dry areas near water, such as lagoons, lakes, rivers, dams, water-holes, sewage farms and marshes; also mudflats, sodaflats and floodplains. Often flies to open country to forage. Sometimes roosts in flocks on islets.
Food and Feeding. Feeds on molluscs, crustaceans, worms and insects in typical plover style. Also forages by foot-trembling, pecking from water surface while wading, and hunting for insects by turning over dung pats. Forages on ploughed land and agricultural fields and among cattle.
Breeding. Laying in all months throughout range; frequently at start of dry season. Monogamous. Territorial and solitarily, with nests at least 400 m apart (South Africa); intraspecific aggression rare.

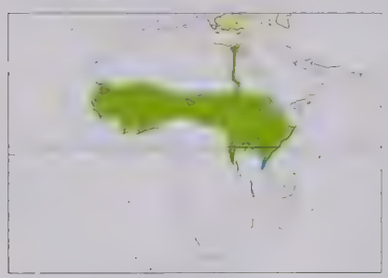
On following pages: 4. Spur-winged Lapwing (*Vanellus spinosus*); 5. River Lapwing (*Vanellus duvaucelii*); 6. Black-headed Lapwing (*Vanellus tectus*); 7. Yellow-wattled Lapwing (*Vanellus malabaricus*); 8. White-headed Lapwing (*Vanellus albiceps*); 9. Lesser Black-winged Lapwing (*Vanellus lugubris*); 10. Greater Black-winged Lapwing (*Vanellus melanopterus*); 11. Crowned Lapwing (*Vanellus coronatus*); 12. African Wattled Lapwing (*Vanellus senegallus*).

Courtship activity occurs in non-breeding flocks, often involving 3-5 birds. Nest is shallow scrape or depression, variably lined with pebbles, plant material and debris; located on ground or in short grass, very close to water. Clutch 3 eggs (1-4); double-brooded; incubation 23-31 days, by both sexes; chick has upperparts mixed brown and buff, underparts and collar white; fledging 41 days; chicks of first brood remain with adults until hatching of second brood. Main causes of egg and chick loss are flooding and predation.

Movements. Mainly sedentary. Occurs as non-breeding migrant in Zaire. Local movements occur due to flooding. Forms non-breeding flocks of up to 100 birds.

Status and Conservation. Not globally threatened. No population estimates available; generally common to locally abundant. In Zimbabwe, has benefited from increasing availability of artificial water supplies. Only recently found S of Orange R and Natal, but range now extending to coasts of SE Cape; reached W Cape in 1939, where first bred in 1947. Total of 2100 birds counted in South Africa in 1986, mostly in W & S Cape.

Bibliography. Benson & Benson (1975), Britton, P.L. (1980), Broekhuysen (1948), Brown (1972), Dowsett & Forbes-Watson (1993), Ginn *et al.* (1989), Hall (1959b, 1964), Henderson & Harper (1992), Kopij & Kok (1994), Kutilek (1974), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Nixon (1987), Penry (1980), Pinto (1983), Reynolds (1980, 1984), Rutgers & Norris (1970), Short *et al.* (1990), Thomas, D.H. (1983), Tucker (1979), Urban *et al.* (1986), Ward (1987, 1988, 1992).



4. Spur-winged Lapwing

Vanellus spinosus

French: Vanneau à éperons **German**: Spornkiebitz **Spanish**: Avefría Espinosa
Other common names: Spur-winged Plover

Taxonomy. *Charadrius spinosus* Linnaeus, 1758, Egypt.
Often placed in genus *Hoplopterus*. Forms superspecies with *V. duvaucelii*, with which sometimes considered conspecific. Monotypic.

Distribution. E Mediterranean and Middle East up R Nile to C & S Sudan, and S of Sahara from Senegal through Nigeria to Ethiopia, and S to Uganda and Kenya.

Descriptive notes. 25-28 cm; 127-177 g; wingspan 69-81 cm. Crown, forehead and throat black, cheeks and sides of neck white; slight crest not normally apparent; breast, upper belly and flanks black; dark red eyes, black spurs. Differs from *V. duvaucelii* most clearly by extensive black on underparts. Female as male, but spurs shorter. No seasonal variation. Juvenile has black parts of plumage brownish, speckled with white; feathers of upperparts have broad buff fringes.

Habitat. Usually on dry ground, but rarely far from water. Inhabits great variety of habitats, including cultivated fields or (burnt) grassland, near pools, lakes, rivers or lagoons, on mudflats, sandflats, sodaflats, rice fields, flooded fields, beaches and dunes. Sometimes in ponds and marshes.

Food and Feeding. Feeds mainly on insects and their larvae, especially beetles; also grasshoppers, flies, midges, termites, ants, spiders, myriapods; occasionally, crustaceans, molluscs, small lizards, tadpoles and adult frogs, fish and seeds. Takes few rapid steps followed by stabbing at prey; also flushes prey by foot-trembling.

Breeding. In tropical Africa, laying dates usually locally restricted, but great geographical variation; Israel Apr-Jul; Greece late Apr-May. Monogamous. Nests solitarily or in loose colonies. Territory aggressively defended against most other bird species, especially waders; conspecifics often tolerated in territory; territory sometimes occupied year round. Nest on bare, dry ground, usually a shallow scrape, unlined or lined with grass or other plant material and debris, or with a rim of earth, small shells or stones; alternatively, natural depression in rock lined with pebbles; nest on mud sometimes more substantial, with grass and reed stems. Lays 2-4 eggs (up to 5) at variable intervals of (1-) 2 days or more; often lays second clutch, and sometimes third; incubation 22-24 days (Europe); both parents incubate and tend chicks, but in case of second clutch, incubation by female while male tends chicks of first clutch; chick cinnamon-buff above, mottled grey and streaked black, with cheeks buff and hindneck white, lacks hind toe; fledging 7-8 weeks. Immatures independent soon after fledging, but sometimes stay with parents until next breeding season. Nests and eggs often trampled by cattle and ungulates. Fledging success in Israel c. 2 young per brood.

Movements. In Africa resident, locally making erratic movements; in places moves into drier areas during rainy season, but leaves driest areas; in general, not very sensitive to seasonal water level changes; local numbers can vary seasonally due to movements. Local migration in E Africa, with some birds occurring S to C Tanzania. Populations of Greece and Turkey migrate S in Oct, but main destinations unclear; some birds to Red Sea coast and presumably elsewhere in Africa. Middle East population probably dispersive or resident; Egyptian population resident. In non-breeding season occurs in flocks of up to 15 birds, maximum 200.

Status and Conservation. Not globally threatened. Probably 10,000-25,000 birds in SE Europe and SW Asia. No population estimate available for Africa, but thousands of pairs breed in Egypt; 1000-5000 birds in Sudan; a common bird in Israel, where 1550 birds, probably more, wintered between 1975 and 1983. Numbers have increased notably in Egypt and Israel since 1960's; at least in Israel, due to new irrigation fields, reservoirs, sewage farms and control of long vegetation bordering fish ponds. Species endangered in Europe; first noted breeding in Greece in 1959; but numbers decreased from 120-170 breeding pairs in 1970 to 32-45 pairs in 1993, due to loss of natural or semi-natural wetland habitat of salt-marshes. Population seems stable in Turkey at 1000-5000 pairs; 5000-15,000 birds occur in Egypt in winter. Locally exposed to hunting pressure.

5. River Lapwing

Vanellus duvaucelii

French: Vanneau pie **German**: Flußkiebitz **Spanish**: Avefría Fluvial
Other common names: Indian/Asian Spur-winged Plover/Lapwing

Taxonomy. *Charadrius Duvaucelii* Lesson, 1826, Calcutta.
Often placed in genus *Hoplopterus*. Forms superspecies with *V. spinosus*, with which sometimes considered conspecific. Monotypic.

Distribution. NC India (Uttar Pradesh) and Nepal through EC & NE India to SC China (SW Yunnan) and Indochina; status unclear further E possibly to Hainan and to Hong Kong.

Descriptive notes. 29·5-31·5 cm; 143-185 g. Black-faced lapwing with dark red eyes; crown and nape feathers can be raised to form a crest; black carpal spurs. Differs from somewhat similar *V. spinosus* in greyish breast, pale grey sides of head and neck, and small black spot on belly. Sexes alike. No seasonal variation. Juvenile similar to adult, with buff fringes and brownish tips to black parts.

Habitat. Generally found near rivers, especially in cultivated land, and on sandbanks and shingle banks; rarely near stagnant water.

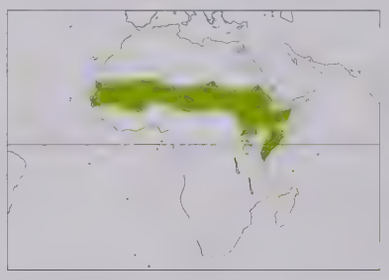
Food and Feeding. Mainly insects, worms, crustaceans and molluscs; also claimed to take frogs and tadpoles.

Breeding. Nesting Mar-Jun. Elaborate display by party of 4 birds has been described on 2 occasions. Nest is shallow scrape on exposed sandbar or shingle bank in river. Clutch 4 eggs (3-4); incubation apparently 22-24 days.

Movements. Sedentary; some seasonal nomadic movements.

Status and Conservation. Not globally threatened. Total population probably very small, unlikely to number more than 25,000 birds, and possibly no more than 15,000 birds. Annual Asian Waterfowl Census has never produced more than 500 birds. Uncommon in Thailand, apparently occurring mainly in NW.

Bibliography. Ali (1979), Ali & Ripley (1980), Bhunya & Mohanty (1990), Deignan (1945), Etchécopar & Hüe (1978), Harvey (1990), Hingston (1932), Inskipp & Inskipp (1991), Lekagul & Round (1991), Medway & Wells (1976), Perennou *et al.* (1994), Ripley (1982), Scott (1989), Smythies (1986).



6. Black-headed Lapwing

Vanellus tectus

French: Vanneau à tête noire **German**: Schwarzschopfkiebitz **Spanish**: Avefría Coletuda
Other common names: Black-headed/Blackhead/Crested Wattled Plover

Taxonomy. *Charadrius tectus* Boddaert, 1783, Senegal.
Sometimes placed in *Hoplopterus*, *Lobivanellus* or monospecific *Sarciophorus*. Two subspecies recognized.

Subspecies and Distribution.
V. t. tectus (Boddaert, 1783) - S Mauritania and Senegal to Ethiopia, Uganda and Kenya.
V. t. latifrons (Reichenow, 1881) - S Somalia to E Kenya.

Descriptive notes. c. 25 cm; 99-120 g (*latifrons*). Crested lapwing with red wattles, black and white head, and pinkish red legs; vertical black streak on upper breast unique in *Vanellus*. Sexes alike. No seasonal variation. Juvenile like adult, but has buff edges to black and brown feathers; also shorter crest and smaller wattles. Race *latifrons* somewhat smaller, with broader white forehead band.

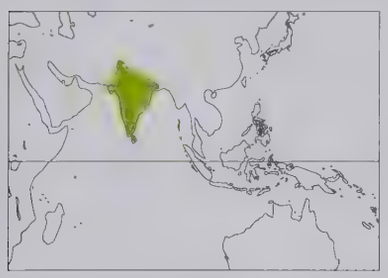
Habitat. Dry plains or desert, bare or with short grass; open bushland; open, bare areas in thornscrub; not necessarily near water. Also found near human settlement, e.g. airfields, football pitches, race courses, etc.; will nest in gardens and near buildings.

Food and Feeding. Diet consists of insects and their larvae and gastropods. Feeds mainly at night, resting in shade during the day.

Breeding. Laying dates locally restricted by seasons, but varying geographically, peaking either during dry or rainy seasons, depending on region; frequently Mar-May. Monogamous. Breeds singly or in loose colonies; in Chad, 14 pairs/ha; in Kenya, 7 nests within radius of 300 m. Colonial birds very aggressive, mobbing all intruders. Nest is shallow depression or scrape in sand or earth, unlined or variably lined with pebbles, gravel, plant material or debris. Lays 1-6 eggs (clutches of 5-6 probably involve 2 females) at interval of under 24 hours (but at least 28 hours in captivity); first eggs are covered before incubation starts; incubation 26 days; chick has upperparts spotted black and yellow, hindneck, cheeks and underparts white; fledging period less than 1 month (in captivity). Cattle cause nest losses.

Movements. Resident; local movements during rains noted in Mauritania, Mali and Nigeria; mainly dry season visitor to Ghana, Nov-May. In Ethiopia some groups move to higher altitudes, Nov-May. Groups of 6-10 birds (up to 40) gather outside breeding season.

Status and Conservation. Not globally threatened. No population estimates available; reported to be generally common throughout sizeable range. Widespread and common in Gambia; not uncommon in Nigeria; uncommon in Ghana. Tolerance of arid to desertic conditions, combined with apparent ability to adapt to man-made habitats suggest species secure at present.



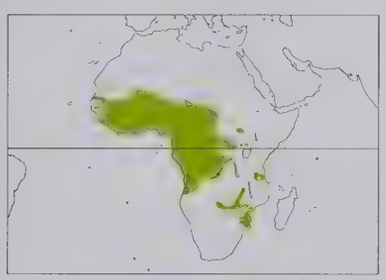
Bibliography. Ash & Miskell (1983), Böhm (1987), Brown & Britton (1980), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Etchécopar & Morel (1960), Gore (1990), Greenham & Greenham (1975), Grimes (1987), Hüe & Etchécopar (1970), Jensen & Kirkeby (1980), Mackworth-Praed & Grant (1957, 1970), Morel & Morel (1990), Newby (1979), Nikolaus (1987), North (1936), van Perlo (1995), Rutgers & Norris (1970), Shirihai (1996), Short *et al.* (1990), Urban *et al.* (1986).

7. Yellow-wattled Lapwing

Vanellus malabaricus

French: Vanneau de Malabar **German**: Gelblappenkiebitz **Spanish**: Avefría Malabar
Other common names: Yellow-wattled Plover

Taxonomy. *Charadrius malarbaricus* [sic] Boddaert, 1783, Malabar Coast.
Formerly placed in monospecific genus *Lobipluvia*; occasionally included in *Hoplopterus*. Monotypic.
Distribution. S Pakistan, India, Bangladesh and Sri Lanka.



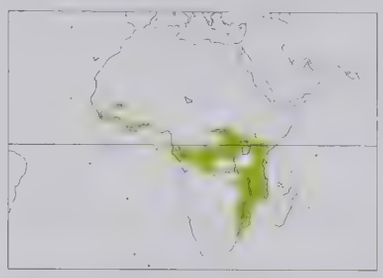
Descriptive notes. 24-28 cm; 108-203 g (3 specimens); wingspan 65-69 cm. Lapwing with yellow wattles and legs; cap black, bordered below by narrow white line; chin and throat blackish, breast and upperparts brown, belly white; white wingbar and rump, black flight-feathers; black bill with yellowish base; tiny yellow carpal spurs. When bird excited, black cap can be raised. Sexes alike. Non-breeding adult has all of black areas mottled with brown. Juvenile has brown crown, small pale wattles; dark subterminal bars and buff fringes on back feathers; chin and throat white. Clinal decrease in size from N to S.
Habitat. Dry and open habitats, including cultivated and fallow fields and wasteland; also on edges of wetlands, e.g. *jheels*, but not necessarily close to water.
Food and Feeding. Primarily insects and their larvae, including grasshoppers and beetles; also molluscs. Mainly feeds nocturnally.
Breeding. Breeds mainly Mar-Jul; season until Aug in Sri Lanka, from late Apr in Pakistan. Adults defend large territories where young and parents feed. Nest is shallow scrape, unlined, sometimes encircled by pebbles or mud pellets, situated on dry, open fallow or waste land. Clutch 4 eggs; on red laterite soil often has reddish eggs; incubation 26-29 days; chick buffy or fawn-grey, stippled black and rufous, with white hindneck collar; fledgling 32 days, or more.
Movements. Mainly sedentary; local movements to drier areas during monsoon. In lower Sind, Pakistan, present only in summer, when breeds; arrives late Feb-Mar and departs probably Aug-Sept. Outside breeding season sometimes occurs in small family groups.
Status and Conservation. Not globally threatened. No population estimates available; widely distributed, and apparently still rather common. No threats known; adaptation to rather dry areas, and tolerance of man-made habitats suggest species probably secure at present. Frequent in lower Sind, Pakistan.
Bibliography. Ali (1979), Ali & Ripley (1980), Bhunya & Mohanty (1990), Dhindsa (1983), George (1985), Harvey (1990), Henry (1971), Inskipp & Inskipp (1991), Jayakar & Spurway (1965a, 1965b, 1968), Johns & Thorpe (1981), Kotagama & Fernando (1994), Perennou *et al.* (1994), Phillips (1978), Phythian-Adams (1940), Ripley (1982), Roberts, T.J. (1991), Santharam (1980), Scott (1989), Tuljapurkar (1986), Vijayagopal & Chacko (1991), Wijesinghe (1994).

8. White-headed Lapwing

Vanellus albiceps

French: Vanneau à tête blanche **German**: Weißscheitelkiebitz **Spanish**: Avefría Coroniblanca
Other common names: White-headed/White-crowned/Black-shouldered (Wattled) Plover/Lapwing

Taxonomy. *Vanellus albiceps* Gould, 1834, Niger River or Fernando Po.
Sometimes placed in genus *Hoplopterus* or in monospecific *Xiphidiopterus*. Monotypic.
Distribution. Senegambia and Sierra Leone E to S Sudan, and S through W & C Zaire to NW Angola; SE Tanzania; R Zambezi and S Mozambique.



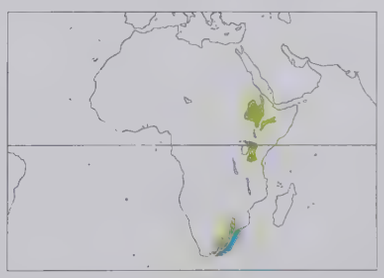
Descriptive notes. 28-32 cm; 201 g (1 adult). Lapwing with large yellow wattles, distinctive white crown band, and long black carpal spurs; wings extensively white, with outer primaries black, recalling race *leucopterus* of *V. crassirostris*, but median and greater coverts mostly black; almost entirely white from below in flight. Female has brown border to crown. No seasonal variation. Juvenile has smaller spurs and wattles, brownish white crown, upperwing-coverts fringed buff, and white and brown upperparts spotted with darker brown.
Habitat. Sandy riverbanks in open country and forests; prefers large rivers with sandbanks or islands; during floods also on small streams, pans and lagoons. Generally found in pairs or groups of 6-12 birds, maximum 30.
Food and Feeding. Takes insects, including beetles, ants, mantids and mutillid wasps; worms, molluscs, crustaceans and small fish; also some vegetable matter.
Breeding. Laying Jan-Mar (Dec-May) in W & C Africa; Jul-Oct (Nov) in E Africa; mainly during dry season. Monogamous. Solitary breeder; in Zaire, forms loose colonies; in Nigeria, nests at least 400 m apart; in South Africa, 1·46 pairs/km of river. Territory aggressively defended against conspecifics and also other bird species, especially after chicks hatch. Nests on sand or shingle in riverbeds when water level is low; nest is shallow scrape in sand or shingle, lined with small sticks and pebbles; rarely unlined. Clutch 2-4 eggs; when clutch is exposed to sun, has to be wetted frequently; incubation over 25 days; chick buff and black speckled upperparts, white underparts and hindneck collar. Parents sometimes cover eggs with plant matter, when leaving nest. Nests susceptible to trampling by crocodiles, hippopotami and ungulates.
Movements. In W Africa, migrates to drier areas when rivers flood, with movements recorded in Gambia, Sierra Leone, Niger, N Nigeria and elsewhere; sometimes moves outside breeding range. Populations S of equator only move during peak rains.
Status and Conservation. Not globally threatened. No population estimates available; said to be common in places, but range is rather limited, as restricted to certain rivers. Not uncommon seasonally in Nigeria; widespread but sparse in Sierra Leone; rare and irregular visitor to Gambia. Total of 50-75 birds known to breed on coast of Gabon.
Bibliography. Atkins, Johnston-Stewart, Atkins & Killick (1989), Bainbridge (1965), Begg & Maclean (1976), Britton, P.L. (1980), Brown & Britton (1980), Brooke (1984a), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Gatter (1988), Ginn *et al.* (1989), Gore (1989, 1990), Grimes (1987), Lippens & Wille (1976), Louette (1981), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Medland (1989b), Morel & Morel (1990), Nikolaus (1987), Pinto (1983), Reynolds (1968), Schepers & Marteijn (1993), Serle (1939a), Short *et al.* (1990), Tarboton & Nel (1980), Urban *et al.* (1986).

9. Lesser Black-winged Lapwing

Vanellus lugubris

French: Vanneau terne **German**: Trauerkiebitz **Spanish**: Avefría Lúgubre
Other common names: Senegal Plover/Lapwing, Lesser Black-winged Plover

Taxonomy. *Charadrius lugubris* Lesson, 1826, Senegal.
Sometimes placed in *Hoplopterus* or *Stephanibyx*. Has been proposed to form superspecies with *V. melanopterus*, but not supported by behavioural or morphological data. Monotypic.
Distribution. S Mali; N of forest zone in Guinea-Bissau and Ivory Coast; coast from Sierra Leone to SW Nigeria; Gabon, W Zaire and CW Angola E to Kenya, and S through Tanzania, NE Zambia, Malawi and Mozambique to E South Africa (Natal); Zanzibar, Latham and Mafia Is.



Descriptive notes. 22-26 cm; 107-120 g. Small, slender grey-headed plover. Slimmer than larger *V. melanopterus*; typically has smaller, more sharply defined white forehead patch; greener upperparts and shorter black bill; in flight, differs from *V. melanopterus* by white, not black, secondaries. Sexes alike. No seasonal variation. Juvenile has buff tips to feathers of white forehead and black breast band; buff-notched tertial edges.
Habitat. Dry, open habitats, sometimes with bushes, scrub and trees; prefers burnt grassland and newly grown grass; also cultivated ground, airfields, lake and river margins. In W Africa, occurs mainly in coastal savannas. Recorded at least once on seashore, on Zanzibar. In Sierra Leone, generally found on drier ground than *V. senegallus*, e.g. burnt laterite pans or grass ridges running into swamps. Occurs in flocks of 5-10 birds, up to 30 after breeding; sometimes loosely associated with *V. armatus*.
Food and Feeding. Small invertebrates, including insects and their larvae, especially beetles; also grass seeds. Sometimes feeds at night.
Breeding. Laying dates geographically very variable: Mar-May in Sierra Leone; Jun-Sept in coastal Gabon; Jun-Oct in S Africa; mainly dry season (Aug-Nov) in E Africa. Monogamous. Loosely colonial, with several pairs scattered over small area; territorial. Nests on burnt ground with new grass, also on bare patches in grassland or ploughed land; nest is scrape or depression on ground, lined with few stalks of dry grass; sometimes no nest at all. Clutch 3 eggs (2-4); incubation 18-20 days; chick has upperparts mottled yellow and blackish brown, white hindneck collar, greyish white below; nestlings stay with parents for c. 2 months.
Movements. Sedentary and intra-African migrant; movements possiby related to brush fires, resulting in new grass, conditions suitable for breeding. In Zaire, migrates in large flocks, with movement N recorded in Feb-Apr, and S in period Apr-Oct. Migratory in E Africa: high numbers occur in W Uganda, around L Victoria (Ugandan sector, Sept-May) and in coastal Tanzania (Jun-Aug) and Kenya (Apr-Jul). Regular seasonal presence in W Kenya in Jan-Mar (Nov-Jun), N Tanzania (Jan-Apr), Zimbabwe (Jul-Nov), South Africa (summer) and Zambia (Apr-Oct, but possibly year round). Some birds sedentary on Zanzibar, but numbers fluctuate, fewest birds present Oct-Dec. In Malawi, breeding birds dispersive Apr-Jun. Movements performed at night.
Status and Conservation. Not globally threatened. No population estimates available; at least regionally fairly common, but little information available. Locally common in Sierra Leone and Ghana; uncommon in SW Nigeria, where may have declined. Total of 300-350 birds on coast of Gabon outside breeding season.
Bibliography. Ash & Miskell (1983), Benson & Benson (1975), Benson *et al.* (1971), Britton, P.L. (1980), Brooke (1984a), Chapin (1939), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Ginn *et al.* (1989), Grimes (1987), Howells (1977), Irwin (1976), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Pakenham (1979), Philips (1988), Pinto (1983), Scott (1983), Short *et al.* (1990), Tree (1978), Urban *et al.* (1986), Vincent (1934), Ward (1987, 1989a, 1989b, 1989c, 1990a, 1992).

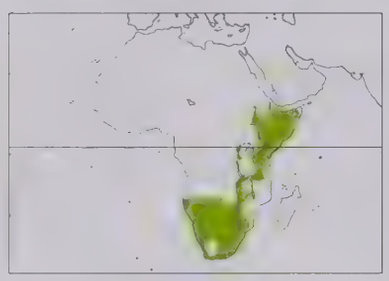
10. Greater Black-winged Lapwing

Vanellus melanopterus

French: Vanneau à ailes noires **German**: Schwarzflügelkiebitz **Spanish**: Avefría Lugubroide
Other common names: Black-winged Lapwing/Plover

Taxonomy. *Charadrius melanopterus* Cretzschmar, 1829, Djedda, Arabia.
Sometimes placed in *Hoplopterus* or *Stephanibyx*. Has been proposed to form superspecies with *V. lugubris*, but not supported by behavioural or morphological data. Two subspecies recognized.
Subspecies and Distribution.
V. m. melanopterus (Cretzschmar, 1829) - extreme E Sudan and Ethiopia; SW Kenya to CN Tanzania.
V. m. minor (Zedlitz, 1908) - NE Transvaal to E Cape Province (South Africa); winters on coast, from extreme S Mozambique to E Cape.

Descriptive notes. 26-27 cm; 163-170 g (3 adults, race *minor*). Very similar to *V. lugubris*, but larger, with legs averaging slightly shorter; shine on upperparts bronze to purplish, not greenish; generally larger, more diffuse white forehead patch; broader black breast band; in flight, secondaries black, not white. Sexes alike. No seasonal variation. Juvenile has grey areas of adult pale brown; feathers of upperparts have broad buff fringes. Races very similar, but *minor* somewhat smaller.
Habitat. Often occupies highland plains and grassland on high plateaux, mountain slopes, open plains and dry savanna; nominate race largely confined to areas above 2000 m, whereas *minor* often occurs at lower altitudes. Attracted to areas with game animals and burnt fields with newly grown grass. In winter, found at lower altitudes, when also occurs in wasteland, cultivated fields and coastal flats.



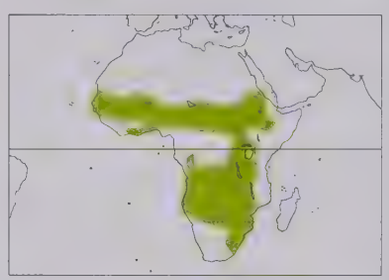
Food and Feeding. Molluscs, worms, adult and larval insects, such as beetles and flies, sometimes small fish. Often feeds in vicinity of wild or domestic animals. When foraging, runs quickly, freezes with body tilted forward and pointing at prey, and stabs 5-6 times.
Breeding. Laying Apr-Jul in Ethiopia; year round in Kenya and Tanzania, depending on rains, and avoiding wettest period; Jul-Oct in South Africa. Monogamous. Territorial. Solitary, but sometimes in small, loose colonies. Performs post-copulatory display consisting of side by side run, with wing on outside partly raised. Breeds in grassland, usually with very short grass; also on bare ground or ploughed land; nest is a scrape, lined with plant material and sometimes dung; eggs sometimes partly buried. Clutch 3 eggs (2-4).
Movements. Resident and intra-African migrant: migratory in most of E Africa, but sedentary in Ethiopia; migratory in South Africa. In Aug-Sept, after breeding, birds in Kenya migrate to lower altitudes, 1500-2000 m lower, returning in Jan-Apr. In South Africa most birds descend to coastal plains after breeding (Apr-Aug); occasional stragglers reach W Cape. Migrates both at night and during day. During non-breeding season, occurs in flocks of up to 50 birds, occasionally thousands, and possibly up to 10,000 prior to migration.
Status and Conservation. Not globally threatened. No population estimates available. Status of race *melanopterus* unknown, but pre-migratory flocks of several thousand birds recorded in W Kenya. Race *minor* is rather common to locally abundant. Type locality in Arabia may be erroneous, as no other records known.
Bibliography. Allan (1983), Britton, P.L. (1980), Cyrus (1982), Dowsett & Forbes-Watson (1993), Ginn *et al.* (1989), Mackworth-Praed & Grant (1957, 1962), Maclean (1972a, 1993), Sessions (1967), Short *et al.* (1990), Urban *et al.* (1986), Vincent (1945), Ward (1987, 1989a, 1989b, 1989c, 1990a, 1992), Ward & Maclean (1988).

11. Crowned Lapwing

Vanellus coronatus

French: Vanneau couronné **German**: Kronenkiebitz **Spanish**: Avefría Coronada
Other common names: Crowned Plover

Taxonomy. *Charadrius Coronatus* Boddaert, 1783, Cape of Good Hope.
Sometimes placed in genus *Hoplopterus* or *Stephanibyx*. Birds from SW Angola, Namibia, Botswana, W Zimbabwe and W Transvaal may be separated as third race *xerophilus*, but doubtfully distinct. Two subspecies recognized.
Subspecies and Distribution.
V. c. coronatus (Boddaert, 1783) - Ethiopia to South Africa; marginal in SW Somalia.
V. c. demissus (Friedmann, 1928) - Somalia.



Descriptive notes. 20-34 cm; 126-200 g (*coronatus*). Very distinctive horizontal black and white bands surrounding black crown; pale brownish above and on breast, with darker lower breast ending in black line. Female smaller than male. No seasonal variation. Juvenile has less well defined white head band, buff brown at front; black head feathers tipped brown; feathers of upperparts fringed buff. Race *demissus* somewhat smaller, with paler, warmer brown on upperparts, wings and breast.
Habitat. Wide variety of dry, open habitats, treeless or sparsely wooded: savanna, open patches in thornbush or bushveld, cultivated land, fallow fields, airports, golf courses, open areas near towns and even desert and dunes. Attracted to recently burnt grasslands. Not associated with water, generally avoiding moist ground; however, large flocks may roost during the day near waterside or on small islands in lakes or rivers.
Food and Feeding. Food includes insects and their larvae, especially termites, beetles, grasshoppers, crickets and ants; possibly earthworms. Most active at dusk, and also active during moonlit nights; probably feeds mainly during late afternoon and night. Sometimes feeds near cattle. Take-off before flight to feeding ground is preceded by display.
Breeding. Breeds during dry season, when fires occur, but timing very variable geographically: year round in E Africa, but depending on rains; mostly Jun-Nov in S Africa. Monogamous. Non-territorial, semi-colonial nester; nests 25-50 m apart; occasionally noted defending territories when densities are high through space limitation; non-breeders often found close to breeding birds; highly demonstrative towards non-conspecific intruders after hatching. Prefers nesting among fresh grass on recently burnt fields; nest is scrape or depression in ground, lined with plant material and debris, which accumulates during incubation; often close to tree, providing shade for off-duty partner; location regularly reused during several years. Clutch 2-3 eggs, occasionally 4, with clutch of 5 from 2 females; laying interval 1 day; double-brooded; incubation 28-32 days; chick has upperparts deep buff blotched black, underparts and hindneck white; fledging takes over 1 month. Several families aggregate, even when young still unable to fly. Hatching success 54 % in Zimbabwe, 88% in South Africa; fledging success 31% in South Africa. Nests frequently destroyed by brush fires; young often taken by predators.
Movements. Commonly resident, but some erratic movements; in E Africa, some birds resident, others dispersive; mainly sedentary in South Africa. Movements related to habitat changes; birds follow dry season fires, and leave during peak rains or when grass grows too long. Occurs in pairs or flocks of 10-40, maximum 150 birds, especially just after breeding season; flocks are loosely associated and wide-ranging.
Status and Conservation. Not globally threatened. No population estimates available; rather common and widespread throughout extensive range. Common and widespread in Somalia. Numbers in the W Cape may have decreased, as *V. armatus* invades habitat of present species.
Bibliography. Ade (1976, 1979), Anderson & Kok (1990, 1991, 1992), Archer & Godman (1937-1961), Ash & Miskell (1983), Benson & Benson (1975), Britton, P.L. (1980), Dowsett & Forbes-Watson (1993), Ginn *et al.* (1989), Hanley (1983, 1988, 1990), Kok & Anderson (1989), Kopij & Kok (1994), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Moore & Vernon (1973), Pinto (1983), Short *et al.* (1990), Skead (1955), Symmes (1952), Tree (1981a), Urban *et al.* (1986), Ward (1987, 1989a, 1989b, 1989c, 1990a, 1992), Ward & Maclean (1988).

12. African Wattled Lapwing

Vanellus senegallus

French: Vanneau du Sénégal **German**: Senegalkiebitz **Spanish**: Avefría Senegalesa
Other common names: (Senegal) Wattled Plover/Lapwing

Taxonomy. *Parra senegalla* Linnaeus, 1766, Senegal.
Sometimes placed in monospecific genus *Afribyx*. Western population of race *lateralis* sometimes considered separate race, *solitaneus*. Race *major* not always accepted, as occurs at end of cline in size from W to E. Three subspecies normally recognized.
Subspecies and Distribution.
V. s. senegallus (Linnaeus, 1766) - SW Mauritania, Senegambia and NW Sierra Leone E to Sudan, NE Zaire and N Uganda.
V. s. major (Neumann, 1914) - W & C Ethiopia and Eritrea.
V. s. lateralis A. Smith, 1839 - S Congo and Angola E to S Uganda, and S through W Tanzania, S Zaire, Zambia and Malawi to Zimbabwe, S Mozambique and NE South Africa.

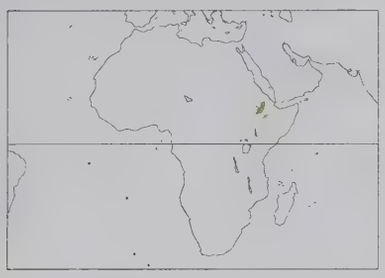
Descriptive notes. c. 34 cm; 197-277 g. Large yellow and red wattles; long yellow legs; yellow bill, with some black on culmen towards tip; black carpal spurs; plumage mainly brown, with white wingbar and black flight-feathers. Female has less black on throat. No seasonal variation. Juvenile has very small wattles; chin and throat whitish with black streaks; less white on forehead. Race *major* virtually identical to nominate, but usually larger; *lateralis* has blackish line on belly, in front of legs, and solid black bill tip.
Habitat. Wide variety of lowland habitats; in Ethiopia and rest of E Africa occurs up to 2200 m. Often near water, but also found in dry places; frequents marshes or areas of grass near lakes, ponds, rivers and streams; also savanna, fields with short grass (e.g. airports), cultivated land and wasteland, flooded rice fields, pools, burnt grassland. Has been found to associate with termite mounds, which are used as look-out posts. In Sierra Leone, shares wet grassland with *V. spinosus* and dry grassland with *V. lugubris*, without rivalry.
Food and Feeding. Chiefly insects, such as grasshoppers, locusts, beetles, crickets, termites and various aquatic insects; also worms and grass seeds. Regurgitated pellets contained insect remains and coarse grass. Does not normally forage in typical plover style; instead, walks slowly, pauses with one leg raised, takes one step or jumps, and grabs prey; also probes in base of grass tufts and uses foot-trembling.
Breeding. Laying dates geographically very variable, depending on rains; Mar-Jun in Nigeria; most frequently Jul-Dec in E & S Africa; Apr-Dec in Zaire and Rwanda; Mar-Jun in Ethiopia. Monogamous. Observed to be highly territorial, defending feeding territory against conspecifics, but also recorded breeding in small colony of 3-4 pairs. Nest usually on bare ground or in short grass within 100 m of water, frequently near roads or human settlements; shallow depression in ground, lined with grass stems, sticks, pebbles and bits of dry dung, which accumulate during incubation. Clutch 2-3 eggs in equatorial regions, 4 in S Africa; laying interval 1-2 days; incubation 30-32 days; chick speckled buff and black, with black patch on crown and back, white forehead and hindneck collar, and underparts yellowish white; chicks feed in adjacent feeding territory, continiously watched by adult, often from hillock; fledging c. 40 days. Young become independent after fledging.
Movements. Resident and dispersive, sometimes nomadic. Movements dependent on water levels and rains, but overall patterns none too clear. In parts of W Africa (Mali, Chad) moves N in wet season, but also southward migration in Nigeria. In E Africa and Rwanda apparently resident, with some local movements. Only seasonally present in some areas of SE Africa, but resident in others. May gather outside breeding season in newly available habitat.
Status and Conservation. Not globally threatened. No population estimates available; apparently common in much of extensive range, e.g. Gambia and Sierra Leone; not uncommon in Ghana and Nigeria; fairly common in Malawi; locally common in S Africa. High tolerance of humans and agricultural practices suggests species probably not threatened.
Bibliography. Beesley (1977), Benson & Benson (1975), Britton, P.L. (1980), Brooke (1967), Brown & Britton (1980), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Gatter (1988), Ginn *et al.* (1989), Gore (1990), Grimes (1987), Harpum (1978), Jensen & Kirkeby (1980), Lippens & Wille (1976), Little (1967), Louette (1981), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Morel & Morel (1990), Nikolaus (1987), Parnell (1968), Penry (1987), Pinto (1983), du Plessis (1987), Reynolds (1977a), Short *et al.* (1990), Urban *et al.* (1986), Van de Weghe & Monfort-Braham (1975), Ward (1987, 1992).

PLATE 36 ➤

PLATE 36

inches 6

cm 15

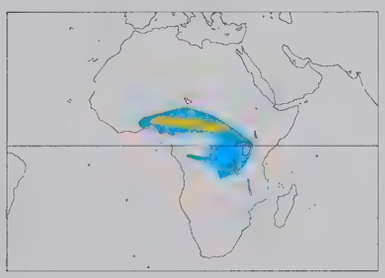


13. Spot-breasted Lapwing

Vanellus melanocephalus

French: Vanneau d'Abyssinie **German**: Strichelbrustkiebitz **Spanish**: Avefría Pechipinta
Other common names: Spot-breasted Plover

Taxonomy. *Lobivanellus melanocephalus* Rüppell, 1845, Mountains of Simien, Ethiopia.
Formerly placed in *Hoplopterus*, *Lobivanellus* or monospecific *Tylibyx*. Monotypic.
Distribution. Ethiopian Highlands.



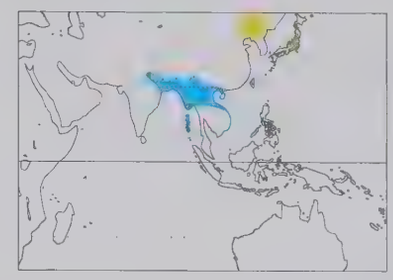
Descriptive notes. c. 34 cm; 2 adults 199 and 228 g. Ashy brown with yellow wattles and black crown, chin and throat; white supercilium; upperparts with greenish tinge; breast distinctly spotted black, even slightly striped, belly white; feathers of nape can be raised to form crest. In flight distinguised from *V. spinosus*, *V. melanopterus* and *V. senegallus* by narrower black tail band. Sexes alike. No seasonal variation. Juvenile not described.
Habitat. Damp grassland, moorland with giant lobelia, giant heath, *Alchemilla* and tussock grass; also marshes and near streams; often on pastures and near cattle. Generally found between 1800 and 4100 m.
Food and Feeding. Diet undescribed. Typically forages by means of a quick run, followed by a pause and a survey of ground. Very mobile during the day, often searching out cattle pastures.
Breeding. Season Apr in Bale Mts, Aug in Shewa district. Only one nest described, which was shallow scrape in patch of grass and moss, situated on tiny rocky island in shallow pool, in giant lobelia moorlands. This same nest contained 4 eggs. No further information available.
Movements. Sedentary, although some local movements probable: north of Gonder numbers increase during rainy season. Outside breeding season, often occurs in parties of 30-40 birds.
Status and Conservation. Not globally threatened. No population estimates available; locally frequent to common, but very restricted range makes species somewhat vulnerable. Like several sympatric endemics, species requires close monitoring; intensive survey would be highly desirable.
Bibliography. Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Mackworth-Praed & Grant (1957), van Perlo (1995), Urban (1980), Urban, Brown *et al.* (1970), Urban, Fry & Keith (1986), Von Heuglin (1869-1873).

14. Brown-chested Lapwing

Vanellus superciliosus

French: Vanneau à poitrine châtaine **German**: Rotbrustkiebitz **Spanish**: Avefría Pechirrufa
Other common names: Brown-chested (Wattled) Plover

Taxonomy. *Lobivanellus superciliosus* Reichenow, 1886, Marungu, Zaire.
Formerly placed in monospecific genus *Anomalophrys*. Monotypic.
Distribution. Probably breeds from Togo to NE Zaire, but only definite records from Nigeria. Non-breeding records from E Ghana across C & N Cameroon and S Chad to most of Zaire (except CW), L Victoria and NW Tanzania. Limits of range poorly known.



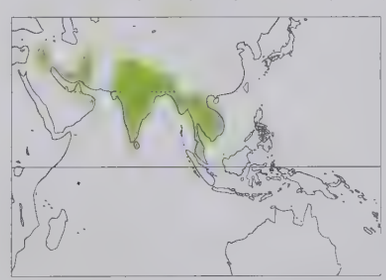
Descriptive notes. c. 23 cm; c. 150 g (estimated). Small lapwing, with black cap, narrow white eyeline, greenish brown upperparts and small yellow wattles; reddish chestnut forehead and breast. Sexes alike. No seasonal variation. Juvenile has no black on head, lacks wattles and has paler chestnut on forehead and breast; upperparts extensively fringed reddish chestnut.
Habitat. Open savanna with or without sparse covering of bushes or woods, with grass or bare ground, often near rivers and lakes; also football fields, lawns and recently burnt grassland. On migration in Zaire also sometimes found in cleared areas within forest.
Food and Feeding. Insects, such as ants. Pecks deep in loose soil. Also active at night, possibly feeding.
Breeding. Laying Jan-Feb in Nigeria; probably Dec-Jun in Zaire; breeding assumed to occur during dry season. Monogamous. Territorial. Breeds on newly burnt ground, often on rather stony red soil; nest is shallow depression in soil with rim, thickly lined with small stones and pieces of anthill, partly covering eggs. Clutch 2-4; many eggs are erythristic or reddish, closely matching lateritic soil on which laid; incubation by both parents, lasting at least 24 days, starting with last egg; chick buff and dark brown above, with dark patch on occiput and white patch on nape, underparts white with brown pectoral band. After fledging families gather in parties of up to 50 birds.
Movements. Intra-African migrant. Adults migrate through E & C Zaire in Nov-Dec, returning in Jul-Aug, then with immatures, suggesting migration to and from breeding grounds. Non-breeders in S Zaire, Rwanda and other parts of E Africa in Jul-Dec. Nigerian breeding birds have been shown to store fat before leaving breeding grounds. Outside breeding season, occurs in flocks of 30 birds, maximum 100.
Status and Conservation. Not globally threatened. Very poorly known, but apparently not particularly rare and reckoned to be secure; widespread though uncommon throughout much of Nigeria. Precise limits of breeding and non-breeding ranges very poorly known, e.g. status in Ghana could be anything from breeding visitor to vagrant, as only 1 record, and this coincides with breeding season in Nigeria; few records from Cameroon; considerable scope for extensive survey work and research.
Bibliography. Bowen (1979), Britton, P.L. (1980), Clarke (1936), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Grimes (1987), Heslop (1937), Lippens & Wille (1976), Louette (1981), Mackworth-Praed & Grant (1957, 1970), Serle (1956b), Short *et al.* (1990), Urban *et al.* (1986).

15. Grey-headed Lapwing

Vanellus cinereus

French: Vanneau à tête grise **German**: Graukopfkiebitz **Spanish**: Avefría Ceniza
Other common names: Grey-headed Plover

Taxonomy. *Pluvianus cinereus* Blyth, 1842, Calcutta.
Sometimes placed in genus *Hoplopterus* or, formerly, in monospecific *Microsarcops*. Monotypic.
Distribution. NE China, neighbouring parts of Russia and Japan; possibly C Manchuria and Inner Mongolia. Non-breeding in S Asia from Nepal, NE India and Bangladesh to SC China, N Indochina and Taiwan, occasionally further S.



Descriptive notes. 34-37 cm; 236-296 g. Large, rather plain lapwing with grey head, neck and upper breast, black breast band, brown upperparts and white belly; secondaries and greater upperwing-coverts white, primaries black; tail white with black tip; iris red, bill yellow with black tip, legs yellow. Sexes alike. Non-breeding adult has browner head and neck, black breast band partly obscured; chin and throat white, streaked brown. Juvenile has brown head and neck; breast band absent or obscure; extensively fringed buff on upperparts.
Habitat. Breeds in rather undisturbed areas in swamps, near rivers and rice fields. In winter also found in wet habitats, like marshes, riverbanks, wet grassland, rice stubble, *jheels*; also ploughed fields.
Food and Feeding. No information available; probably feeds on insects, worms and molluscs. Gregarious.
Breeding. Monogamous. Territorial. Breeds in undisturbed wetlands, e.g. river flats; but also in rice fields; nest is scrape, often lined with twigs. Clutch 4 eggs; incubation 28-29 days; chicks fledge mid-Jun, and families soon merge into flocks.
Movements. Mainly migratory, but sedentary in places. Breeding populations of NE China and SE Russia winter in SE Asia. Japanese population partly sendentary, with birds in N of range avoiding snow by migrating S. Outside breeding season occurs in flocks of 5-50 birds. Present in India from Sept/Oct to late Mar/Apr; returns to breeding grounds in mid-Feb.
Status and Conservation. Not globally threatened. Currently considered near-threatened. Population, excluding Japan, numbers less than 10,000-25,000 birds, and probably decreasing, with highest numbers wintering in India and Bangladesh; size of Japanese population unknown. On wintering grounds, possible problems through pesticides, especially herbicides on paddy fields, and through increased urbanization; in Japan, at S end of breeding range, increasing frequency of double-cropping, instead of single-cropping, in rice fields may negatively affect breeding opportunities.
Bibliography. Ali & Ripley (1980), Austin (1948), Austin & Kuroda (1953), Brazil (1991), Deignan (1945), Étchécopar & Hüe (1978), Grubh (1968), Harvey (1990), Inskipp & Inskipp (1991), Knystautas (1993), Lainer (1991), Lekagul & Round (1991), MacKinnon & Phillipps (1993), Meyer de Schauensee (1984), Okugawa *et al.* (1973), Perennou *et al.* (1994), Ripley (1982), Sakane (1957, 1958), Scott (1989), Smythies (1986), Subramanya (1987), Tanaka & Lida (1991), White & Bruce (1986), Williams, M.D. (1986), Won (1993), Yan Anhou (1986).

16. Red-wattled Lapwing

Vanellus indicus

French: Vanneau indien **German**: Rotlappenkiebitz **Spanish**: Avefría India
Other common names: Red-wattled Plover, Indian Decorated Lapwing

Taxonomy. *Tringa Indica* Boddaert, 1783, Goa.
Sometimes placed in *Hoplopterus* or *Lobivanellus*. Apart from *atronuchalis*, differences between races mostly clinal, involving depth of gloss, coloration of upperparts and size. Four subspecies normally recognized.
Subspecies and Distribution.
V. i. aigneri (Laubman, 1913) - SE Turkey, Iraq, Iran, S Transcaspia, E Arabia and Pakistan.
V. i. indicus (Boddaert, 1783) - E Pakistan, India, Nepal and Bangladesh.
V. i. lankae (Koelz, 1939) - Sri Lanka.
V. i. atronuchalis (Jerdon, 1864) - NE India (Assam) and Myanmar to N Malaysia and Vietnam.

Descriptive notes. 32-35 cm; 110-230 g; wingspan 80-81 cm. Boldly patterned lapwing with black breast, red bill with black tip, small red wattles and long yellow legs. Sexes alike. Non-breeding adult, during wing moult, has brown tinged crown and white speckling on throat. Juvenile has generally duller plumage, with whitish throat; greyish brown breast and crown, latter with white speckles. Races generally differ only rather slightly, mainly in amount of gloss, coloration of upperparts and size; *atronuchalis* has slender white hindneck collar, with white patch on ear-coverts isolated from white breast; other races very similar to nominate, with *aigneri* largest and palest, *lankae* smallest, darkest and glossiest.
Habitat. From lowlands up to c. 1800 m, in open areas near fresh or brackish water: *jheels*, rivers, mudbanks, wet grassland, pools, particularly on cultivated land, such as corn fields, grass fields and large gardens; also within open forests, and on waste, fallow and ploughed land; occasionally on grass along highways.
Food and Feeding. Beetles and other insects, including ants, butterfly and fly larvae, grasshoppers, crickets, bugs, earwigs and termites; also molluscs, worms and crustaceans. Feeds mostly at dawn and dusk, and during moonlit night.

On following pages: 17. Javanese Wattled Lapwing (*Vanellus macropterus*); 18. Banded Lapwing (*Vanellus tricolor*); 19. Masked Lapwing (*Vanellus miles*); 20. Sociable Lapwing (*Vanellus gregarius*); 21. White-tailed Lapwing (*Vanellus leucurus*); 22. Pied Lapwing (*Vanellus cayanus*); 23. Southern Lapwing (*Vanellus chilensis*); 24. Andean Lapwing (*Vanellus resplendens*); 25. Red-kneed Dotterel (*Erythrogonys cinctus*).

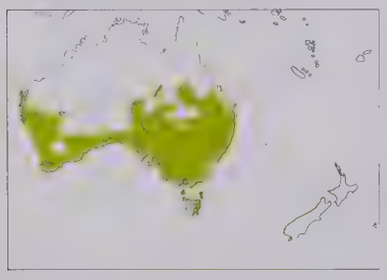
Breeding. Laying mid-Apr to late Jun in Iraq; race *indicus* breeds Mar-Aug/Sept; in Sri Lanka, breeds during SW monsoon, primarily Jun. Monogamous. Solitary and territorial. Nest is shallow scrape, unlined or lined with small stones and debris, usually situated near water. Clutch 3–4 eggs; possibly double-brooded; incubation c. 26-30 days; chick has upperparts grey-brown mottled with black, broad black collar from behind eye around occiput and a white collar below it, underparts whitish with black pectoral band; fledging 38 days.
Movements. Resident, dispersive and in places migratory. In winter, generally moves down from high altitudes. Resident to dispersive in Middle East, in Iraq leaving dried up places after breeding season. Breeding birds of S Turkmenistan migratory, probably wintering in Afghanistan or Pakistan, or both, arriving back in Turkmenistan in second half of Apr.
Status and Conservation. Not globally threatened. SW Asia holds in the order of 100,000 birds, SC Asia more than 100,000 birds, and unknown number in SE Asia. Occupies wide variety of niches, and also occurs in areas densely populated with humans. More than 5000 birds winter in Iran. Apparently in process of spreading up valley of R Tigris into SE Turkey, where first recorded in 1983; no recent reports on status, due to political turmoil in zone.
Bibliography. Ali & Ripley (1980), Cramp & Simmons (1983), Deignan (1945), Dementiev & Gladkov (1951b), Desai & Malhotra (1976), Étchécopar & Hüe (1978), Evans (1994), Flint *et al.* (1984), Green & Moorhouse (1995), Haeftelin (1987), Hollom *et al.* (1988), Hüe & Étchécopar (1970), Inskipp & Inskipp (1991), Kalsi & Khera (1986, 1987, 1990, 1992), Khajuria (1970), Knystautas (1993), Lekagul & Round (1991), MacKinnon & Phillipps (1993), Madoc (1976), Medway & Wells (1976), Mian *et al.* (1994), Mukherjee (1975), Mundkur (1985), Naik *et al.* (1961), Perennou *et al.* (1994), Phillips (1978), Polozov *et al.* (1990), Richardson, C. (1990), Ripley (1982), Roberts, T.J. (1991), Roos & Schrijvershof (1993), Rutgers & Norris (1970), Samaraweera (1967), Scott (1989), Shirihai (1996), Smythies (1986), Sundararaman (1989), Tehsin & Lokhandwala (1982).

17. **Javanese Wattled Lapwing**

Vanellus macropterus

French: Vanneau hirondelle **German**: Javakiebitz **Spanish**: Avefría Javanesa
Other common names: Javanese Wattled Plover, Sunda/Black-thighed Wattled Lapwing

Taxonomy. *Charadrius macropterus* Wagler, 1827, Java.
Has also been placed in monospecific genus *Rogibyx*; *R. tricolor* is synonym. Monotypic.
Distribution. Java, possibly on Sumatra and Timor. Almost certainly extinct.



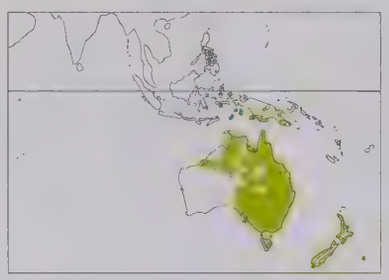
Descriptive notes. 27-29 cm; 325 g (estimated). Generally rather dark lapwing, with large yellow or white wattles; head, belly patch and flight-feathers deep black; upperparts, breast and upper belly dark brown; uppertail-coverts and vent white; curved black spurs; legs yellow-orange. Sexual and seasonal differences and juvenile plumage remain undescribed.
Habitat. Open areas near freshwater ponds; presumably also on agricultural land.
Food and Feeding. No information available.
Breeding. Breeding evidently occurred in May-Jun, in W Java.
Movements. Apparently resident. Some dubious reports suggest birds might have migrated to Sumatra or even Timor, though latter, in particular, generally treated with scepticism; one report of several birds perched on railing of ship off N coast of Java.
Status and Conservation. Almost certainly EXTINCT. Decrease caused by intensive agricultural and hunting activities within presumed range, with effects intensified by massive growth of human population. Some observations made on Java in late 19th century; in 1920's, collected from Citarum Delta and at Tangerang, W of Jakarta; not recorded since observation on S coast of E Java in 1939. Claimed to have bred in Sumatra, on grounds of single specimen and egg, although accuracy of collecting labels has been questioned. Traditionally listed as occurring on Timor, but origin of specimens thus labelled seems highly dubious.
Bibliography. Andrew, P. (1992), Collar & Andrew (1988), Collar *et al.* (1994), Hellebrekers & Hoogerwerf (1967), King (1978/79), Kooiman (1940), Kuroda (1936a), MacKinnon (1988), MacKinnon & Phillipps (1993), van Marle & Voous (1988), Temple (1979), White & Bruce (1986).

18. **Banded Lapwing**

Vanellus tricolor

French: Vanneau tricolore **German**: Schwarzbandkiebitz **Spanish**: Avefría Tricolor
Other common names: Black-breasted/Banded Plover

Taxonomy. *Charadrius tricolor* Vieillot, 1818, "Terres Australes" = New South Wales.
Formerly placed in *Lobivanellus* or in monospecific *Zonifer*. Monotypic.
Distribution. S Australia and Tasmania.



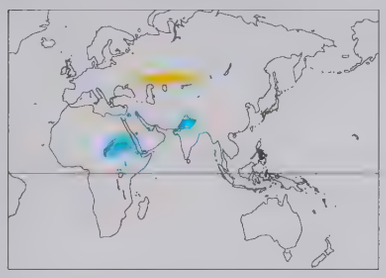
Descriptive notes. 25-29 cm; 150-200 g; wingspan 61-67 cm. Dark U-shaped breast band and clear white stripe behind eye; black and white head; upperparts dull purplish brown; small red wattle, fairly pale yellow bill and eye. Sexes alike. No seasonal variation. Juvenile like adult, but with dull yellowish brown bill and very small wattles; crown and breast band browner; brown feathers of upperparts have broad buff fringes.
Habitat. Prefers open, short grassland, including pastures, airfields and open savanna in semi-arid regions, and ploughed fields and salt-bush plains. Usually encountered inland, in drier areas than *V. miles*; not particularly attracted to open water.
Food and Feeding. Diet includes seeds, leaves, molluscs, worms, insects and spiders; seems to have a high vegetable content, especially seeds. Many stomachs contained grit. Often forages by foot-trembling. Feeds diurnally, but usually roosts in shade during very hot periods. Forages on grassland and often on ploughed or heavily grazed land; also at haystacks, where picks up seeds.
Breeding. Laying year round, depending on rains, but frequently Jun-Nov; often breeds opportunistically, e.g after rains; in Western Australia, pairs select territories within 2 weeks after rains. Monogamous. Solitary, rarely in loose colonies; highly territorial. Breeds on pastures, ploughed land, dry plains, salt-bush plains and airfields; nest is shallow scrape or depression in ground, unlined or lined with grass and other plant materials and debris. Clutch 4 eggs (3-5), laid at intervals of 24 hours, except last egg, which can take 4 days to be laid; incubation by both parents, 26-28 days, beginning after 3rd egg laid; chick has upperparts mottled buff, orange-buff and black-brown, hindneck and stripe behind eye white bordered above with dark brown stripe, underparts white; fledging c. 8 weeks, but young fully feathered at c. 5½ weeks. Nests may be lost due to flooding, predation or trampling by cattle. Reported fledging success ranges from 5·5% to 64%.
Movements. Generally resident with some erratic movements, apparently dependent on water and food conditions; sometimes moves over large distances. In inland areas, occurs in highest numbers after heavy rains and in lowest numbers (or absent) during drought, when higher numbers occur at coast. Moves by both day and night. Occurs in pairs and flocks of 3-20 birds, on occasion over 100.
Status and Conservation. Not globally threatened. Total population reckoned to number c. 27,000 individuals. Suitable habitat has increased due to cultivation of forest and scrubland. In some areas numbers have decreased due to termination of wheat farming and due to pasture vegetation having grown too tall.
Bibliography. Blakers *et al.* (1984), Bonnin (1982), Christian *et al.* (1992a), Dann (1981), Favaloro (1944), Flegg & Madge (1995), Frith (1969), Lane & Davies (1987), Lindsey (1992), Macdonald (1988), Marchant & Higgins (1993), Masters & Milhinch (1974), Pizzey & Doyle (1980), Pringle (1987), Rutgers & Norris (1970), Schodde & Tidemann (1986), Simpson & Day (1994), Slater *et al.* (1989), Trounson (1987).

19. **Masked Lapwing**

Vanellus miles

French: Vanneau soldat **German**: Maskenkiebitz **Spanish**: Avefría Militar
Other common names: Masked Plover, Spur-winged Plover/Lapwing

Taxonomy. *Tringa miles* Boddaert, 1783, Louisiana; error = Australia.
Sometimes placed in *Hoplopterus*, *Lobivanellus* or monospecific *Lobibyx*. Race *novaehollandiae* on occasion considered distinct species, but intergrades with nominate form in at least two areas of overlap, in N Queensland and in L Eyre catchment area. Birds of N Australia formerly awarded separate race, *personatus*. Two subspecies recognized.
Subspecies and Distribution.
V. m. miles (Boddaert, 1783) - NE & S New Guinea and Aru Is to N Australia; probably non-breeding visitor to SE Wallacea.
V. m. novaehollandiae (Stephens, 1819) - E & SE Australia, Tasmania and New Zealand.



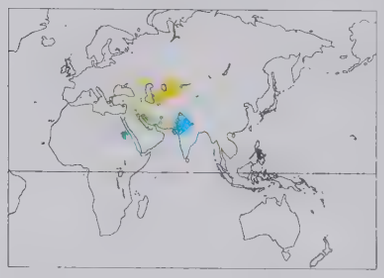
Descriptive notes. 30-37 cm; 230-440 g; wingspan 75-85 cm. Large lapwing with outsize yellow wattles and long yellow carpal spurs; crown black, upperparts plain olive brown, underparts white. Sexes alike. No seasonal variation. Juvenile has feathers on greyish upperparts fringed with buff; small wing spurs and wattles. Race *novaehollandiae* has somewhat smaller wattles; much more extensive black cap continuing down hindneck to black breast patches; forms intermediate between this race and nominate occur widely.
Habitat. Wide range of open habitats with, preferably, short grass, either natural or cultivated, including pastures, fallow fields, airfields and margins of various kinds of wetlands, ranging from temporary pools and water-holes to lakes and lagoons; usually close to water. Also found in sheltered coastal areas. Common within urban areas, including parks, playing fields and grassy roadsides.
Food and Feeding. Mainly insects, worms and spiders; also molluscs, crustaceans, seeds and leaves. Young seem to feed mainly on worms, beetles and beetle larvae. Apart from typical plover-style feeding, also feeds by foot-trembling. Usually forages in short grass, sometimes in gravel and mud. Possibly also feeds at night.
Breeding. Laying in all months in N Australia, Jun-Dec in S Australia, Jun to late Nov in New Zealand; breeding season covers 9-11 months. Monogamous on long-term basis; very faithful to breeding site. Piping-parties of up to 6-7 birds probably play role in pair formation. Breeds solitarily in territory, but may occasionally join nearby flocks. Usually nests in short grass, often near water; nest is depression in ground, unlined or lined with plant material, pebbles and debris. Clutch 4 eggs, sometimes 3; incubation 28-30 days; chick has upperparts pale brown speckled buff and mottled black, white hindneck collar, underparts mostly white; young can swim from early age; fledging usually 6-7 weeks (5-8); families from adjacent territories merge after fledging of young; young are dependent for up to 6 months; thereafter start associating with other birds, but often still with one or both parents nearby. One female observed breeding at end of 1 year old, others at 2. In Victoria, of 180 eggs laid, 45% hatched and 8·9% fledged; on North I, New Zealand, of 542 eggs, 74% hatched, c. 18% fledged. Large proportion of nests may fail through destruction by cattle, disturbance, mowing, predation and flooding. Longevity at least 12 years.
Movements. Resident and dispersive, responding to new food sources in recently constructed and temporary wetlands, leaving as soon as they dry out. Young more dispersive than adults. Numbers at Australian coastal areas seem to increase in autumn, when inland wetlands dry up. May fly as far as Christmas I (Indian Ocean) and Solomon Is, and from Australia to New Zealand. Status in Moluccas, Tanimbar and nearby islands unclear, but probably regular non-breeding visitor. In non-breeding season occurs in small flocks, sometimes of up to several hundreds; small flocks of non-breeders and failed breeders occur during breeding season.
Status and Conservation. Not globally threatened. Total population estimated at c. 287,000 birds, of which 258,000 in Australia. Breeding habitat has increased considerably due to cultivation of woodland. Rare on Tasmania until 1888, but now a common bird; has also increased numbers in C Australia. First reached New Zealand between 1886 and 1932; first breeding record in 1932 in Southland; population has increased and expanded since; first breeding record on North I 1970. Also in New Zealand, as species expands range, increasing number of collisions (or near-collisions) with aircraft; these caused 22% of all plane accidents in 1991, so species is extensively controlled on airfields, e.g. by destruction of nests, shooting of adults and maintenance of unsuitable habitat.
Bibliography. Alcorn (1990), Ashby (1991), Barlow (1972, 1978, 1988b), Barlow *et al.* (1972), Barter (1992d), Beehler *et al.* (1986), Blakers *et al.* (1984), Burger & Gochfeld (1985c), Chambers (1989), Chatto (1987), Christian *et al.* (1992a), Coates (1985), Dann (1977, 1981), Dowding & Murphy (1993b), Finch (1982c), Lane & Davies (1987), Luttrell (1991), Marchant & Higgins (1993), Morton *et al.* (1990), Pettigrew & Frost (1985), Pringle (1987), Rutgers & Norris (1970), Scott (1989), van Tets *et al.* (1967), Thomas (1969), Thomas & Dartnall (1971c), White & Bruce (1986).

20. Sociable Lapwing

Vanellus gregarius

French: Vanneau sociable **German**: Steppenkiebitz **Spanish**: Avefría Sociable
Other common names: Sociable Plover

Taxonomy. *Charadrius gregarius* Pallas, 1771, Volga, Jaiku and Samara.
Often placed in genus *Chettusia*. Monotypic.
Distribution. SC Russia and Kazakhstan. Winters in Sudan (formerly?) and Eritrea, Israel and Arabian Peninsula, Pakistan and NW India; possibly also Iraq.



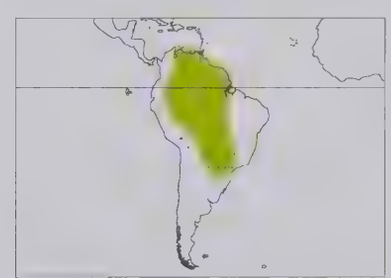
Descriptive notes. 27-30 cm; 150-260 g; wingspan 70-76 cm. Olive brown lapwing with bold, white supercilia meeting on forehead and nape; black crown and lores, thin dark line behind eye; belly black and chestnut; legs blackish. Differs from partially sympatric *V. leucurus* in dark belly, shorter dark legs, and contrasting head pattern. Female less intensely coloured than male, especially on belly. Non-breeding adult has buff wash to supercilia; pale belly. Juvenile similar to non-breeding adult, but with clear buff fringes and dark terminal lines to feathers of upperparts; breast heavily streaked brown.
Habitat. Breeding habitat mainly on transition zones of *Stipa* and *Artemisia* steppes; dry wasteland, cultivated, ploughed and stubble fields. During migration, found mainly on sandy plains with short grass, dry meadows, fallow land and cultivated fields. On wintering grounds, prefers burnt steppe and savanna, uncultivated wasteland, dump pastures and harvested millet fields; usually near water. In Arabia, often occurs in desert near coast.
Food and Feeding. Chiefly insects, such as grasshoppers, beetles, crickets and moth larvae; spiders; frequently small amounts of plant material (grains, leaves and flowers). Usually some small stones in stomach, occasionally remains of vertebrate bones and mollusc shells. Diet varies through breeding season; in winter, apparently chiefly grasshoppers and other insects. Diurnal.
Breeding. Laying mid Apr to late May or early Jun in N. Monogamous. Before start of breeding season, parties of 5-10 birds land on open field for display fights of males in front of females. Semi-colonial, with neighbouring parties 20-50 m apart, each consisting of 3-20 pairs; each pair is territorial; occasionally breeds alongside other wader species, e.g. Collared Pratincole (*Glareola pratincola*). Nests on bare saline patches or in short vegetation, near water; nest is scrape, unlined or lined with some plant material, pebbles and debris, but amount of lining material accumulates during incubation. Clutch 2-5 eggs; single brood, but replacement brood is laid after egg loss; incubation not more than 22 days, mainly by female; chick pale pinkish buff to creamy buff above with black speckles and stripes, cheeks plain cream, hindneck and underparts buffy white; fledging 35-40 days.
Movements. Migratory. Migrates from breeding grounds by Aug-Sept, varying between years. Disperses through Kyrgyzstan, Tadjikistan, Uzbekistan, Turkmenistan, Iran, Turkey and Israel; migrates through Middle East mostly Sept-Nov and Mar; reaches India and Pakistan by Sept-Oct, and, at least formerly, Sudan by late Oct; uncommon migrant, wintering in small numbers on Arabian Peninsula. Leaves wintering grounds in Mar or early Apr and arrives on breeding grounds mid Apr to early May. Migrating flocks are small, of 15-20 birds, rarely several hundreds. Vagrant to Sri Lanka, with only two records.
Status and Conservation. VULNERABLE. On steppes between R Volga and R Ural 1000-2100 pairs, but slowly decreasing; in Kazakhstan densities dropped from 13·2 birds/km² in 1930's to 0·12 birds/km² in 1992, and 0·08 birds/km² in 1993. In NE Africa and SW Asia less than 10,000 birds winter; numbers wintering in Indian Subcontinent probably do not exceed 1000; in total perhaps less than 10,000 mature individuals remain. Population has decreased throughout range due to rapid cultivation of steppe areas and high grazing pressure on remaining grasslands. Many nests are destroyed by cattle and agricultural activities. Change to drier climate in 20th century in breeding and wintering areas may have negatively influenced population too. Expansion of Rook (*Corvus frugilegus*), the main predator of its nests, may have had additional adverse effects. Breeding distribution reduced since 19th century; formerly in Ukraine, Crimea and Volga region. Numbers have dropped dramatically in N Kazakhstan since 1930, when post-breeding flocks consisted of 100's and 1000's of birds, but after 1970 only of 10's. Large wintering flocks (up to 270 birds) only recently seen in Eritrea and W Negev (Israel), but generally scarce in Eritrea and Oman; no records from Sudan since 1950; once a regular and fairly common wintering bird in Pakistan and NW India, but now rare. Contrary to earlier reports, may well not winter at all in Iraq; during period 1914-1918, huge flocks reported in C Iraq in Feb.
Bibliography. Ali & Ripley (1980), Bannikov (1978), Belik, V. (1994b), van den Berg (1984), Borodin *et al.* (1984), Calinin (1987), Chekmenev (1961), Collar & Andrew (1988), Collar *et al.* (1994), Cramp & Simmons (1983), Davygora *et al.* (1989), Dementiev & Gladkov (1951b), Dowsett & Forbes-Watson (1993), Étchécopar & Hüe (1964), Evans (1994), Flint *et al.* (1984), Goodman *et al.* (1989), Gordienko (1991), Grazhdankin (1985), Grisser (1983), Heredia & Máñez (1985), Hüe & Étchécopar (1970), Inskipp & Collins (1993), Kasparek (1992a), Khokhlov (1987), Khrokov (1978), Knystautas (1993), Kuchin & Chekcheev (1987a), Kürschner (1976), Mackworth-Praed & Grant (1957), Mawby (1988), Nikolaus (1987), Nikolaus & Hamed (1984), Paz (1987), Perennou *et al.* (1994), Phillips (1978), Riley & Rooke (1962), Ripley (1982), Roberts, T.J. (1991), Rogacheva (1992), Rutgers & Norris (1970), Sermet (1986), Shevchenko & Debelo (1991), Shirihai (1996), Solomatin (1973), Urban *et al.* (1986).

21. White-tailed Lapwing

Vanellus leucurus

French: Vanneau à queue blanche **German**: Weißschwanzkiebitz **Spanish**: Avefría Coliblanca
Other common names: White-tailed Plover

Taxonomy. *Charadrius leucurus* Lichtenstein, 1823, between the Kuwan and Ian Daria, Turkestan.
Often placed in genus *Chettusia*, in past sometimes in monospecific *Vanellochettusia*. Species name frequently misspelt *leucura*. Monotypic.
Distribution. C & SE Turkey and E Syria NE through Azerbaijan and Transcaspia to L Balkhash, and SE through Iraq and Iran to W Pakistan. Winters from Sudan through Iraq and Iran to C & E Pakistan and NW & NC India; also extreme SW Turkmenistan.
Descriptive notes. 26-29 cm; 99-198 g; wingspan 67-70 cm. Graceful, slim, long-legged lapwing, with pale, whitish face and all white tail; pinkish brown rest of head and back; grey breast, rosy-buff belly. Sexes alike. No seasonal variation. Juvenile has feathers of upperparts with dark centres and bright buff fringes; neck and breast mottled brown-grey.



Habitat. Lake shores and river valleys; nearly always in vicinity of shallow standing or slow-flowing water with suitable bed for wading. Also flooded or recently dried out marshy meadows and salt-shrub terrain. Breeds in damp, vegetated areas near salt or fresh water; also small vegetated islets and swampy shores of brackish lakes. Small flock observed flying to dry ploughed field at dusk to roost, in Pakistan.
Food and Feeding. Diet probably consists mainly of insects, especially beetles and grasshoppers, but also caterpillars and fly larvae; also takes worms, molluscs and crustaceans, including freshwater shrimps. Usually feeds on dry land, but also by foot-dabbling in shallow water, and sometimes catches prey by probing in soft mud; in Africa also wades in deeper water. Diurnal.
Breeding. Laying mid-Apr to May. Monogamous. Often in loose colonies, sometimes of several hundred pairs (Iraq); frequently together with other colonial breeders, often pratincoles, Black-winged Stilts (*Himantopus himantopus*) and terns; occasionally solitary. Nest is shallow scrape with sparse lining of plant material, in the open, usually near water. Clutch 4 eggs, sometimes 3; single-brooded in Iraq; incubation 21-24 days, starting with last egg; chick has upperparts greyish buff with black streaks, rusty-red ring around eye, underparts buffy white; tended by both parents; fledging c. 30 days; stays with parents at natal site after fledging. Age of first breeding probably 1-2 years.
Movements. Sedentary in much of Middle East, partly migratory in C Asia. Departs from breeding grounds in C Asia Jul to mid-Sept. Present in N Iran Apr-Aug, and in Sudan Sept-Mar. Migratory flocks small, of 1-6 birds, but possibly augmented during passage; flocks in spring generally slightly larger, up to 100. Few birds winter in extreme SW Turkmenistan. Rare migrant and occasional winterer in Egypt, Israel and Arabia; probably migrates on broad front across Arabia. In Iraq, moves from breeding sites in summer when water bodies dry up, and makes local movements in winter, deserting flooded zones. Wintering birds in Sudan, Pakistan and India present Sept-Mar. Reaches breeding grounds in C Asia from mid-Mar. In winter usually found in flocks of 6-25 birds.
Status and Conservation. Not globally threatened. Population wintering in E Africa and SW Asia numbers 10,000-100,000 birds, with similar numbers in SC Asia; 500-1000 birds in Sudan; very common in marshes of Euphrates; c. 1400 birds in Iran; common wintering bird in Pakistan. Evidently rather abundant in CIS, within fairly restricted range. Probably recently expanded westward: in 1950's and 1960's a few pairs found breeding in Azerbaijan, where maximum 100 pairs now estimated; in 1970's discovered breeding in C & SE Turkey, coinciding with first records of spring migration across Cyprus, but no expansion noted after 1970's and now probably only a few pairs remain; in late 1970's started breeding on N Caspian coast. First breeding pair recorded in Pakistan in 1987; probably breeds in NE Afghanistan. Increasing numbers in deserts of C Asia, where has started breeding in cultivated areas.
Bibliography. 22. Pied Lapwing

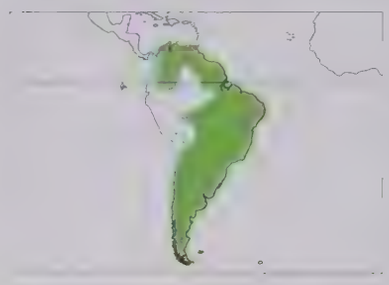
Vanellus cayanus

French: Vanneau de Cayenne **German**: Cayennekiebitz **Spanish**: Avefría de Cayena
Other common names: (Three-toed) Cayenne/Pied/Little White-winged Plover/Lapwing

Taxonomy. *Charadrius cayanus* Latham, 1790, Cayenne.
Sometimes placed in monospecific *Hoploxypterus*. Shows several similarities with *Charadrius*, including plumage details and some physiological features. Monotypic.
Distribution. South America E of Andes, from E Colombia to mouth of R Amazon, then S to Paraguay, SE Brazil and extreme NE Argentina (Misiones).



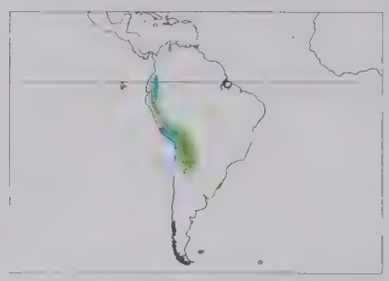
Descriptive notes. 21-24 cm; 55-84 g. Small lapwing, resembling *Charadrius* plovers in some aspects, but with long red legs and black carpal spurs; bold pattern in black, white and brownish grey; narrow white line encircles dark crown; forehead to nape deep black, sometimes with a little white on forehead; fairly narrow black breast band across otherwise white underparts; striking longitudinal black and white bar down scapulars; broad white wingbar stretches across most of secondaries and greater coverts to inner primary coverts. Sexes alike. No seasonal variation. Juvenile like adult, but with browner mask; smaller, dusky grey breast band; grey-brown with cinnamon-buff fringes on upperparts; less developed scapular markings.
Habitat. Mudflats and sandbanks of savanna ponds and rivers in forested zone; also along sea coast.
Food and Feeding. Poorly known. Items recorded mainly insects, including Hemiptera, Heteroptera, Hymenoptera, and Coleoptera, as well as Myriopoda; also snails.
Breeding. Display behaviour observed in May-Jul, and flightless young in Jun and Jul in NE Venezuela. Display included birds flying overhead, with peculiar undulating flight, while calling; also standing in front of each other with spread wings. Nest is slight depression in ground. One clutch comprised 2 eggs.
Movements. Sedentary.
Status and Conservation. Not globally threatened. No population estimates available; apparently very uncommon, although substantial numbers have been observed in savannas of Venezuela, with some 100 birds congregating around ponds. Uncommon and local in Colombia, where apparently restricted to sandy areas. Rare in Surinam and exceptional in French Guiana, with last record in latter in 1976; may be merely rare non-breeding visitor to the zone.
Bibliography. Blake (1977), Dubs (1992), Forrester (1993), Friedmann & Smith (1955), Haverschmidt (1968), Haverschmidt & Mees (1995), Hellmayr & Conover (1948), Hilty & Brown (1986), Meyer de Schauensee (1966, 1982), Meyer de Schauensee & Phelps (1978), de la Peña (1992), Pinto (1964), Remsen & Traylor (1989), Sargeant (1994), Scott & Carbonell (1986), Sick (1985c, 1993), Snyder (1966), Tostain *et al.* (1992), Zusi & Jehl (1970).

23. **Southern Lapwing**

Vanellus chilensis

French: Vanneau téro **German**: Bronzekiebitz **Spanish**: Avefría Tero
Other common names: Chilean Lapwing

Taxonomy. *Parra Chilensis* Molina, 1782, Chile.
Formerly placed in monospecific *Belonopterus*. Based on proportions and vocalization, might comprise two species, with separation of *cayennensis*, incorporating *lampronotus*; however, intergradation known at one locality. Race *fretensis* sometimes merged with nominate race. Four subspecies usually recognized.
Subspecies and Distribution.
V. c. cayennensis (Gmelin, 1789) - N South America, N of R Amazon.
V. c. lampronotus (Wagler, 1827) - R Amazon S through C, E & S Brazil to N Chile and N Argentina.
V. c. chilensis (Molina, 1782) - Argentina and Chile S to Chiloé I and Comodoro Rivadavia.
V. c. fretensis Brodkorb, 1934 - S Chile and S Argentina.



Descriptive notes. 32-38 cm; 1 male *cayennensis* 280 g, 1 adult *fretensis* c. 425 g. Large, crested lapwing with red carpal spurs, blackish breast band and bronze sheen on greyish brown upperparts. Sexes alike. No seasonal variation. Juvenile has crown feathers tipped buff, white facial band much reduced and infused buff, diffuse breast band, short crest and spurs; buff fringes and barring to feathers of upperparts. Race *fretensis* similar to nominate, but smaller; *cayennensis* has more white and less black on face, with rest of head and neck cinnamon brown; in *lampronotus*, head mainly intermediate brown-grey, with neat white line down face.
Habitat. Breeds in pastures, damp meadows, river plains and open boggy areas with short matted vegetation; has also been found breeding on ploughed land. During non-breeding season also occurs on inland wetlands and marshes, and tidal flats; occasionally open areas in woodland. Around ranch houses, or even in urban gardens; in Chile and Brazil, wing-clipped birds sometimes kept as sentinels.
Food and Feeding. Mainly insects, e.g. grasshoppers; also earthworms, and perhaps other terrestrial invertebrates; small fish and insect larvae disturbed by foot-trembling. Hatchlings mainly fed on earthworms.
Breeding. Season Apr-Jul in Venezuela; Mar in Colombia; in Chile, from Jul (nominate) and from Sept/Oct (*fretensis*); on Tierra del Fuego, eggs found in Oct and young birds observed late Nov and Dec. Monogamous, but co-operative breeding has been observed in Venezuela, with 2-3 adults or immatures helping in territory defence. Loosely colonial; territorial and highly aggressive, mobbing potential predators. Nest is shallow scrape, unlined or sparsely lined with grasses, usually on dry spot in, or very close to, wet area. Clutch 4 eggs, on occasion 3; incubation c. 27 days; chick variegated greyish cinnamon and black above with heavy black margins to white nape, underparts white with fuscous pectoral bar; fledging takes over 1 month.
Movements. Largely sedentary, with limited dispersion after breeding season. Populations of extreme S migrate to less cold areas in winter. Outside breeding season, occurs in small flocks, occasionally up to 200 birds.
Status and Conservation. Not globally threatened. No population estimates available; widespread and abundant throughout much of range. Apparently spreading due to forest clearance and cultivation; adaptability to use of some humanized habitats suggests species secure.
Bibliography. Belton (1984), Blake (1977), Canevari *et al.* (1991), Contreras *et al.* (1990), Fjeldså & Krabbe (1990), Gallegos (1984), Greer & Greer (1967), Haverschmidt (1968), Hayes & Fox (1991), Hellmayr & Conover (1948), Hilty & Brown (1986), Humphrey *et al.* (1970), Johnson (1965b), Maclean (1972a), Meyer de Schauensee (1966), Meyer de Schauensee & Phelps (1978), Myers (1978, 1980c), Naranjo (1991b), de Oliveira & Rech (1988), Oniki (1987), Ortega *et al.* (1988), de la Peña (1981a, 1987, 1992), Ridgely & Gwynne (1989), Scott & Carbonell (1986), Sick (1985c, 1993), Snyder (1966), Tostain *et al.* (1992), Walters & Walters (1980), Ward (1992), Wetmore (1926, 1965).

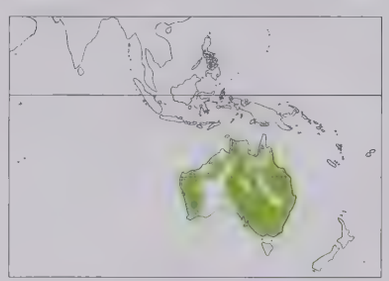
24. **Andean Lapwing**

Vanellus resplendens

French: Vanneau des Andes **German**: Andenkiebitz **Spanish**: Avefría Andina

Taxonomy. *Charadrius resplendens* Tschudi, 1843, Andes of Peru.
Formerly placed in monospecific *Ptiloscelys*. Monotypic.
Distribution. Andes from SW Colombia to N Chile and NW Argentina.
Descriptive notes. c. 33 cm; 193-230 g. Creamy grey head with dark brownish grey eye patch, bronzy green upperparts, purple patch on wing-coverts, and dark grey breast ending in sharp grey line; small red carpal spurs. Sexes alike. No seasonal variation. Juvenile like adult, but has brownish head and neck, breast mottled buff; pale buff fringes and dark green subterminal lines to feathers of upperparts.
Habitat. Breeds in open grassy areas, shore meadows, open parts of marshes, rushy pasture and boggy terrain of *páramo* and *puna* zones in Andes, at altitudes of 3000-4500 m, usually near lakes or rivers and often on partly inundated and hummocky ground; avoids saline water; sometimes in short grass of dry fields and hill sides. In southernmost portion of range, occurs down to 1500 m. During austral winter, found at lower altitudes and occasionally on coast.
Food and Feeding. No information available.
Breeding. Eggs found mainly Oct-Dec, occasionally later. One nest on barren ground was lined with plant material. Clutch 4 eggs (2 nests); chick mottled buff and black above, with thin, incomplete black demarcations of white nape. No further information available.

Movements. Essentially resident, with only altitudinal migration, birds descending slopes during austral winter.
Status and Conservation. Not globally threatened. No population estimates available. Locally very common at 3000-4500 m. Occupation of bleak high altitude habitats with relatively low densities of humans suggests species probably secure at present.
Bibliography. Blake (1977), Canevari *et al.* (1991), Fjeldså & Krabbe (1990), Graves (1981), Hellmayr & Conover (1948), Hilty & Brown (1986), Hughes, R.A. (1984), Johnson (1965b), Koepcke (1970), Meyer de Schauensee (1966, 1982), Narosky & Yzurieta (1987), Olrog (1984), Parker *et al.* (1982), de la Peña (1992), Peris & Alaberce (1992), Remsen & Traylor (1989), Rocha & Peñaranda (1995), Scott & Carbonell (1986), Ward (1992).



Genus *ERYTHROGONYS* Gould, 1838

25. **Red-kneed Dotterel**

Erythrogonys cinctus

French: Pluvier ceinturé **German**: Schwarzbrust-Regenpfeifer **Spanish**: Chorlito Pechinegro

Taxonomy. *Erythrogonys cinctus* Gould, 1838, New South Wales.
Often placed in genus *Charadrius*, and traditionally grouped with other Australasian aberrant *Charadrius*-like genera; however, recently grouped in Vanellinae on basis of allozymes, patterning of wing and presence of hind toe. Monotypic.
Distribution. Extreme S New Guinea and Australia.

Descriptive notes. 17-19·5 cm; 35-77 g; wingspan 33-38 cm. Medium-sized, boldly patterned wader; black cap contrasts with white throat; black breast band and middle flanks, turning to chestnut towards rear; upper flanks white; long legs bicoloured, with tibiae and "knees" pinkish red, tarsi and feet grey; long, slender, very slightly decurved bill. Sexes similar. No seasonal variation. Juvenile as adult, but cap, nape and hindneck pale brown; back feathers have whitish buff fringes; mostly white underparts with brownish breast patches; duller red bill.
Habitat. Inland wetlands, including swamps, lakes, creeks, and various kinds of man-made water bodies and pools; prefers temporary or permanent freshwater wetlands, particularly when inundated by rain or floodwater. Habitat usually exposed, with scattered short emergent vegetation, shallow water and mud or clay; rarely in brackish or salt water; lacks supraorbital salt gland.
Food and Feeding. Snails, bivalves, crustaceans, spiders, all sorts of insects and their larvae, and seeds. Feeds diurnally, gleaning and probing along muddy edges of water, or wading in shallow water; occasionally swims in deeper water; also uses foot-trembling. Often in loose flocks of 10-100 birds, occasionally more; sometimes exhibiting many aggressive interactions.
Breeding. Lays in summer, autumn or early winter after heavy rains, usually Aug-Dec (Jan). Occurs in flocks before breeding; breeds solitarily or in loose colonies of up to 30 nests; territorial. Nests on sand, damp soil or mud, along shore or on small islet, often among dense vegetation; regularly in mixed colonies with Black-winged Stilts (*Himantopus himantopus*), Red-necked Avocets (*Recurvirostra novaehollandiae*) and Hoary-headed Grebes (*Poliocephalus poliocephalus*); nest is depression in ground, usually scantly lined, though in areas susceptible to flooding sometimes substantial; built of twigs, grass and other plant material and debris; may be located inder clumps of wetland plants. Usually 4 eggs (2-5), probably laid at daily intervals; both parents incubate, starting when clutch complete, period unrecorded; chick has golden brown upperparts with black patches, white underparts; tended by both parents; at alarm call of parents, chick wades or swims to nearest plant in water. Nest failure high, due to trampling by cattle, predation by Australian Ravens (*Corvus coronoides*) and introduced mammalian predators, or human disturbance.
Movements. Generally resident, showing erratic movements; probably reponds to availability of fresh water; during drought moves S and towards coastal regions; during wet season and after flooding, numbers inland increase. After successful inland breeding, seems to show northward movements. During movements and at flooded sites can appear in large flocks of several hundreds.
Status and Conservation. Not globally threatened. Widespread, with estimated population of at least c. 26,000, but probably more. Numbers have increased in SE coastal region since 1940's and 1950's. Status in S New Guinea uncertain, with several records from Trans-Fly; may breed locally.
Bibliography. Subfamily CHARADRIINAE

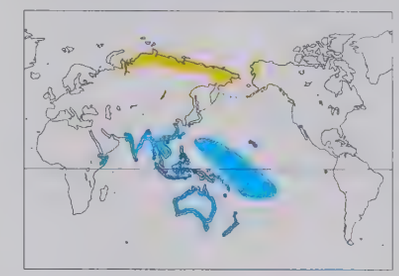
Genus *PLUVIALIS* Brisson, 1760

26. Eurasian Golden Plover

Pluvialis apricaria

French: Pluvier doré **German**: Goldregenpfeifer **Spanish**: Chorlito Dorado Europeo
Other common names: (Greater/European) Golden Plover

Taxonomy. *Charadrius apricarius* Linnaeus, 1758, Lappland.
Validity of subspecific division regularly debated, due to considerable variation within local populations and no apparent differences in measurements. Birds of British Is to N Germany formerly considered separate race, *oreophilos*. Two subspecies normally recognized.
Subspecies and Distribution.
P. a. altifrons (C. L. Brehm, 1831) - EC Greenland, Iceland and Faeroes to N Fenno-Scandia, and thence E to Taymyr Peninsula.
P. a. apricaria (Linnaeus, 1758) - British Is, through W Germany, Denmark and S Fenno-Scandia to Baltic states.
Winters from British Is through Mediterranean to S Caspian Sea.



Descriptive notes. 26-29 cm; 157-312 g; wingspan 67-76 cm. Largest and bulkiest of golden plovers, with underwing white, as opposed to brownish grey; also differs in shape and plumage colour; wings equal in length to tail or slightly longer. Female less extensively black, with some brown markings below. Non-breeding adult lacks black on face and underparts; upperparts less distinctly spotted with yellow, can turn greyish. Juvenile as non-breeding adult, with faint grey fringes on flanks and belly. In race *altifrons* male more uniformly black below, whereas nominate male has cheeks, throat, breast and belly infused with white; female *altifrons* has yellowish cheeks with black marks, whereas nominate female very variable, can have very pale head, but sometimes virtually identical to male.
Habitat. Race *altifrons* breeds in humid moss, moss-and-lichen and hummock tundra, shrub tundra, open bogs in forest tundra and alpine tundra; nominate race breeds on highland heaths and peatlands. On migration and in winter, occurs on pastures and open agricultural land, such as stubble and fallow fields, and regularly feeds on intertidal flats. Often roosts on ploughed land or amongst low crops; sometimes roosts on flats and salt-marshes in shallow bays and estuaries.
Food and Feeding. Mainly invertebrate prey, especially beetles (including pupae and larvae) and earthworms; sometimes plant material, e.g. berries, seeds and grass; all kinds of insects and their larvae, spiders, millipedes and snails; on intertidal flats polychaete worms. Pecks from surface or probes for 1-2 cm; evidently also detects prey by sound. Sometimes feeds at night. Moves in flocks of 10's to 1000's; during breeding, flocks are smaller. During breeding season, Dunlins (*Calidris alpina*) often mix with off-duty birds, benefiting from vigilance of present species.
Breeding. Laying Apr to mid-May in Britain, mid-May to late Jul further N. Monogamous, with lifelong pair-bond. Solitary, with nests sometimes only few hundred metres apart; 1-4 pairs/km in linear survey, and 2-10·9 pairs/km² in Taymyr, but very variable between years; in Britain, up to 16 pairs/km² on fertile soil and 0·1-0·5 pairs/km² in montane zone; strong breeding-site fidelity and natal philopatry. Territorial; adults feed mostly outside territory. Breeds in flat and openly vegetated areas; nest is shallow scrape, lined with moss and plant material. Usually 4 eggs, occasionally 3 or 2, laid at intervals of 48-60 hours; incubation 28-31 days; chick has mottled black and bright yellow upperparts, whitish underparts; fledging 25-33 days; young independent soon after fledging. Hatching success 81% in Lappland. Many broods subject to predation. Breeds first at 2 years old. Oldest ringed bird 12 years, 2 months.
Movements. Migratory; only partially migratory in Britain and Ireland. Icelandic population leaves late Sept to early Nov, probably wintering mainly in Ireland, and in W Britain, W France and Iberia; birds from Scandinavia to Siberia winter from Britain and Netherlands to N Africa, but mainly in S Britain, France, Iberia and Maghreb; birds from Taymyr possibly fly across W Siberia and Kazakhstan and also S along R Yenisey across taiga, towards Caspian Sea and Mediterranean. Adults leave breeding areas late Jul to early Sept, juveniles Oct-Nov. N extremes of wintering distribution left as soon as frost starts, but soon reoccupied as weather improves. Ringing recoveries suggest more E route during return migration. In Netherlands and W Germany numbers grow in Apr and early May, and breeding areas reoccupied in May or early Jun on N tundra. In Britain, birds do not generally move far from breeding areas, which are abandoned Jul-Feb.
Status and Conservation. Not globally threatened. Breeding population of race *apricaria* estimated at 1,800,000 birds (1994), and is declining; no population estimates available for race *altifrons*, but range in Russia has been expanding in recent years. In W Europe c. 609,000 breeding pairs, with 300,000 in Iceland (1985), 130,000 in Norway (1981), 100,000 in Finland (1986) and 30,000 in Sweden (1984). Contraction of S limit of range in NW Europe since mid-19th century, mainly due to habitat changes, notably cultivation and afforestation of heathland: numbers have decreased in Ireland and Britain, with 22,600 pairs in 1987; breeders from former range of Belgium to Denmark to Poland have practically disappeared; in Norway recovered somewhat after decline in late 19th and early 20th centuries; in S Sweden decreased dramatically since mid-20th century, possibly due to climatic amelioration, but some recovery now in Sweden; major increase in Finland from 26,000 pairs in 1950's to 258,000 pairs in 1973-1976, but apparently followed by more recent decrease. Until 1950's, large numbers, probably up to 80,000 birds per year, caught in Netherlands by specialized plover-netting. Frequently taken by hunters on wintering grounds, especially in France. Counts of Dutch wintering birds suggest marked decrease in population since 1978; maximum numbers present in winter, up to 300,000 birds in Britain (85,000 in 1992), 400,000 in Netherlands (1978), 200,000 in Denmark, and 170,000 in Germany.

27. Pacific Golden Plover

Pluvialis fulva

French: Pluvier fauvem **German**: Pazifischer Goldregenpfeifer **Spanish**: Chorlito Dorado Siberiano
Other common names: Asian/Asiatic/Eastern Golden Plover

Taxonomy. *Charadrius fulvus* Gmelin, 1789, Tahiti.
Forms superspecies with *P. dominica*, with which formerly considered conspecific (see page 386). Monotypic.
Distribution. NC & NE Russia, from Yamal Peninsula to Chukotskiy Peninsula and S across Koryakskiy highlands to N Kamchatka; W Alaska. Winters from E Africa through S Asia and Indonesia to Oceania, Australia and New Zealand; small numbers in S California.

Descriptive notes. 23-26 cm; 100-192 g; wingspan 60-72 cm. Black underparts with narrow white flanking line; vent tends to be mostly white with scattering of black. Very similar to *P. apricaria* and *P. dominica*, but smaller; has longer legs and is yellower than *P. apricaria*, with brownish grey underwing, and wings clearly longer than tail. Female somewhat less black than male. Non-breeding adult has yellowish buff on breast, grading to whitish on belly and vent; golden spotting less prominent. Juvenile as non-breeding adult, but with brown barring on flank.
Habitat. Breeds in drier parts of typical tundra, but not on coastline; on shrub tundra, rarely forest tundra, and on stony well drained upland, with moss and lichens; montane tundra in Chukotskiy and Koryakskiy highlands. Winters in coastal areas, in fields with short grass, prairies, ploughed land, salt-marshes, beaches and open sandflats and mudflats; often on golf courses, playing fields, airfields, etc. Young birds occur more frequently on mud by inland waters and tidal flats. Roosts in same places used for feeding, but also near feeding areas on exposed sandy beaches or rocks; where such roosting sites are lacking, may roost on roofs of buildings.
Food and Feeding. Mainly insects, molluscs, worms, crustaceans and spiders; berries particularly important on tundra; occasionally seeds and leaves. Feeds in typical plover style; also gleans and probes in mud, sand and pastures. Feeds alone or in flocks of 100 birds or more. Some wintering birds occupy territories for entire season, returning each year.
Breeding. Breeds in N summer, with laying in Jun. Presumably monogamous. High degree of site fidelity, especially so for males; often breeding within 100 m of nest-site of previous year, and sometimes in same nest cup. Densities usually c. 1 pair/km², locally up to 6-7 pairs/km²; can vary considerably between years. Nest on dry spots, on hummock, lichen, *Dryas* or moss tundra; nest is shallow scrape, lined with lichens. Clutch 4 eggs; incubation 26 days, by both sexes; chick has black and bright yellow upperparts and white underparts; after hatching, chicks and parents move to moist shrubby or grassy tundra or patches with green moss; chick tended by both parents, or by male only if brood is late. Oldest ringed bird at least 6½ years.
Movements. Migratory. Appears in Siberian tundra in early Jun; Taymyr population migrates over middle taiga along R Yenisey in late May, stopping in parties of 3-7 birds at thawed patches in forest openings and near villages; departs late Aug or early Sept; some birds migrate E in broad front across taiga. Southward migration takes place in large flocks, and at night. Non-breeders leave 2-4 weeks before breeders, and young birds some weeks after adults. Some Alaskan breeders fly 4500 km nonstop across Pacific Ocean to Hawaiian Is; adults reach Hawaiian Is in Aug, juveniles in Sept; arrival in Fiji in early Sept, New Zealand in Oct. E Africa and E Asia probably reached by overland migration across W Siberia; Indian winterers cross Tibet. Highly faithful to wintering sites.
Status and Conservation. Not globally threatened. Population wintering in SW & SC Asia probably c. 100,000 birds, and in CE & SE Asia at least 100,000 birds; c. 9000 in Australia, 500 New Zealand. In past, was a favourite species of hunters in India, but current situation unknown. Small population apparently wintered in W Europe in first half of 20th century, but has now disappeared (see page 409).

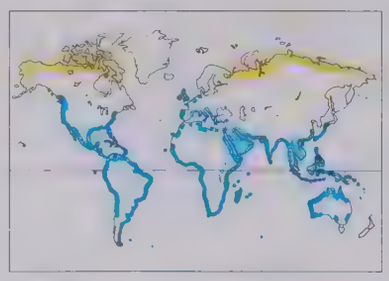
28. American Golden Plover

Pluvialis dominica

French: Pluvier bronzé **Spanish**: Chorlito Dorado Americano
German: Amerikanischer Goldregenpfeifer
Other common names: Lesser Golden Plover

Taxonomy. *Charadrius Dominicus* P. L. S. Müller, 1776, Hispaniola.
Forms superspecies with *P. fulva*, with which formerly considered conspecific (see page 386). Monotypic.
Distribution. W Alaska E through N Canada to Baffin I. Winters in South America S to Tierra del Fuego.



Descriptive notes. 24-28 cm; 122-194 g; wingspan 65-72 cm. Large white patches on sides of breast. Generally greyer, with paler flecks, than very similar *P. apricaria* and *P. fulva*; white flanks usually absent and vent mostly black; also differs from former in brownish grey underwing, and in wings being clearly longer than tail. Female somewhat whiter below. Non-breeding adult lacks black on underparts and breast; upperparts extensively grey, especially around head and neck; overall less yellow than *P. fulva*. Juvenile almost totally lacks golden colour, and has heavily marked greyish underparts.
Habitat. Breeds in Arctic and subarctic tundra beyond tree limit, in valleys and well drained uplands with short vegetation of moss and lichens. During northern winter, mostly inland on short-grass fields, prairies, ploughed land, wetlands and open sandflats or mudflats; young birds found more often on inland and tidal mudflats and saltings. Forms roosting flocks in salt-marshes and fields near lagoons or marshes, and occasionally on ocean beaches.
Food and Feeding. Insects, especially grasshoppers, crickets, beetles and caterpillars; also worms, spiders, molluscs, crustaceans; berries important on tundra; occasionally seeds and leaves. Feeds in typical plover style; also gleans and probes in mud, sand and pastures. Feeds alone or in flocks of 100 or more. Often defends feeding territory on wintering grounds.
Breeding. Laying Jun to mid-Jul. Monogamous, often for several years. Density c. 6 pairs/km². High degree of site fidelity. Nest is exposed, shallow scrape on dry patch amidst moss or lichen; lined with moss, lichen and dead leaves. Usually 4 eggs, sometimes 3, laid at intervals of 1-2 days; incubation c. 26 days, starting with 3rd egg; male incubates during day, female at night; chick mottled black and bright yellow above, with whitish cheeks and underparts; after hatching, chicks and parents move to moister areas; soon after fledging of young, adults collect in flocks on higher tundra during first half of Jul, just prior to migration; juveniles flock from mid-Aug. Hatching success c. 80% in Alaska.
Movements. Migratory, with elliptical migration pattern. Adults leave breeding grounds from early Aug, juveniles from mid-Aug; migrate across Canada to Hudson and James Bays, then SE, crossing W Atlantic to Lesser Antilles and N South America, and thence S, arriving in Argentina early Sept; regularly some birds S to region of Tierra del Fuego. May migrate without pause from James Bay to South America, if weather permits. During 19th century, may have followed route further E, as large numbers formerly used Nova Scotia as staging area. Return migration starts early Feb in Argentina, and follows route across interior South America, over Central America, across Gulf of Mexico and up Mississippi flyway; pauses on prairies of Texas in second half Mar, and on prairies of Canada in May, reoccupying Canadian breeding grounds late May to mid-Jun.
Status and Conservation. Not globally threatened. Total population 10,000-50,000 birds, apparently stable. Numbers dramatically reduced during 19th century, due to excessive hunting pressure in North and South America; exploitation similar to that of Eskimo Curlew (*Numenius borealis*), as both served as alternative game birds after Passenger Pigeon (*Ectopistes migratorius*) had been persecuted to extinction in second half of 19th century; records of 48,000 birds killed on single day; protection measures resulted in increasing numbers at beginning of 20th century. During 1980's numbers declined by 34-69% at one small staging site in NC Texas; might reflect population decline caused by degeneration of Cheyenne Bottoms staging site.

29. Grey Plover

Pluvialis squatarola

French: Pluvier argenté **German**: Kiebitzregenpfeifer **Spanish**: Chorlito Gris
Other common names: Black-bellied/Silver Plover

Taxonomy. *Tringa Squatarola* Linnaeus, 1758, Sweden.
Sometimes placed in monospecific genus *Squatarola*. Monotypic.
Distribution. Arctic Russia, from Kanin Peninsula to Chukotskiy Peninsula and Anadyrskaya; Alaska E to Melville Peninsula and Baffin I. Winters on coasts of North and South America, W Europe, Africa, S Asia, Indonesia and Australia.
Descriptive notes. 27-31 cm; 174-320 g; wingspan 71-83 cm. Sparkling silver upperparts with contrasting black underparts; black axillaries conspicuous in flight. Larger, chunkier and much greyer than congeners. Female has browner underparts than male, with pale flecking. Non-breeding adult lacks black of underparts; duller brownish grey above, dirty white below. Juvenile like non-breeding adult, but upperparts darker with pale yellow spots; faint streaking on breast and flanks.
Habitat. In Taymyr breeds from polar deserts to forest tundra, but commonest in Arctic tundra subzone. Typically found on dry hilly sites spotted with stony *Dryas* tundra; or on tundra with sedges, moss and lichens in both upland locations and river valleys. In non-breeding season, on intertidal mudflats and beaches; during migration, also frequents inland lakes and pools and more rarely grassland. Wintering birds roost in large flocks, of up to several thousand, in salt-marshes and on sandbanks and beaches.

Food and Feeding. On tundra, mainly insects and their larvae, such as beetles and Diptera, and other invertebrates; occasionally some grass seeds and stems. In winter, takes marine polychaete worms, molluscs, crustaceans; occasional insects, such as grasshoppers and beetles, and earthworms; primarily feeds on intertidal flats at low tide. During foraging, sometimes exposes prey by making a sideways flick combined with a peck, sending a piece of mud in the air. Sometimes feeds at night. Most frequently alone or in small parties of up to 30 birds. In winter quarters, some birds defend feeding territories, to which they return yearly; similar pattern during spring migration.
Breeding. Laying late May to first half Jun. Monogamous, often for several years. Solitary, with nests not less than 400 m apart; breeds in densities of 0·3-3·6 birds/km²; shows high degree of site fidelity, sometimes nesting 30-100 m from previous year's nest-site. Nest is shallow scrape, lined with small stones, moss and lichens. Usually 4 eggs, sometimes 3, laid at intervals of 36-72 hours; incubation 26-27 days, by both sexes, sometimes perhaps starting before clutch is completed; single brood, replacement clutch laid only if first fails very early on; chick variegated sulphur yellow and black above, white below, with white collar and white cheeks bordered below by black stripe; chick tended in wet areas by both parents for 2-3 weeks, after which female usually leaves; fledging c. 23 days; young independent just before or just after fledging. Age of first breeding 2-3 years. In Alaska c. 80% of eggs hatch and in Canada 67%, producing 2·7 young per pair. Oldest ringed bird 20 years, 4 months.
Movements. Migratory. Departs from breeding grounds Jul-Sept; juveniles leave 5-6 weeks after adults; southward movements take place into Nov, and possibly later. Return migration starts Apr, and most N wintering birds do not leave until early Jun; first departures from South Africa in Feb. Returns to tundra late May to early Jun. Part of Russian population flies W, down W Palearctic coasts to W Africa; other birds migrate S along E Mediterranean flyway to E & S Africa, and to S Asia and Australia; regular migrant through Korea, Japan and NE China; birds in E Atlantic flyway come from all of Russia, but possibly also from E Canadian Arctic; birds depart from Taymyr in W & S directions. Nearctic population mainly winters on coasts of North and South America; flies N in broad front across S North America, up Atlantic and Pacific coasts and Mississippi Valley; on southward journey, route further E. In Old World, females winter further S than males; juveniles and other non-breeders stay in winter quarters or migrate part way N in their first summer. In autumn, usually migrates during morning and evening.
Status and Conservation. Not globally threatened. E Atlantic flyway population c. 170,000 individuals (1989), of which c. 103,000 birds winter in W Europe, 20,000 in Gulf of Gabès in Tunisia, 39,000 in Guinea-Bissau, and 14,500 in S Africa; 50,000 winter in E Africa and SW Asia, including 17,000-21,000 in Tanzania; c. 30,000 in SC Asia; probably 25,000-100,000 in E & SE Asia and Australia, including 12,000 in latter. Probably over 50,000 birds breed in North America, of which 27,500 winter in South America. Since 1930's, wintering population in British estuaries has increased, even by factor of 6 in period 1970-1992, to 47,600 birds in 1992; numbers in Wadden Sea increased too, indicating overall increase in wintering population of W Palearctic. Decline in numbers of 80-100% at small staging site in NC Texas during 1980's might indicate population decline, possibly caused by degeneration of Cheyenne Bottoms staging area; monitoring of numbers of staging birds on Atlantic coast in 1980's did not reveal decline, although the trend was real; it now seems clear that this population is decreasing. Almost entire W Palearctic population stages in Wadden Sea in late May, and probably during southward migration too, with maximum count of 140,000 birds.

Genus *CHARADRIUS* Linnaeus, 1758

30. Red-breasted Plover

Charadrius obscurus

French: Pluvier roux **German**: Maoriregenpfeifer **Spanish**: Chorlito Maorí
Other common names: New Zealand/Red-breasted Dotterel

Taxonomy. *Charadrius obscurus* Gmelin, 1789, Dusky Sound, South Island, New Zealand.
Occasionally placed in *Pluvialis* or awarded monospecific genus *Pluviorhynchus*. Has alternatively been linked with *C. bicinctus*. Recently divided in two races, based on differences in morphometrics, plumage, ecology and behaviour. Two subspecies recognized.
Subspecies and Distribution.
C. o. aquilonius Dowding, 1994 - North I, New Zealand.
C. o. obscurus Gmelin, 1789 - Stewart I, New Zealand.
Descriptive notes. 26-28 cm; 128-179 g; wingspan 46-50 cm. Extent of reddish chestnut coloration on underparts very variable; bill often appears uptilted at tip. Sexes alike, male sometimes brighter. Non-breeding adult smudged grey-brown with white chin, throat and underparts, and whitish fringes to feathers of upperparts. Juvenile has darker upperparts, underparts washed pale orange-buff and dark marks on sides of breast. Races differ somewhat in plumage and size, male of nominate race usually dark brown above, rich chestnut below, whereas *aquilonius* tends to be paler and smaller.

Habitat. Race *aquilonius* inhabits sandy beaches, sandbanks, shell banks, dunes; occasionally, stony beaches and short-grass pastures. Nominate breeds inland, on exposed hill tops above 300 m; winters coastally, in flocks of 20-60 birds, on sandy beaches and tidal mudflats. Formerly occurred on mountain slopes, foothills and plains of E South I.

Food and Feeding. Molluscs, insects, amphipods, crabs and fish, e.g. 1-2 cm flounder; nominate race also takes earthworms. Feeds in typical plover style; occasionally uses stand-wait-peck, sewing-machine technique and foot-trembling. Feeds by night and day.

Breeding. Laying late Aug to early Jan, usually late Aug to Sept, on North I; probably 1 month later on Stewart I. Monogamous on long-term basis, with pair-bond held year round. Solitary, occasionally in groups of 2-10 pairs; 0·6-10 pairs/ha or less, on North I; territorial, showing high degree of site fidelity. Nest (nominate race) in depression among cushion-plants or rocks, lined with leaves; nest of *aquilonius* is shallow depression in sand, unlined or lined with few shells or small pieces of seaweed. Usually 3 eggs, sometimes 2, laid over c. 7 days; single brood, but up to 3 replacement clutches may be laid; incubation by both parents 28-32 days, starting 1-2 days after completion of clutch; males probably incubate at night; chick buffy white, speckled and blotched black, brown and yellowish above, white on face and underparts; tended by both parents; fledging 28-52 days; young independent soon, or remain with parents for weeks or even months. Fledging success 0·1-0·6 per pair. Nests may be flooded or trampled by cattle, and eggs and young may be taken by (introduced) mammalian predators. First breeding in second year. Several birds reach 14-19 years old; oldest bird recorded 41 years, 1 month.

Movements. Sedentary in places, short distance migrant elsewhere. Race *aquilonius* essentially sedentary, moving only short distance between breeding territory and post-breeding flocking site, showing high degree of site fidelity in latter. Nominate race leaves inland breeding areas for coast; juveniles often dispersive, some wintering on S coast of South I; regularly recorded elsewhere in small numbers, e.g. NW South I. Post-breeding flocks form Jan-Feb; *aquilonius* returns to territory Apr-May, nominate Aug; some birds of race *aquilonius* do not leave territory.

Status and Conservation. ENDANGERED. Until 19th century, widespread in all of New Zealand, but has declined considerably in range and numbers during past 150 years. Two well separated breeding populations now remain: c. 1400 birds on North I, and c. 65 on Stewart I; based on old accounts of breeding habitat, a division between the two populations may already have existed for a long time, and was possibly situated in C North I. Annual adult mortality nearly three times higher on Stewart I than on North I. Only few males present in nominate population, where effective population size may be as low as 12 pairs, and therefore in serious danger of extinction. North I population threatened by developments of coastal regions and deterioration of habitat due to introduced weeds. Further threats come from introduced predators, i.e. cats and rats on Stewart I, cats, rats, stoats, possums and hedgehogs on North I.

Bibliography. Barlow (1993), Chambers (1989), Collar *et al.* (1994), Dowding (1989, 1993, 1994), Dowding & Chamberlin (1991), Dowding & Murphy (1993a), Edgar (1969), Falla *et al.* (1981), Foreman (1991), Gaza (1994), Graeme (1989), Habraken (1980), Heather (1980), Latham (1979), Latham & Parrish (1987), Marchant & Higgins (1993), McKenzie, H.R. 31. **Common Ringed Plover**

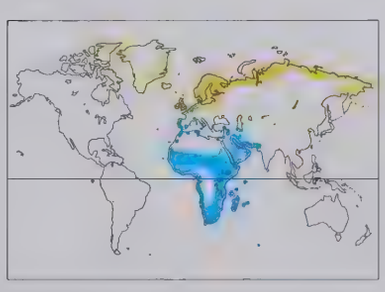
Charadrius hiaticula

French: Pluvier grand-gravelot **German**: Sandregenpfeifer **Spanish**: Chorlitejo Grande
Other common names: (Greater) Ringed Plover



Taxonomy. *Charadrius Hiaticula* Linnaeus, 1758, Sweden.

Probably forms superspecies with *C. semipalmatus*, with which sometimes considered conspecific; some hybridization on Baffin I. Distinction between subspecies based on moult; features changing clinally N-S, rather than E-W, make it impossible to draw dividing line in NW Europe. Populations from Canada to Faeroes formerly awarded race *psammodroma*, but based on extremely minor differences in average size, and not nowadays accepted. Two subspecies recognized.

Subspecies and Distribution.

C. h. hiaticula Linnaeus, 1758 - NE Canada through Greenland and Iceland to S Scandinavia, and S to NW France; winters from British Is S to Africa.

C. h. tundrae (Lowe, 1915) - N Scandinavia and N Russia; winters from Caspian Sea and SW Asia S to S Africa.

Descriptive notes. 18-20 cm; 42-78 g; wingspan 48-57 cm. More robust plover than *C. dubius*; very similar to *C. semipalmatus*, but lacks basal web between middle and inner toes, and has slightly broader breast band, larger white supercilium and clearer yellow eye-ring. Female has breast band and ear-coverts tinged brown on sides. Distinct non-breeding plumage absent in nominate race. Juvenile resembles pale adult with buffy fringes, but these soon lost; no black; narrow or broken frontal part of breast band. Race *tundrae* smaller, with darker, duller upperparts, often narrower white patch behind eye, and orange on bill often less extensive; in non-breeding plumage, black replaced by olive brown, bill duller.

Habitat. Along coast on sand or shingle beaches, sandbanks and mudflats, estuaries and, occasionally, rivers, lakes, lagoons, salt-marshes, short grassland, flooded fields and some artificial habitats, e.g. gravel pits, reservoirs, farmland and playing fields; also occurs on tundra. Prefers moist substrates, but rarely in shallow water; generally, at least during migration, race *tundrae* occurs on softer sediments than *hiaticula*. Roosts communally, close to feeding area, on exposed, bare ground, or that with short vegetation; usually on coast, above high water mark.

Food and Feeding. Small crustaceans, molluscs, polychaete worms, isopods, amphipods, various insects (e.g. ants, beetles, flies and their larvae) and millipedes. Sometimes uses foot-trembling. Typically in small flocks of up to 50, rarely 1200-1500 birds. Forages by day and night, often on tidal flats. In Morocco, Mar-Apr, may defend small feeding territories, overlapping with those of *Pluvialis squatarola*, on intertidal flats rich in ragworms (*Nereis diversicolor*).

Breeding. Laying Apr around North Sea, Jun to mid-Jul in Iceland, Jun in N Eurasia. Seasonally monogamous; pair-bond occasionally maintained over successive years. Solitary or in loose neighbourhood groups, with nests 5-100 m apart; in NE Greenland average 5-7 pairs/km² (maximum 16); densities in Taymyr 0·5-8 birds/km of shoreline, occasionally 50-80 birds/km², comparable to German Wadden Sea; high degree of site fidelity (90%) and natal philopatry (57%); often breeds in association with larger Charadriiformes species for protection; territorial, usually feeding outside territory; some birds pair up in special preliminary pairing territory. Participation of third bird in incubation and chick-rearing reported. Nest is shallow scrape, lined with pebbles, debris and pieces of vegetation. 3-4 eggs, usually 4, laid at intervals of 1-3 days; replacement clutch laid after loss; 2-3 broods, but only 1 in N of range; incubation 21-27 days, by both parents, starting with last or penultimate egg; chick pale buffy grey finely mottled with dusky and some cinnamon-buff above, white underparts, with blackish bordering band; fledging c. 24 days; young independent soon after. Hatching success 36%; fledging success 15%, but 65% of survivors may die in 1st year. In Britain 60-87% of clutches failed completely, due to predation, flooding and desertion. Age of first breeding 1 year. Annual mortality 18-42% and 61% in first-year birds; average longevity after 1st year 5·2 years; oldest ringed bird over 10 years.

Movements. Migratory. Northernmost birds migrate furthest S, while southernmost breeders are also northernmost winterers; some W European birds may remain close to their breeding grounds. Mainly winters in Africa, but also in Mediterranean Basin, Iberian Peninsula, Red Sea and Persian Gulf. Small numbers migrate through, or possibly winter in, China and Japan. Nearctic breeders all migrate across N Atlantic, in a single flight or via Greenland and Iceland, probably to winter in W Africa. Race *tundrae* migrates via Europe, but also crosses Eurasian and African landmasses in broad front, towards E & S Africa; possibly crosses Sahara. In Egypt arrives early Sept and departs late May, in South Africa Sept-Oct and Apr, in Morocco Aug-Nov and Apr-Jun. Returns to breeding grounds late Mar to May; Nearctic and N Eurasian populations arrive late May to mid-Jun. High degree of site fidelity during migration and wintering.

Status and Conservation. Not globally threatened. Population wintering in NW Africa and Europe c. 47,500 birds, of which 23,000 in Britain; in W & S Africa c. 195,000 birds, of which up to 30,000 in Guinea-Bissau, and possibly up to 30,000-50,000 more in Guinea; in E Africa and Asia at least 200,000 birds. Breeding population of race *hiaticula* 55,000-76,000 pairs in Arctic and subarctic W Europe, 12,500-13,800 in temperate W Europe (1986) and c. 25,000 pairs in Greenland and Ellesmere I (1985); race *tundrae* c. 36,500 pairs in Fenno-Scandia (1986). Numbers can fluctuate markedly: marked increase in Wadden Sea area during 1930-1950, but decreasing numbers since 1940 in other areas; apparently some decrease recently in Finland and E Germany, and some increase in W Germany, Britain and perhaps France and Netherlands. Decrease in Britain mainly due to disturbance. Number of inland breeders has decreased in Poland since 19th century, but has increased recently in Britain. Wintering numbers in W Europe have increased since 1970's.

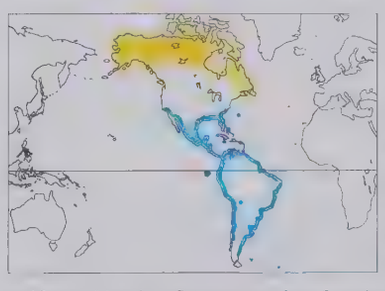
32. **Semipalmated Plover**



Charadrius semipalmatus

French: Pluvier semipalmé **Spanish**: Chorlitejo Semipalmeado
German: Amerikanischer Sandregenpfeifer
Other common names: Semipalmated Ringed Plover

Taxonomy. *Charadrius semipalmatus* Bonaparte, 1825, coast of New Jersey.

Probably forms superspecies with *C. hiaticula*, with which sometimes considered conspecific; some hybridization on Baffin I. Monotypic.

Distribution. Alaska and N Canada, S to C British Columbia and S Nova Scotia. Winters on coasts of North and South America, from California to Chile, and from South Carolina to Patagonia; also Bermuda, West Indies, Galapagos.

Descriptive notes. 17-19 cm; 28-69 g; wingspan 43-52 cm. Closely resembles *C. hiaticula*, but slightly smaller and less robust, with narrower breast band and smaller white supercillium; more extensive basal webbing between toes; black bands over forehead and bill until just behind eye. Female has brownish tinge to the black markings. Non-breeding adult paler, with black replaced by brown; bill blacker, breast band sometimes broken in centre. Juvenile like pale non-breeding adult; feathers of upperparts with buff fringes; breast band smaller, sometimes rather obscure; legs duller yellow-brownish.

Habitat. Freshwater and salt mudflat, intertidal mudflats and beaches, flat open margins of ponds, lakes and rivers, sparsely vegetated low gravel ridges, gravelly plains and dunes.

Food and Feeding. Primarily polychaete worms; also small gastropods, inarticulata, small crustaceans and insects, such as grasshoppers, beetles and ants. Frequently forages by foot-trembling. Feeds by sight; diurnal and nocturnal, and dependent on low water period during tidal cycle. Can be territorial during feeding.

Breeding. Laying early to late Jun. Solitary or in loose colonies. Density 0·4-1·3 pairs/ha. Nest is shallow depression in sparsely vegetated, sandy or gravelly area, lined with some debris. Clutch 3-4 eggs, completed within a week; incubation 24-25 days, by both parents, starting after laying of last or penultimate egg; chick similar to that of *C. hiaticula*; fledging 22-31 days; both parents tend young. Hatching success 29-100%, apparently higher at coast than inland.

Movements. Migratory. Winters on coasts of South and North America and all larger islands in the general zone; many birds remain in winter quarters during breeding season. Migrates mainly along coast, but also across interior Canada; breeding birds of C Arctic migrate N via interior USA, but S along coast; species probably crosses part of W Atlantic in autumn, but follows Atlantic coast in spring

when 70% of population visits Delaware Bay to feed on eggs laid by horseshoe crabs (*Limulus polyphemus*). Departs from breeding grounds in Canada from early Jul; adults leave before juveniles; arrives in South America Sept to early Nov. Spring return starts Mar, reaching S of breeding range in late May, and N in early Jun. Many adults follow same migration route every year, at roughly same dates.

Status and Conservation. Not globally threatened. Total population probably numbers c. 50,000 birds, and seems stable; no threats identified. Approximately 84% of South American wintering population occurs in Surinam and French Guiana.

33. Long-billed Plover

Charadrius placidus

French: Pluvier à long bec **German**: Ussuriregenpfeifer **Spanish**: Chorlitejo Piquilargo
Other common names: Long-billed Ringed Plover

Taxonomy. *Charadrius placidus* J. E. and G. R. Gray, 1863, Nepal.
Has on occasion been considered a race of *C. hiaticula*; sometimes included within the *C. hiaticula* superspecies. Monotypic.

Distribution. Russian Far East, EC to NE China and Japan. Winters from E Nepal and NE India to N Indochina, S China, S Korea and Japan.

Descriptive notes. 19-21 cm; 41-70 g. Very similar to *C. hiaticula*, *C. semipalmatus* and *C. dubius*, but generally larger, with longer dark bill and longer tail; black breast band narrow; eyestripe brownish black. Sexes alike. Non-breeding adult has duller head and breast pattern, and brownish supercilium. Juvenile resembles non-breeding adult, but lacks blackish on forecrown; supercilium very pale; upperparts fringed with buff.

Habitat. Breeds in gravel, shingle or stony areas at edges of rivers and lakes. During non-breeding season, frequents shingle banks of large rivers and muddy areas, such as cut rice stubble fields and mudflats.

Food and Feeding. Very little information available. Diet apparently includes flies and beetles. Usually solitary feeder.

Breeding. Little known. Breeds from mid-Apr. Apparently lays 4 eggs. Nest is depression on sandy ground among pebbles and rocks on elevated riverbank.

Movements. Populations of Russia and China migratory, moving S to E Nepal, NE India, N Indochina, S China and S Korea. Japanese population appears to be mainly sedentary.

Status and Conservation. Not globally threatened. Currently considered near-threatened. Total continental wintering population probably numbers less than 10,000 birds; nowhere seen in large numbers; altogether, only a few records from Bangladesh, Myanmar, Malaysia and China; this population appears to be declining. Size and trends of sedentary Japanese population unknown.

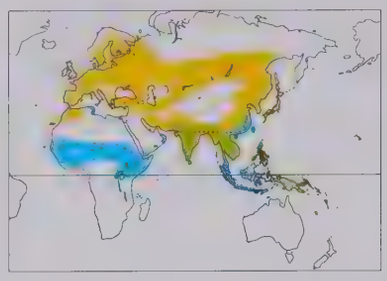
Bibliography. Ali & Ripley (1980), Austin (1948), Austin & Kuroda (1953), Beaman (1994), Brazil (1991), Deignan (1945), Dementiev & Gladkov (1951b), Eck (1976b), Étchécopar & Hüe (1978), Flint *et al.* (1984), Knystautas (1993), Kolomijtsev (1988), MacKinnon & Phillipps (1993), Meeth & Meeth (1989), Meyer de Schauensee (1984), Panov (1963), Perennou *et al.* (1994), Ripley (1982), Scott (1989), de Silva & Perera (1993), Smythies (1986), Taylor, R.C. (1979), Won (1993).

34. Little Ringed Plover

Charadrius dubius

French: Pluvier petit-gravelot **German**: Flußregenpfeifer **Spanish**: Chorlitejo Chico

Taxonomy. *Charadrius dubius* Scopoli, 1786, Luzon.
In past, birds of S Japan and China erroneously attributed to nominate race, and those of New Guinea region erroneously placed in *jerdoni*. Three subspecies recognized.



Subspecies and Distribution
C. d. curonicus Gmelin, 1789 - Eurasia, from British Is, N Africa and Canary Is to Russian Far East, Korea, E China and Japan; winters in Africa S of Sahara, Arabia, E China and Indonesia.
C. d. jerdoni (Legge, 1880) - India and SE Asia.
C. d. dubius Scopoli, 1786 - Philippines S to New Guinea and Bismarck Archipelago.

Descriptive notes. 14-17 cm; 26-53 g; wingspan 42-48 cm. Eye-ring bright yellow. Smaller and less bulky than *C. hiaticula*, *C. semipalmatus* and *C. placidus*; also differs in having narrow white line behind black frontal bar, and in general shape of head pattern. Female has brown tinge to black parts and slightly narrower eye-ring. Non-breeding plumage of nominate race hardly differs from breeding plumage. Juvenile resembles non-breeding adult but olive brown upperparts have buff fringes. Races differ in size and bill coloration; in *curonicus*, non-breeding adult has reduced brownish breast band, and black on head brownish; *jerdoni*, like nominate, lacks markedly distinct non-breeding plumage.

Habitat. Mainly lowlands, up to 800 m; rarely coastal. On bare or sparsely vegetated flats of sand, shingle or silt; avoids rough terrain and tall or dense vegetation. Often in vicinity of standing or slow-flowing fresh water; sometimes saline inland pools and flats, or brackish lagoons and estuaries. Also found in artificial, often only temporarily suitable, habitats, such as gravel pits, sewage works and industrial wastelands. Habitat often unstable due to fast changing water level, growth of vegetation, etc.

Food and Feeding. Mainly insects, including beetles, flies, ants, mayfly and dragonfly larvae and crickets; spiders, shrimps and other invertabrates. Sometimes uses foot-trembling. Feeds on dry or moist surface, and occasionally in shallow water.

Breeding. Laying Apr-Jun in Europe, Mar-May in N Africa; breeding Dec-Jun, mainly Mar-May, in S India; nominate race breeds Feb-May. Monogamous for at least one brood, occasionally for several

years; sometimes 3rd bird joins during breeding, but family relation of these "helpers" unknown. Solitary or in loose neighbourhood groups, 7-200 m apart; densities along R Yenisey 0·4-2 birds/km of shoreline. Low degree of natal philopatry, but high of site fidelity, usually breeding within few km of previous year's site. Territorial and highly aggressive, usually feeding outside territory; frequently breeds in vicinity of aggressive or demonstrative species, resulting in less egg loss due to predators; associations at least sometimes deliberately sought. Nest is shallow scrape, unlined or lined with some vegetation and stones, on bare ground or among low vegetation, in vicinity of water; often on small island. Usually 4 eggs, sometimes 3, laid at intervals of c. 36 hours; up to 3 replacement clutches laid; incubation 22-28 days, by both parents, beginning with last or penultimate egg; chick mottled cinnamon-orange, grey and dusky, with black band above whitish forehead, and underparts white with dark patches on sides of breast; chicks leave territory, tended by both parents, but female leaves family party before male in order to lay new clutch or to migrate; fledging 24-29 days; young independent 8-25 days thereafter. Hatching success 65-86%; fledging success 26-64%. Usually breeds for first time in second year. Annual mortality 35-55%, highest in first-year birds (53%). Oldest ringed bird 11 years.

Movements. Race *curonicus* migratory, but possibly resident in S breeding areas; W European population migrates across Sahara to tropics; leaves breeding areas Jun to early Jul, and migrates late Jul to early Sept, reaching tropical Africa late Aug to Sept; returns from late Feb, reaching NW Europe from mid-Mar, peaking Apr to early May, and a month later in NE; along R Yenisey, return migration peaks late May. Siberian and other Asian populations migrate to SE Asia and India, where they mix with resident *jerdoni*; cross Japan only on northward migration. Often migrates singly or in small flocks often of not more than 10 birds. Nominate race resident and locally nomadic in New Guinea; *jerdoni* resident, but moves about locally in response to water conditions. Race *curonicus* recently recorded regularly in small numbers in Australia.

Status and Conservation. Not globally threatened. Race *curonicus* in Europe and NW Africa numbers 100,000-1,000,000 birds, of which 17,000-28,000 breeding pairs in W & C Europe (1986); unknown numbers in rest of extensive range; races *jerdoni* and *dubius* number 25,000-100,000 birds each. Probably marked decrease from late 19th century in Europe, caused by habitat loss due to flood regulation; increasing numbers from 1930's in NW Europe, especially since late 1960's, linked to development of suitable man-made habitats like gravel and sand pits. Formerly common breeder on Mediterranean coast and along R Jordan, but pollution, especially from oil and tar, has had detrimental effects. In Russia, drainage and cultivation of riverine floodplains has created suitable new habitat; however, many such suitable sites are only temporary, because they will become overgrown or will be planted. Many breeding sites disturbed by recreational activities. Has recently expanded range N in Finland; first bred in Britain 1938 and has since spread: 608 pairs in 1984, and still increasing.

Bibliography. Albrecht (1992), Ali & Ripley (1980), Andrews, J. (1991), Baudraz & Guillaume (1993), Beehler *et al.* (1986), Beser (1977), Biondi *et al.* (1992), Brazil (1991), Chikina (1985), Christen (1980a), Coates (1985), Cramp & Simmons (1983), Deignan (1945), Dickinson *et al.* (1991), Dowsett & Forbes-Watson (1993), Dubois & Maheo (1986), Dvorsky & Dvorská (1980), Elgood *et al.* (1994), Étchécopar & Hüe (1964, 1978), Evans (1994), Finch (1983), Fjeldså (1977), Flint *et al.* (1984), Gatter (1971a, 1971b), Gavrilov & Bekbayev (1988), Glutz von Blotzheim (1972), Goodman *et al.* (1989), Grimes (1987), Grossler (1977), Hamann (1988), Hedenström (1985, 1987), Hölzinger (1975a, 1975b), Hölzinger & Schilhansl (1971, 1972), Hüe & Étchécopar (1970), Jacob & Fouarge (1992), Jaensch (1982), Khrokov (1973), Knystautas (1993), Krebs (1956), Kuhnapfel (1991), Lekagul & Round (1991), MacKinnon & Phillipps (1993), Mackworth-Praed & Grant (1957, 1970), Marchant & Higgins (1993), van Marle & Voous (1988), Medway & Wells (1976), Melde (1991), Osing (1992, 1993a), Parrinder, E.D. 35. Wilson's Plover

Charadrius wilsonia

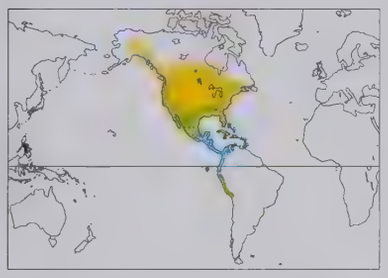
French: Pluvier de Wilson **German**: Wilsonregenpfeifer **Spanish**: Chorlitejo Piquigrueso
Other common names: Thick-billed Plover

Taxonomy. *Charadrius wilsonia* Ord, 1814, shore of Cape May, New Jersey.
Birds breeding on Bahamas and Greater Antilles sometimes separated as fourth subspecies *rufinucha*. Three subspecies normally recognized.

Subspecies and Distribution.
C. w. wilsonia Ord, 1814 - E USA to E Mexico and Belize, Bahamas, Greater Antilles, and N Lesser Antilles; winters S to E Brazil.
C. w. beldingi (Ridgway, 1919) - Pacific coast from Baja California to Panama and Ecuador, ranging S to C Peru.
C. w. cinnamominus (Ridgway, 1919) - Colombia to French Guiana; also Netherlands Antilles, islands off Venezuela, Trinidad, Grenada and Mustique.

Descriptive notes. 16·5-20cm; c. 55 g. Distinctive plover with large, thick black bill. Female has black of breast band and forecrown replaced with brown. Non-breeding adult like breeding female, but lacks rufous tinges. Juvenile has breast band mottled buff and brown, sometimes broken; darker upperparts fringed buff. Races *beldingi* and *cinnamominus* darker above than nominate, with broader mask, shorter supercilium and more rufous on crown; in *beldingi*, male has black frontal bar, lores and breast band, female has breast band more rufous; in *cinnamominus*, male has crown, mask and breast band much more rufous, female has strongly rufous breast band, rufous mask and forecrown. Birds from West Indies like nominate, but with strongly rufous crown.

Habitat. Strictly coastal, occurring on barren or nearly barren sandy beaches and sandbars, preferring islands or edges of coastal lagoons. Outside breeding season, also on estuarine mudflats and near fresh water bodies that are only short distance inland.



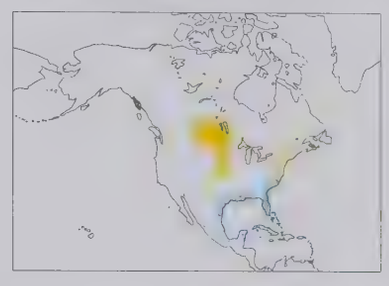
Food and Feeding. Apparently mainly fiddler crabs, also blue crabs (*Callinectus*); insects and their larvae, e.g. Diptera; and isopods, amphipods, molluscs, shrimps and polychaete worms. Feeding action remarkably slow and deliberate; sometimes lunges at prey from up to 1 m away, and then runs to capture it. Feeds on intertidal flats and also on higher, drier part of beach. Feeds by day and by night, but in non-breeding season sometimes chiefly by night, probably to avoid predators. Usually feeds in small flocks or with other small plovers.
Breeding. Eggs found Apr to early Jul. Often nests in loose colonies, usually no nearer than 20 m apart, once at least 50 nests found on sandbank 800 m long. Breeds on open, unvegetated or sparsely vegetated sand; nest is shallow scrape, unlined or lined with shells, exposed or sheltered among open vegetation. Site fidelity 19-50% in males, much less in females and very low degree of natal philopatry. Usually 3 eggs (2-4), laid at intervals of 2 or more days; incubation 24-25 days, by both sexes, female performing larger share; chick creamy buff, mottled with black above and white below, with white bar on outer joint of wing; tended by both parents; fledging 21 days. In one study, less than 20% of nests raised at least 1 young. Nest failure caused by high tides and raccoons (*Procyon lotor*).
Movements. Partial migrant, with partially overlapping breeding and winter range. Nominate race migrates S to Brazil; Florida population sedentary. Some birds of race *beldingi* migrate S to C Peru; large numbers arrive alongside local breeders on beaches of Bay of Panama late Sept to mid-Oct, leaving during late Mar. Returns to breeding grounds mid-Mar to late Apr. Race *cinnamominus* essentially sedentary.
Status and Conservation. Not globally threatened. No population estimates available. Population of race *cinnamominus* seems to be stable. Locally common to fairly common in USA, Mexico, Panama and Colombia; very scarce and local breeder in French Guiana. In Panama, commoner on Pacific coast, where breeds locally; not yet known to breed on Caribbean coast, but may do so. Known to have bred S to Huacho, C Peru.
Bibliography. Bent (1927-1929), Bergstrom (1981, 1982, 1986, 1988a, 1988b, 1989), Bergstrom & Terwilliger (1987), Biaggi (1983), Blake (1977), Boland (1991), Dinsmore & Humphrey (1987), Duncan (1973), Eckert (1981), Fisk (1978a), Galindo (1987), Haverschmidt (1968), Haverschmidt & Mees (1995), Hellmayr & Conover (1948), Hilty & Brown (1986), Howell & Webb (1995a), Lee (1989), McMahon (1982), Meyer de Schauensee & Phelps (1978), Monroe (1968), Morrier & McNeil (1991), Ridgely & Gwynne (1989), Robert & McNeil (1989), Rodrigues & Lopes (1992), Root (1988), Scott & Carbonell (1986), Sick (1985c, 1993), Slud (1964), Snyder (1966), Stiles & Skutch (1989), Strauch & Abele (1979), Thibault & McNeil (1994, 1995a, 1995b), Tompkins (1944), Tostain *et al.* (1992), Wetmore (1965).

36. Killdeer

Charadrius vociferus

French: Pluvier kildir **German**: Keilschwanz-Regenpfeifer **Spanish**: Chorlitejo Culirrojo

Taxonomy. *Charadrius vociferus* Linnaeus, 1758, South Carolina.
Subspecies and Distribution.
C. v. vociferus Linnaeus, 1758 - Canada, USA and Mexico; winters S to NW South America.
C. v. ternominatus Bangs & Kennard, 1920 - Greater Antilles.
C. v. peruvianus (Chapman, 1920) - Peru and NW Chile.



Descriptive notes. 23-26 cm; 72-93 g; wingspan 59-63 cm. Distinctive large plover with double blackish breast band and long tail; bright orange-brown rump and uppertail; brown upperparts with rufous fringes. Characteristic call "kill-dee" reflected in vernacular name. Female tends to have browner mask and breast bands. Non-breeding adult has rufous and buffish brown fringes to upperparts. Juvenile like dull non-breeding adult. Race *ternominatus* smaller, paler and greyer; *peruvianus* also smaller than nominate, and has more extensive rufous feather fringes.
Habitat. Open fields and flats with short vegetation, not necessarily near water. Exploits many open agricultural habitats. Breeds on well drained short-grass or sparsely vegetated savannas, meadows and pastures, ploughed land, bare gravel, gravel pits, golf courses, roadside ditches and wasteland; occasionally on gravelled roofs. After young fledge, birds move to moister areas in valleys, and on edges of rivers. In winter also found on beaches, mudflats, wet grassland and, rarely, salt-marshes.
Food and Feeding. Insects, mainly beetles and flies, also grasshoppers, crickets, caterpillars, dragonflies, etc.; millipedes, worms, snails, spiders, crustaceans and some seeds. Sometimes uses foot-trembling. Active day and night. Does not occur in big flocks.
Breeding. Eggs found Mar to early Jun in S, and mid-Apr to mid-Jul in N. Seasonally monogamous. Density 1-30 pairs/km²; territorial. Males show high degree of site fidelity, females less; very little natal philopatry. Nest is shallow scrape, unlined or lined with vegetation, stones and debris; in exposed, bare or sparsely vegetated site, often with gravelly or stony ground. Usually 4 eggs (3-5), laid at intervals of 24-48 hours; up to 3 replacement clutches laid; occasionally double-brooded; incubation 24-28 days, by both parents, starting with last egg; chick buffish and dusky above, white below and on forehead, neck and chin, with long downy tail; tended by both parents; fledging 31 days; fledged young sometimes stay with parents for up to 10 days. Total of 52-63% of nests fail; fledging success 27%. Breeds from 1 year old. Oldest ringed bird at least 6½ years.
Movements. Races *ternominatus* and *peruvianus* believed to be resident. Nominate migratory: winters from S of breeding range S to Central America, West Indies, Colombia, Ecuador and islands off Venezuela; departs breeding grounds from mid-Jul and gathers in flocks in wet valleys, along rivers and on coast; migration from late Aug to Nov, with peak in late Sept; flies along coast, but also in broad front over land; reaches S USA in Oct, some remaining till late Mar; returns to N & NE USA by Mar to early Apr. Late autumn storms may carry vagrants up Atlantic coast; possible cause of W European vagrants turning up Nov-Apr. Migrates at night.
Status and Conservation. Not globally threatened. No population estimates available; North American breeding population stable; this population was dramatically reduced, to local extinction, during second half of 19th century, especially in E of breeding range, due to excessive hunting; after protection measures taken, it partially reoccupied former breeding grounds in NE USA, in period 1910-1920. During second half of 20th century, has expanded range S in Florida, and NE towards Newfoundland. Quite tolerant of frequent disturbance during breeding. Common to fairly common in Mexico.
Bibliography. Anderson, E. (1993), Ankney & Hopkins (1985), Armstrong (1983), Baldassarre & Fischer (1984), Bent (1927-1929), Bergstrom (1989), Biaggi (1983), Blake (1977), Boland (1991), Brunton (1986, 1987, 1988a, 1988b, 1988c, 1990), Bunni (1959), Colwell & Oring (1989b), Costas (1990), Cramp & Simmons (1983), Cronan (1974), Culbert (1991), Demaree (1975), Fjeldså & Krabbe (1990), Furniss (1933), Hamas (1988), Hellmayr & Conover (1948), Hilty & Brown (1986), Howell & Webb (1995a), Johnson (1965b), Kull (1978), Lenington (1980), Lenington & Mace (1975), Mace (1978), Magyar (1988), Meyer de Schauensee & Phelps (1978), Monroe (1968), Mundahl (1982), Nickell (1943), Nol & Brooks (1982), Nol & Lambert (1984), Phillips (1972), Powell (1990, 1993), Powell & Cuthbert (1993), Ridgely & Gwynne (1989), Root (1988), Schardien, B.J & Jackson (1979), Schardien, S. (1981), Scott & Carbonell (1986), Slud (1964), Stiles & Skutch (1989), Strauch (1971), Tamar (1983), Walbeck (1989), Wetmore (1965), Young (1991).

37. Piping Plover

Charadrius melodus

French: Pluvier siffleur **German**: Flötenregenpfeifer **Spanish**: Chorlitejo Silbador

Taxonomy. *Charadrius melodus* Ord, 1824, Great Egg Harbor, New Jersey.
In past, two subspecies recognized on basis of extent of breast band, with nominate (coastal nesters), and *circumcinctus* (Great Lakes and prairies); but subdivision rendered unsatisfactory due to considerable individual and seasonal variation. Monotypic.
Distribution. N Great Plains, Great Lakes and Atlantic coast from Newfoundland S to North Carolina. Winters on Atlantic coast of S USA, Gulf of Mexico, Bahamas and rather locally in Greater Antilles; also W Mexico.

Descriptive notes. 17-18 cm; 43-64 g. Small, chubby plover; stubby orange bill with black tip; short bright orange legs; black frontal bar and breast band, latter often broken, especially in coastal breeders. Resembles *C. semipalmatus* and allies, but has much paler back and is somewhat bulkier. Female has black of forehead and breast browner; yellower bill. Non-breeding adult has greyish forehead and breast band, and often all black bill. Juvenile like adult non-breeding, but upperparts fringed pale buff; bill black.
Habitat. Coastal population breeds on sandy beaches; birds of Great Plains and Canadian prairie prefer muddy gravel, sand or gravel beaches of large alkaline lakes, or shores along prairie rivers, alkaline flats, sandflats and floodplains, favouring bare or scantily vegetated areas. In winter, occurs on coastal beaches and adjacent sandflats, sometimes intertidal mudflats. Sometimes makes scrape in sand to roost in.
Food and Feeding. Aquatic and terrestrial invertebrates, along with their larvae and eggs; polychaete worms, insects (e.g. midges, flies, grasshoppers and beetles), crustaceans and molluscs. Forages within several metres of water's edge, also on higher gravelly ground, small ponds and among detritus; also on drier ground near nest; during non-breeding season, on moist surface of muddy or sandy ground. Frequently uses foot-trembling. Forages day and night, alone or in small, loose flocks.
Breeding. Laying late Apr to early May. Seasonally monogamous, sometimes for longer; occasionally polyandrous. Solitary or in small, loose colonies; density up to 2·4 pairs/km of shoreline, 15-100 m apart. Territories include nesting and feeding sites; 25-70% return to previous year's breeding area, but degree of natal philopatry very low; regularly breeds in or near tern colonies (*Sterna antillarum*, *S. hirundo* and *S. paradisaea*). Nest is shallow scrape, unlined or lined with bits of shell and pebbles, well above high water mark, among sparse to moderately dense vegetation, often near clump of vegetation, large rock or log. Usually 4 eggs, sometimes 3, laid at intervals of 1-2 days; single-brooded, but up to 5 replacement clutches may be laid; incubation (mean) 25-28 days, by both parents, starting after clutch fully completed; chick brown-black above with creamy buff and greyish speckles, wings and thighs marked with brown spots, forehead buffish white and underparts white; tended by both parents, remaining within 150 m of nest; fledging 25-30 days. Eggs and nest suffer due to predation by mammals, including domestic dogs and cats, probably also avian predators, and flooding. Mean yearly fledging success 0·2-3 fledglings/pair; on remote, undisturbed site, hatching success 84%, fledging success 37%. Breeds at 1 year old. Annual adult mortality 34%; total of 13-28% reach age of 5 years; oldest ringed bird 14 years.
Movements. Inland breeders seem to undertake non-stop autumn migration to coast of Gulf of Mexico, as suggested by lack of sightings of migrating birds inland. Coastal breeders winter from North Carolina S to Florida and into Caribbean. Spring migration takes place late-Feb to early Apr, peaking in Mar; arrives on coastal breeding grounds along Atlantic mainly late Mar to Apr, and inland late Apr to mid-May. Departure from coastal breeding grounds in Aug, and southward movements noted into Oct; inland breeders may depart as early as Jun, especially when breeding fails, but otherwise Sept; females depart first, followed by unpaired males, males with fledglings, and finally juveniles; arrives on Texas coast in two peaks, early Jul to early Aug and Oct to early Nov. Shows high degree of fidelity to wintering site. Usually migrates in small flocks of 3-6 birds.
Status and Conservation. VULNERABLE. Came close to extinction around 1900, due to excessive hunting, with range decreasing considerably during second half of 19th century. Numbers now decreasing again, as result of expanding recreational use of beaches, increasing water levels and development of winter habitat. Total of 3535-4147 birds counted in breeding areas during 1977-1984; total of 2334 breeding pairs in 1991, with 500 pairs in Canadian prairie, 872 in Great Plains of USA, 16 in Great Lakes area, 245 on Atlantic coast of Canada, and 701 on Atlantic coast of USA. In Great Plains, numbers are decreasing by more than 7% annually, due to severe drought and inappropriate water management practices; also, in Great Lakes numbers are still decreasing; on Atlantic coast, numbers stable due to intense predator control and human management. Protection measures involve: closing nesting beaches to humans and restricting access of off-road vehicles; constructing predator exclosures around nests; avian and mammalian predator control; mitigation of water level policies; vegetation control; and creation of artificial habitat.
Bibliography. Bent (1927-1929), Bergstrom & Terwilliger (1987), Biaggi (1983), Blanco, P. *et al* (1993), Boland (1991), Boyd (1991), Brown (1987), Burger, J. (1987c, 1991, 1994), Cairns, W.E. 38. Black-banded Plover

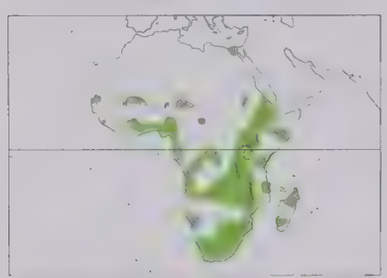
Charadrius thoracicus

French: Pluvier à bandeau noir **German**: Madagaskarregenpfeifer **Spanish**: Chorlitejo Malgache
Other common names: Madagascar/Black-banded Sandplover, Plover

Taxonomy. *Ægialitis thoracica*, Richmond, 1896, Loholoka, east coast of Madagascar.
Probably best considered to form superspecies with *C. pecuarius* and *C. sanctaehelenae*. Monotypic.
Distribution. SW coast of Madagascar; occasionally reported from E coast.



Descriptive notes. 13-14 cm. Yellowish orange underparts, darkest on central belly; black breast band separates from otherwise very similar *C. pecuarius* and *C. sanctaehelenae*. Female like male, but may have slightly paler underparts. Non-breeding adult has much of black replaced with brown, and upperparts tinged orange. Juvenile like adult, but has greyish legs and greyish brown breast band; head pattern dull brown and pale buffish; upperpart feathers broadly fringed pale buff.
Habitat. Coastal grazed grasslands, often very dry; also edges of shallow brackish marshes and ponds, occasionally sandy beaches and sandy or muddy estuarine flats. Seems to prefer drier areas than *C. pecuarius* and to avoid flooded grassland.
Food and Feeding. Very poorly known, but habits apparently rather similar to *C. pecuarius*. Takes large and small insects. Commonly seen in company of other coastal plovers, such as *C. hiaticula* and *C. marginatus*.
Breeding. Evidently rather similar to *C. pecuarius*. Nesting probably mainly Nov-Jan; eggs reported in Nov and Jan, young in Dec and Aug. 2 clutches of 2 eggs each.
Movements. Sedentary. Almost all records from SW coast between Morondava and Androka; species originally described from E coast, where still reported very occasionally.
Status and Conservation. VULNERABLE. Declining, with possibly fewer than 1000 individuals remaining. Reported to be locally abundant at Lake Tsimanampetsotsa Nature Reserve in 1988, and occurring at two other protected areas; rather common in Morombe region, NW part of known range, in 1984; breeding range may not be yet fully described. Decline may be due to competition with relatively recently arrived *C. pecuarius* or by *C. marginatus*, or both; nowadays outnumbered by both of these species.
Bibliography. Appert (1971), Collar & Andrew (1988), Collar & Stuart (1985), Collar *et al.* (1994), Dee (1986), Delacour (1932), Dhondt (1975), Dowsett & Forbes-Watson (1993), Keith (1980), Langrand (1990), Milon (1948), Milon *et al.* (1973), Nicoll & Langrand (1989), Rand (1936), Salvan (1971).

39. Kittlitz's Plover

Charadrius pecuarius

French: Pluvier pâtre **German**: Hirtenregenpfeifer **Spanish**: Chorlitejo Pecuario
Other common names: Kittlitz's Sandplover

Taxonomy. *Charadrius pecuarius* Temminck, 1823, Cape of Good Hope.
Probably best considered to form superspecies with *C. thoracicus* and *C. sanctaehelenae*; often considered conspecific with latter (see page 406). Various races have been proposed: *allenbyi* (Egypt), *isabellinus* (Egypt to Zaire, Kenya), *tephricolor* (SW Africa and N Botswana); but variation is slight, overlapping and mainly clinal, and reported sample sizes are too small. Monotypic.
Distribution. NE Egypt; Africa S of Sahara; Madagascar.

Descriptive notes. 12-14 cm; 26-54 g; wingspan 40-44 cm. Black eyestripe, white supercilium and dark brown upperparts with sandy rufous fringes; breast and belly sandy rufous. Resembles *C. thoracicus*, but lacks breast band, and has slightly longer legs; very similar to *C. sanctahelenae*, but smaller with shorter legs, and more brightly coloured underparts. Female has slightly paler underparts and narrower black forecrown. Non-breeding adult has variable depth of colour; black on head browner, white parts of head may turn sandy brownish. Juvenile resembles non-breeding adult, but no black head lines, broader fringes on upperpart feathers and brownish lateral breast patches. Madagascan birds sometimes have orange-buff wash to supercilium.
Habitat. From coast to uplands; primarily inland in varied flat, open habitats with poor soil, usually close to water; often near margins of lakes, reservoirs, small, sometimes temporary, pools or flooded ground; also salt-pans, tidal mudflats and lagoons, salt-marshes, sandbanks and along sandy riverbeds. Avoids tall, dense closed vegetation and steep or broken terrain. Along coast, roosts at high water with other small *Charadrius* plovers.
Food and Feeding. Mainly terrestrial invertebrates, chiefly insects (e.g. beetles, flies, bugs, grasshoppers and butterfly and moth larvae) and spiders; also worms and molluscs. Sometimes uses foot-trembling. May feed during moonlit nights. Feeds singly or in flocks of 2-5 birds, rarely up to 50.
Breeding. Laying Apr in Egypt; very variable throughout rest of range, laying in 2-12 months of year. Monogamous. Solitary or in loose neighbourhood groups, nests mostly at least 20 m apart; territorial, feeding either in or out of territory; territory predominantly defended by male. Nest exposed, in sand or dry mud; shallow scrape, lined with plant material, pebbles and debris, sometimes unlined. Usually 2 eggs (1-3), laid at intervals of 1-2 days; 1-2 broods; incubation by both parents, female by day, male by night, 22-28 days, starting with last egg. Eggs totally covered with nest material and sand before disturbed bird leaves nest; bird stands up and runs around nest 2-3 times, making rapid inward-kicking movements ("Leaving-scuffle"), in total taking 3-6 seconds, but up to 90 seconds when ground damp or with high wind; hatchling sometimes covered in same way. Chick pale buff, mottled black above with dark centre line on back, but no dark band across nape; forehead and underparts white, buffish on flanks. Both parents care for young; fledging 26-32 days; young independent soon after; subsequently, young birds gather into flocks. Hatching success 19-77%, fledging success 0·5 to under 2 young/pair; mortality caused mainly by flooding, but also by motor vehicles and predators; birds will move eggs to new site after heavy rains, and possibly also as a anti-predator reaction. Some birds breed in first year.
Movements. Generally resident, but locally making seasonal movements, possibly related to seasonal rainfall and flooding; patterns poorly understood. Occasionally occurs in large numbers on shores of L Victoria; summer visitor to Botswana; dry season visitor to Sierra Leone (Dec-Apr), and to Zambia and Zimbabwe (Apr-Dec); presumably birds from Zimbabwe fly to Botswana, Namibia and Cape Province, to join sedentary coastal populations. Flocks of 100-200 birds reported during local movements.
Status and Conservation. Not globally threatened. No population estimates available; c. 2600 birds on South African coast, most in W Cape; 615-1170 birds, probably breeders, recorded on coast of Gabon. Locally common on L Mabesi, S Sierra Leone; locally not uncommon in Ghana and Nigeria; scarce in Egypt and Gambia.
Bibliography. Ash & Miskell (1983), Bennett (1992), Benson (1968b), Benson & Benson (1975), Britton, P.L. (1980), Clancey (1971c), Clark (1982a), Conway & Bell (1969), Cramp & Simmons (1983), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Étchécopar & Hüe (1964), Ginn *et al.* (1989), Goodman *et al.* (1989), Gore (1990), Grimes (1987), Hall (1958, 1959a, 1965), Hanmer (1994), Kutilek (1974), Langrand (1990), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Pinto (1983), Schepers & Marteijn (1993), Shirihai (1996), Shirihai & van den Berg (1987), Short *et al.* (1990), Slight (1966), Taylor, P.B. 40. St Helena Plover

Charadrius sanctaehelenae

French: Pluvier de Sainte-Hélène **Spanish**: Chorlitejo de Santa Elena
German: St.-Helena-Regenpfeifer
Other common names: (St Helena) Wirebird, St Helena Sandplover

Taxonomy. *Ægialitis sanctæhelenæ* Harting, 1873, St Helena.
Often considered conspecific with *C. pecuarius* (see page 406); probably best considered to form superspecies with *C. pecuarius* and *C. thoracicus*. Monotypic.
Distribution. St Helena, S Atlantic Ocean.

Descriptive notes. c. 15 cm. Resembles *C. pecuarius*, but larger, with longer bill and longer "wiry" legs; less buff on breast and on feather fringes of upperparts; black lines do not meet on nape. Sexes alike. No seasonal variation. Juvenile has dull brown head pattern, without black areas on head and neck; crown and upperpart feathers narrowly fringed pale buff.
Habitat. Widespread, particularly in flatter, more open upland habitats at medium elevations, and around edges of island. Forages on hot stony plains with wire-grass (*Cynodon dactylon*) and eroded areas of kaffir fig (*Carpobrotus edulis*); also upland pastures, especially when recently grazed by cattle, ploughed fields, and even large, remote vegetable gardens; never occurs on the shore. It has been suggested that, until deforestation at end of 19th century, species may have been woodland floor-dweller.
Food and Feeding. Very poorly known. Insects and snails recorded. Usually seen in pairs, rarely in groups of up to 6 birds.
Breeding. Breeds in drier part of year, late Sept to Jan, mainly Dec-Jan, possibly varying considerably between years, depending on conditions. Breeds on quite remote, open plains in N half of island. Probably solitary. Nest is simple scrape. 1-2 eggs (up to 3); possibly double-brooded; chick buff, streaked black, with grey tinge. Eggs and young occasionally taken by feral cats, introduced Indian Myna (*Acridotheres tristis*) and possibly rats, which occasionally form plagues on the island; *A. tristis* may also be competing for same food resources.
Movements. Sedentary.
Status and Conservation. ENDANGERED. Only occurs in northern, flatter parts of interior of St Helena; but distribution of species now shifting towards E, due to expansion of urban areas. All bird species on St Helena protected by law since 1894. Total population estimated at less than 100 pairs in 1952; in late 1960's, species thought to be commoner than that, a view supported in 1983 by an estimate of several hundred birds. In 1984, species seemed to be less numerous than 10 years before. Intensive survey in 1988/89 showed that c. 450 birds were present; recent censuses suggest continuous, steady decline from c. 375 birds in 1991, to c. 315 birds in 1993; numbers at a key area, Deadwood Plain, have halved since late 1980's. Several breeding areas now threatened by habitat changes; 11 separate breeding areas known in 1952. Species appears to be reasonably safe unless major habitat changes take place, especially if these affect important habitats, although ecological research still required in order to define precise requirements.
Bibliography. Anon. (1989b), Basilewsky (1970), Benson (1950), Collar & Andrew (1988), Collar & Stuart (1985), Collar *et al.* (1994), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Haydock (1954), McCulloch (1991, 1992), Pitman (1965b).

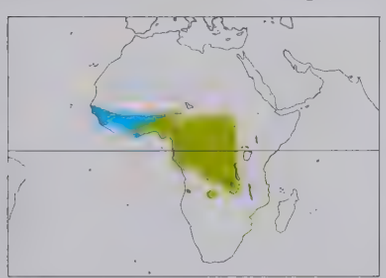
41. Three-banded Plover

Charadrius tricollaris

French: Pluvier à triple collier **German**: Dreiband-Regenpfeifer **Spanish**: Chorlitejo Tricollar
Other common names: Treble-banded/Three-banded/Tri-collared Plover/Sandplover

Taxonomy. *Charadrius tricollaris* Vieillot, 1818, Cape Town.
Sometimes considered conspecific with *C. forbesi*; probably best considered to form superspecies. Two subspecies recognized.
Subspecies and Distribution.
C. t. tricollaris Vieillot, 1818 - Ethiopia to Tanzania and Gabon, and S to South Africa; non-breeding also around L Chad.
C. t. bifrontatus Cabanis, 1882 - Madagascar.



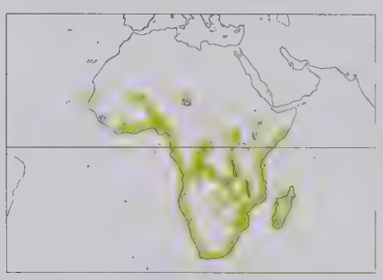
Descriptive notes. c. 18 cm; 25-43 g. Small, dark plover with red eye-ring, distinguished from *C. forbesi* by white forehead, paler upperparts and red bill with black tip. Sexes alike. No seasonal variation. Juvenile has narrow buff fringes on upperpart feathers, and pale brown forehead. Race *bifrontatus* has grey band between white forehead and bill; darker face and throat.
Habitat. Firm gravelly or sometimes muddy ground along edges of inland freshwater lakes, pools and rivers; occasionally at coastal lagoons and estuaries, when mostly uses the least saline areas; rarely on beaches and inland brackish water; also found at margins of some artificial water bodies, e.g. sewage tanks in Malawi. Roosts higher up shore, on gravelly or stony ground, in mixed flocks or solitarily.
Food and Feeding. Terrestrial and aquatic insects and their larvae, crustaceans, small molluscs and worms. Often feeds at water's edge, picking up food from surface, or just below; also uses foot-trembling. Probably feeds by night, as well as by day. Often solitary, but also mixes with other small waders; occasionally in loose flocks, rarely up to 40 birds.
Breeding. Breeds opportunistically, but mainly lays Apr-Sept in tropics, Jul-Dec further S, and Jul-Sept in Madagascar. Monogamous; solitary and territorial; territory usually along shoreline; sometimes 2 territories, 1 for nesting and 1 for feeding. Nest situated in sand or dry mud, close to water; sometimes on hard rock; simple scrape, lined with pieces of plants, pebbles and debris. Usually 2 eggs, sometimes 1, probably laid at interval of 2-4 days; frequently double-brooded, female starting second brood well before first brood fully-fledged; incubation 26-28 days, by both parents, probably starting when clutch complete; chick has sandy upperparts speckled black with black median stripe, white underparts; fledging 30-32 days; young sometimes remain with parents until 40-42 days old. Fledging success almost 2 young per pair in Botswana. Probably lives at least 10 years.
Movements. Essentially resident, showing some erratic movements, but movements poorly known; more widespread during non-breeding season, making use of temporary pools. Records of apparently non-breeding birds from Nigeria and Cameroon in dry season (Aug-Feb) suggest that longer movements occur; in Ethiopia, only present Mar-Apr and Jul-Dec; in E Zaire and Rwanda, numbers increase in Mar; in S Africa, movements complex, seeming to depend on rains.
Status and Conservation. Not globally threatened. No population estimates available. Total of c. 750 birds recorded on coasts of South Africa, with highest numbers in Cape Province.
Bibliography. Ash & Miskell (1983), Benson & Benson (1975), Blake (1977), Britton, P.L. (1980), Brown, A. (1992), Brown, L.H. & Britton (1980), Clancey (1981c), Clark (1982b), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Freeman (1970), Ginn *et al.* (1989), Langrand (1990), Lippens & Wille (1976), Louette (1981), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1965, 1982, 1993), Martin (1971), Milon *et al.* (1973), Moreau (1946), Nikolaus (1987), van Perlo (1995), Pinto (1983), Short *et al.* (1990), Tree (1980b), Tyler (1978), Urban *et al.* (1986), Winterbottom (1963).

42. Forbes's Plover

Charadrius forbesi

French: Pluvier de Forbes **German**: Forbesregenpfeifer **Spanish**: Chorlitejo de Forbes
Other common names: Forbes's Banded Plover

Taxonomy. *Ægialitis forbesi* Shelley, 1883, Shonga, Niger River.
Has been considered conspecific with *C. tricollaris*; probably best considered to form superspecies. Monotypic.
Distribution. Ghana to SW Sudan, and S through Zaire and W Uganda locally to C & S Angola and extreme W Zambia. Recorded W to Senegal, but not known to breed W of Ghana.



Descriptive notes. 20 cm; 46-49 g (4 specimens). Two black breast bands; red eye-ring. Resembles *C. tricollaris*, but larger, with darker upperparts; darker, browner head; dark brown bill with red at base of lower mandible. Sexes alike. In non-breeding adult, breast band can be dark brown; white on head is replaced with buff. Juvenile like non-breeding adult, but feathers of upperparts have narrow buff fringes.
Habitat. Not particularly attached to water. Breeds in rocky upland habitats with granite outcrops, in Nigeria sometimes on inselbergs. During dry, non-breeding season affects grassland habitats, even in open places within forests; also bare ground and recently burnt areas, and muddy areas near lakes and rivers; often close to habitation, on airfields or golf courses; occasionally at cultivated areas, pools or reservoirs.
Food and Feeding. Beetles, grasshoppers and other insects, and their larvae; also small molluscs, crustaceans and worms. Usually solitary, but sometimes in small flocks of 15-20 birds.
Breeding. Lays during rainy season, Jul-Aug in Ghana, Mar-Aug in Nigeria; during dry season in Gabon, Jun-Sept. Monogamous; solitary. Nest is scrape, lined with tiny pebbles, often on top of granite outcrop to avoid surface water run-off or in gravel stream bed; same nest-site may be used for several years. 2-3 eggs; possibly double-brooded; incubation at least 22 days, by both parents, starting probably after clutch completed; chick undescribed; tended by both parents; after fledging, young birds go to nearby cultivation, e.g. rice fields.
Movements. Migratory, at least on local basis; during dry season, breeding grounds deserted for nearby grassland habitats, but longer movements likely to occur too. Occurs in Sierra Leone and Ivory Coast only Nov-Apr. Vagrant to E Africa, recorded mainly Apr-Jul.
Status and Conservation. Not globally threatened. No population estimates available. Locally common to uncommon; not uncommon in Sierra Leone and Ghana; locally common in Nigeria; only 1 record in Gambia; apparently very uncommon in Angola, with very few records.
Bibliography. Brown (1948), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Gatter (1988), Grimes (1987), Herroelen (1987), Lippens & Wille (1976), Louette (1981), Mackworth-Praed & Grant (1957, 1962, 1970), Morel & Morel (1990), Nikolaus (1987), Pinto (1983), Serle (1956a), Short *et al.* (1990), Tree (1964), Urban *et al.* (1986).

43. White-fronted Plover

Charadrius marginatus

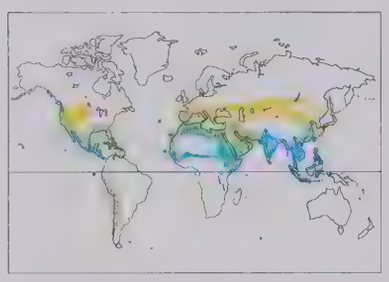
French: Pluvier à front blanc **German**: Weißstirn-Regenpfeifer **Spanish**: Chorlitejo Frentiblanco
Other common name: White-fronted Sandplover

Taxonomy *Charadrius marginatus* Vieillot, 1818, Cape Peninsula.
Forms superspecies with *C. alexandrinus*, *C. javanicus* and *C. ruficapillus*; all of these have on occasion been considered conspecific (see page 386). Some authors consider population from Sudan and Ethiopia to E Natal as belonging to race *tenellus*. Other races proposed: *hesperius* (W Africa to Central African Republic); *nigirius* (R Niger); *spatzi* (Rio de Oro); and *pons* (S Somalia); but evidence too scanty to support recognition of these possible forms. Four subspecies normally recognized.
Subspecies and Distribution.
C. m. mechowi (Cabanis, 1884) - locally in Africa S of Sahara to N Angola, Botswana, Zimbabwe and N Mozambique.
C. m. marginatus Vieillot, 1818 - S Angola to SW Cape.
C. m. arenaceus Clancey, 1971 - S Mozambique to SW Cape.
C. m. tenellus Hartlaub, 1861 - Madagascar.

Descriptive notes. 18 cm; nominate 42-55 g, *mechowi* 27-40 g. Differs from similar species in always lacking well defined black or brown patches at sides of breast; conspicuous white forehead, with sharp black bar behind; narrow black eyestripe. Individually very variable: upperparts range from rufous to dull brown to brownish grey; underparts variably pure white to extensively creamy or rufous. Female like male, but black areas paler, and rufous on breast more often paler or lacking. Non-breeding male like breeding female, but black replaced by brown; non-breeding female sometimes loses black frontal bar. Juvenile lacks black frontal bar; brownish lores; underparts white; upperparts with buff fringes. Much racial variation in colour falls in range of individual variation: rufous breast patches may join to complete rufous breast band; *arenaceus* has slightly browner upperparts with cinnamon-buff, not off-white, fringes; race *mechowi* smaller; population of coastal E Africa often has rufous on upperparts; *tenellus* typically has rufous on neck and sides of breast.
Habitat. Sandy seashores and inland along sandy shores of larger rivers and lakes; also rocky coasts, coastal and inland mudflats, salt-pans and estuaries. Roosts higher up beach, in (mixed) flocks or solitarily.
Food and Feeding. Insects, such as sandflies, grasshoppers, termites, mosquito pupae and *Cheirocephalus* larvae; also gastropods, bivalves and bivalve siphons, small crustaceans, isopods and worms. Probes and jabs in wet sediment, or pecks; also uses foot-trembling, and occasionally hawks flying termites. Forages on sandy parts of mudflats or in shallow water, on upper levels of beaches, in intertidal areas mainly at low tide, and in damp areas between dunes; forages during daytime and on moonlit nights. Forages in pairs or small parties, in non-breeding season occasionally larger flocks of up to 375 birds.
Breeding. Laying Feb-Sept from Senegambia to Nigeria, mainly May-Jul in E Africa, and somewhat later further S, but all year round in S Africa with peak Jul-Sept and Jan in Namibia. Seasonally monogamous. Solitary; territorial, with separate territories for nesting and feeding; sedentary populations may have territories year round. Nest can be as close as 16 m; densities 1 pair/2 ha along R Zambezi, c. 7 birds/km of open shoreline in South Africa, and 0·4 birds/km shoreline in Gabon; strongly site-faithful. Nest is shallow scrape, often lined with pebbles, shell fragments, dried seaweed or twigs, in sand near high water mark, on dune, sandbar or occasionally in quarry. Normally 2 eggs (1-4), laid at intervals of 2-4 days; several replacement clutches may be laid; incubation 26-33 days, by both parents. Usually eggs partly covered with sand early in morning or when adult leaves nest, and uncovered at night; degree of cover increases as incubation proceeds, and probably serves for temperature regulation and camouflage. Chick grey above with black mottling forming lines down centre of head and back, white below; stay in dunes until almost fledged, moving to beaches thereafter; fledging 35-38 days. In S Africa, hatching success 38%, fledging success 0·08-1·4 young/pair; mortality caused by predators (mongooses), floods, high tides and motor vehicles. Average longevity 7·5 years, maximum 9+ years.
Movements. Sedentary, with some local seasonal movements of immatures. Inland populations of C & S Africa tend to be migratory, moving to E coast (S to E Cape) when rivers flood (Dec-May). In Nigeria, some movement related to changing water levels; in Mali, present all year, with higher numbers Dec-Jan; probably non-breeding visitor to Sierra Leone, where present Nov-May in small numbers.
Status and Conservation. Not globally threatened. No population estimates available. In N of range, uncommon to frequent (Ethiopia) to locally common (Somalia, Nigeria, Ghana, Gabon, Mali) to abundant (Kenyan and Tanzanian coasts). Total of 5000-6000 birds on Tanzanian coast in Feb; highest

On following pages: 44. Kentish Plover (*Charadrius alexandrinus*); 45. Javan Plover (*Charadrius javanicus*); 46. Red-capped Plover (*Charadrius ruficapillus*); 47. Malaysian Plover (*Charadrius peronii*); 48. Chestnut-banded Plover (*Charadrius pallidus*); 49. Collared Plover (*Charadrius collaris*); 50. Puna Plover (*Charadrius alticola*); 51. Two-banded Plover (*Charadrius falklandicus*); 52. Double-banded Plover (*Charadrius bicinctus*).

known densities inland at L Turkana and L Malawi; common on S African coasts with some 18,000 individuals recorded.



Bibliography. Ash & Miskell (1983), Atkins & Johnston-Stewart (1989), Benson & Benson (1975), Blaker (1966), Bregnballe *et al.* (1990), Britton, P.L. (1980), Clancey (1971d, 1975a), Crowe (1981, 1986), Crowe & Crowe (1984), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Ginn *et al.* (1989), Gore (1990), Grimes (1987), Kieser & Liversidge (1981), Langrand (1990), Liversidge (1965), Mackworth-Praed & Grant (1957, 1962, 1970), MacLachlan *et al.* (1980), Maclean (1993), Maclean & Moran (1965), Martin & Baird (1987), Medland (1988), van der Merwe (1987), van der Merwe *et al.* (1992, 1994), Milon *et al.* (1973), Pinto (1983), Reynolds (1977c), Roberts (1977), Shewell (1951), Short *et al.* (1990), Skead (1966), Steyn (1966), Summers & Hockey (1980, 1981), Taylor, P.B. 44. **Kentish Plover**

Charadrius alexandrinus

French: Pluvier à collier interrompu **German**: Seeregenpfeifer **Spanish**: Chorlitejo Patinegro
Other common names: Snowy Plover (New World races), Sandplover

Taxonomy. *Charadrius alexandrinus* Linnaeus, 1758, Egypt.
Forms superspecies with *C. marginatus*, *C. javanicus* and *C. ruficapillus*; all of these have on occasion been considered conspecific with present species, especially *C. javanicus* (see page 386); in contrast, races *nivosus* and *occidentalis* sometimes considered to constitute one or two additional distinct species. Part of population on Gulf of Mexico often separated as race *tenuirostris*, on basis of supposedly paler coloration, but many recent authors include it in *nivosus*. Five subspecies usually recognized.
Subspecies and Distribution.
C. a. alexandrinus Linnaeus, 1758 - W Europe, E Atlantic Is and N Africa (S to Senegal) E through Mediterranean, NE Africa, Middle East, SW & C Asia to Russian Far East and NE China; winters S to sub-Saharan Africa, S Asia and W Indonesia.
C. a. dealbatus (Swinhoe, 1870) - S Japan, Ryukyu Is and E & SE China; winters S to Philippines and Borneo.
C. a. seebohmi Hartert & Jackson, 1915 - SE India and Sri Lanka.
C. a. nivosus (Cassin, 1858) - W, C & SC USA, NW, C & E Mexico, Bahamas, Greater Antilles and Netherlands Antilles; winters S to Panama.
C. a. occidentalis (Cabanis, 1872) - coastal Peru to SC Chile.

Descriptive notes. 15-17·5 cm; 32-56 g; wingspan 42-45 cm. Differs from most similar species by white collar on hindneck; black patches on sides of breast, black bar on forecrown, black eyeline; very variable rufous cap. Female has black areas replaced with brown to blackish brown. Non-breeding adult resembles breeding female. Juvenile like pale breeding female with buff fringes to upperparts. Racial variation fairly complex: *dealbatus* very similar to nominate, but has longer bill, and non-breeding male can have little rufous on cap; male of race *seebohmi* has no black bar on forecrown; most *seebohmi* and *occidentalis* and some *nivosus* have white lores and no rufous cap; *occidentalis* and *nivosus* have greyer, often much paler, upperparts, and are shorter-legged; in *occidentalis*, and sometimes in *nivosus*, sexes very similar.
Habitat. Chiefly sea coasts, but also open flats near brackish or saline lakes, lagoons, seasonal water courses, salt-works and depressions. Usually on sand, silt or dry mud with even surface, avoiding rocky or broken ground. Quickly invades newly created suitable habitats, such as gravel pits and reservoirs, although not in large numbers, nor far from possible areas of origin.
Food and Feeding. Inland takes mainly insects, such as beetles and flies, also crustaceans, molluscs and spiders; in brackish and salt water, chiefly crustaceans, polychaete worms and molluscs. Sometimes probes in wet sand and mud and frequently feeds by foot-trembling. Usually in small flocks of up to 20-30 birds.
Breeding. Laying mid-Apr to May in NW Europe; Mar-Jun in NW Africa; Feb-Jul in Ethiopia, Eritrea and Somalia; early Mar to mid-Jul in Iraq; from late Apr in interior W USA. Monogamous, occasionally over several years; polyandry and polygyny may occur if a parent deserts early in season, or if a parent hatches young or loses brood early. Solitary or in loose groups, with nests usually more than 20 m apart (0·8-80 m); site fidelity 60-70%, but may disperse long distance; very low degree of natal philopatry. Territorial; feeds in neutral area outside territory. Densities up to 96 pairs/ha in suitable habitat, but more often 0·5-2 pairs/ha. Nest often near water on bare or scantly vegetated ground; shallow scrape lined with small pebbles, shell fragments and vegetation. 3 eggs, occasionally 2, laid at intervals of c. 2 days; females single- to triple-brooded, males single- or double-brooded; replacement broods after egg loss; incubation 23-29 days, by both parents (female by day, male by night) starting with last egg; in some areas, eggs often partly buried in sand before adult leaves nest, probably for protection against sun; chick has pale grey crown and upperparts with buff tinge, finely speckled dull black and lacking distinct solid lines, underparts white; frequently, one parent, often female, deserts brood about 6 days (0-30) after hatching; fledging 27-31 days; young independent some time after fledging. Breeding success enhanced by associative breeding with more demonstrative and aggressive species. Main cause of breeding failure is predation. Hatching success 20-94%; 0·55 chicks/successful brood. Breeds first at 1 year; annual adult mortality 12-42%; oldest ringed bird at least 18 years.
Movements. Nominate race mainly migratory N of 40° N, dispersive and resident to S; winters in S Eurasia, Africa N of equator (where most birds occur on coast) to W Indonesia. W European breeders winter mainly in SW Europe; origin of large numbers of W African winterers not known. Dispersal from breeding grounds starts immediately after fledging of young from late Jun, and southward migration peaks in Sept; passage through Morocco in Sept, and largest numbers on Banc d'Arguin (Mauritania) in Oct, passage through E Mediterranean in Sept. NW African breeding grounds reoccupied Mar-Apr or May, and northernmost breeding areas in Kyrgyzstan from May. Race *dealbatus* has been reported wintering on Philippines and N Borneo. Race *nivosus* partly migratory, some birds wintering outside breeding range on W & E coasts of Mexico and S to Panama; inland breeders move to coast. Races *seebohmi* and *occidentalis* sedentary.
Status and Conservation. Not globally threatened. Nominate race: c. 67,000 birds winter on E Atlantic coasts, among which minimum 6400-9600 breeding pairs from W & C Europe (1986) and 5000 pairs from Tunisia (1983); 25,000-100,000 birds breed on Black Sea and E Mediterranean, c. 100,000 birds winter in SW Asia and NE Africa, with 15,000-20,000 in lakes of Nile Delta, and 25,000-100,000 birds winter in SC Asia. Population of *dealbatus* in order of 100,000 birds. Race *nivosus* has estimated 21,000 birds wintering in USA, of which 87% W of Rocky Mts; c. 18,500 birds estimated breeding in W USA, of which 2500 coastal. No estimates available for other races. Overall decline in NW & C Europe and Israel since 1950's, probably by 25-50% or more; southward retreat reported in Sweden; Sept counts on Sea of Azov showed decrease from 3000 to 1200 birds, from 1940 to 1970; probable decline by 20% in W North America from 1977/80 to 1988/89; main causes of declines are disturbance of mostly coastal habitats and habitat reduction and fragmentation through reclamation and urbanization. Small numbers of nominate *alexandrinus* formerly bred in S Britain and Norway.

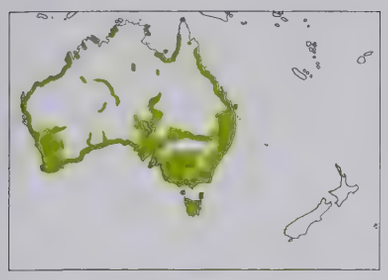
45. **Javan Plover**

Charadrius javanicus

French: Pluvier de Java **German**: Javaregenpfeifer **Spanish**: Chorlitejo Javanés
Other common names: Javan Sandplover

Taxonomy. *Charadrius javanicus* Chasen, 1938, Java.
Taxonomic status very unclear: may well not merit full species status, but various authors associate it with different species; most often treated as race of *C. alexandrinus*; alternatively linked with *C. ruficapillus* or with *C. peronii*, although structurally appears to be quite different from latter; very poorly known, and much more research needed. Tentatively treated as distinct species, forming superspecies with *C. marginatus*, *C. alexandrinus* and *C. ruficapillus*. Monotypic.
Distribution. Java and Kangean Is; possibly also Bali.

Descriptive notes. 15 cm. Differs from similar species by rufous-cinnamon extending from crown down hindneck onto sides of breast, with reduced dark brown to blackish brown patch below; black bar on forecrown; lores and eyeline mainly dark brown. Female has somewhat browner cap, and black areas replaced with drab brown. Non-breeding male resembles breeding female. No data available on juvenile plumage, but presumably similar to that of non-breeding adult.
Habitat. Coastal lowlands.
Food and Feeding. No information available. Probably similar to *C. alexandrinus*.
Breeding. Virtually no information available. Breeding recently recorded in Jun, W Java; also records of birds in breeding condition in May. Eggs much like those of *C. alexandrinus*.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Currently considered near-threatened. No population estimates available; not encountered during Asian Waterfowl Censuses of 1987 to 1992; recently found to be common on S coast of Madura I (E Java). Very poorly known: confused taxonomic status, together with inaccurate descriptions, with result of very little definite information gathered. Considerable scope for research into biology and ecology; extensive surveys required in order to establish conservation status and potential threats; taxonomic reappraisal highly desirable, but much more field information required.



Bibliography. Andrew, P. (1992), Collar *et al.* (1994), Hellebrekers & Hoogerwerf (1967), Hoogerwerf (1936, 1949, 1966, 1969), Hoogerwerf & Siccama (1937), Kooiman (1940), MacKinnon (1988), MacKinnon & Phillipps (1993), Roselaar (1983), Sibley & Monroe (1990), White & Bruce (1986).

46. **Red-capped Plover**

Charadrius ruficapillus

French: Pluvier à tête rousse **German**: Rotkopf-Regenpfeifer **Spanish**: Chorlitejo Capelirrojo
Other common names: Red-capped Dotterel/Sandplover

Taxonomy. *Charadrius ruficapillus* Temminck, 1822, New South Wales.
Forms superspecies with *C. marginatus*, *C. alexandrinus* and *C. javanicus*; all of these have on occasion been considered conspecific (see page 386). Monotypic.
Distribution. Australia, mainly avoiding arid interior; Tasmania.
Descriptive notes. 14-16 cm; 27-54 g; wingspan 27-34 cm. Small, slim plover with short white supercilium and no white hindneck; black eyestripe, lores, frontal bar and breast patches; cap and nape rufous. Female has centre of crown pale grey-brown. Non-breeding adult has black and rufous head pattern mainly replaced with brown, but some tinges of rufous chestnut may remain; upperparts with buff fringes. Juvenile resembles non-breeding adult, but lacks traces of rufous chestnut; upperpart feathers have buff fringes; recalls juvenile *C. bicinctus*, but smaller, longer-legged and paler brown.
Habitat. Coastal habitats, especially sandy or shell beaches with muddy or sandy flats nearby, with preference for saline wetlands behind coast, such as salt-marshes and salt-pans; also bare areas at inland wetlands, preferring exposed inland salt-lakes, and artificial wetlands and watering points, including sewage ponds and salt-works.
Food and Feeding. Annelids, molluscs, small crustaceans, marine and terrestrial insects and their larvae, including ants and beetles, and some seeds and vegetation. Forages in typical *Charadrius* fashion, by sight. Feeds on sandy beaches and mudflats at sea shores, lakes, streams and inland wetlands,

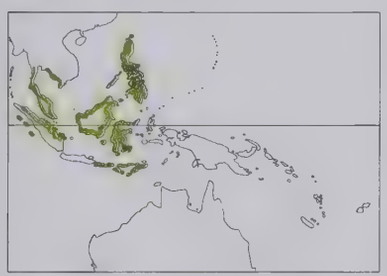
salt-marshes, pasture and gibber plains; often among beachcast seaweed and sparse vegetation. Usually in small parties, but in flocks of hundreds after breeding season.

Breeding. Laying seasonal at coast (Jul-Jan), but at inland wetlands occurs in response to unpredictable rainfall and flooding. Solitary on coast, and inland solitary or in loose colonies of 4-44 pairs (up to 100), usually 70-100 m apart; territorial. Mixed flocks of non-breeders and breeders occur next to nesting sites. Nests on sand, shell-grit, sandy mud, weed mats or beachcast seaweed, on bare or sparsely vegetated ground, usually not less than 40 m from water; shallow scrape, unlined or lined with some shell fragments, pebbles, vegetation and debris; nests on damp mud more substantial, built of water weed. Usually 2 eggs, rarely 3, laid at 1 day intervals, occasionally 2-3 days; single-brooded, but can lay perhaps up to 5 replacement clutches; incubation 30-31 days, starting when clutch complete, mostly by female; chick cream above, with black-brown blotches and speckles forming mid-dorsal line from mantle to rump, poorly defined whitish hindneck collar without broad black bordering, white underparts; tended by both parents. Fledging period and age of first breeding unknown. Nests can be flooded by irrigation works; breeding birds susceptible to disturbance, leaving nest when approached by people or dogs; eggs recorded being trampled by sheep. Hatching success 19-31%. Oldest ringed bird at least 6 years and 5 months.

Movements. Poorly known. Delimitation between breeding and non-breeding distribution very obscure. Birds move between inland wetlands and coast, and between inland wetlands, in response to flooding, drought and varying food availability. Present at all sites almost year round, but numbers can fluctuate without any apparent large-scale seasonal pattern; in some areas, changing numbers related to seasonality of rainfall; usually higher numbers on coast in summer, when inland wetlands are dried up. Probably moves at night in flocks of 8-50 birds.

Status and Conservation. Not globally threatened. Total population c. 95,000 birds; widespread throughout Australia and Tasmania. Vagrant to New Zealand, where small numbers even appear to have bred from 1950 to 1980. Coastal habitats may be threatened by low-density residential development.

Bibliography. Abensperg-Traun & Dickman (1989), Alcorn (1990), Ashby (1991), Blakers *et al.* (1984), Christian *et al.* (1992a), Davis (1980), Flegg & Madge (1995), Green (1956), Hobbs (1972), Hoogerwerf (1966), Hughey (1989), Jessop (1990), Lane & Davies (1987), Lane & Jessop (1983), Lindsey (1992), Macdonald (1988), Marchant & Higgins (1993), McKenzie (1980), Pizzey & Doyle (1980), Poore *et al.* (1979), Pringle (1987), Saunders & de Rebeira (1986), Schodde & Tidemann (1986), Simpson & Day (1994), Slater *et al.* (1989), Trounson (1987), Watkins (1993), White & Bruce (1986).



47. Malaysian Plover

Charadrius peronii

French: Pluvier de Péron **German**: Malaienregenpfeifer **Spanish**: Chorlitejo Malayo
Other common names: Malaysian/Malay Sandplover

Taxonomy *Charadrius peronii* Schlegel, 1865, Semao (= Samau), near Timor.
Has been linked with *C. javanicus* for biogeographical reasons, but structurally quite different. Proposed race *chaseni* is erroneous. Monotypic.

Distribution. S Thailand, Malay Peninsula and S Vietnam to Sumatra, Borneo, Philippines, Sulawesi and Bali to Timor.

Descriptive notes. 14-16 cm; c. 42 g. Resembles *C. alexandrinus* but slightly smaller and chunkier, with black hind collar on upper back; upperparts with dark feather centres; chestnut crown, black frontal bar and eyeline; black breast patches sometimes almost forming complete band. Female has black parts of male rufous brown, sometimes with black flecking and less chestnut in crown; narrower white hindneck; rufous breast patches or breast band separate from female of *C. alexandrinus*. No seasonal variation. Juvenile like female, but never has black flecks in breast patches.

Habitat. Sandy beaches, especially small bays with coral sands, open dunes, either bare or with sparse, low vegetation, and artificial coastal sand-fills.

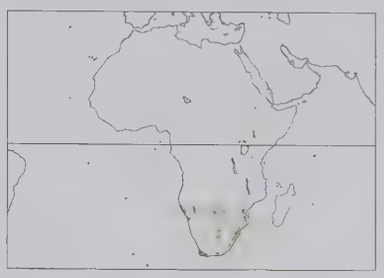
Food and Feeding. No information available on diet. Feeds among tide-wrack at low tide or on exposed flats; often close to water's edge. Typically found feeding in pairs, though may form communal roosts of up to 27 birds.

Breeding. Eggs found late Feb to Jul; May on Luzon (N Philippines). Chicks found mid-Mar to mid-Jun; downy young in Jun on Sumba. Solitary; occasionally nesting as close as 75 m from neighbour; density 0·5-4 pairs/km of shoreline. Nest is shallow, unlined depression, located high up beach, with little or no plant cover. Usually 3 eggs, sometimes 2. No further information available.

Movements. Essentially resident; minor dispersion along SW coast of Peninsular Malaysia mostly during non-breeding season.

Status and Conservation. Not globally threatened. Currently considered near-threatened. Total population may number less than 10,000 birds and possibly declining, but no good estimate available due to scarcity of data. Highest total in Asian Waterfowl Census was 410 birds in 1992. Recently colonized coastal sand-fill in Singapore, but habitat there is sure to degenerate; main cause of nest failure in Singapore is disturbance through beach recreation. Grass sowing and urban development of coastal habitats form major threats.

Bibliography. Andrew & Holmes (1990), Davidson *et al.* (1995), Dickinson *et al.* (1991), Duckworth & Kelsh (1988), Gibbs (1990), Holmes (1995), Hoogerwerf (1966), Lekagul & Round (1991), MacKinnon (1988), MacKinnon & Phillipps (1993), Madoc (1976), van Marle & Voous (1988), Mayr (1944), Medway & Wells (1976), Perennou *et al.* (1994), Scott (1989), Silvius *et al.* (1986), Smythies (1981, 1986), White & Bruce (1986).



48. Chestnut-banded Plover

Charadrius pallidus

French: Pluvier élégant **German**: Rotband-Regenpfeifer **Spanish**: Chorlitejo Pálido
Other common names: Chestnut-banded Sandplover

Taxonomy. *Charadrius pallidus*, Strickland, 1852, Walvis Bay.
Considerable confusion with nomenclature in past: name *C. pallidus* was considered synonymous with *C. (alexandrinus) marginatus*; present species was known as *C. venustus*, and S race as *C. v. rufocinctus*. Two subspecies recognized.

Subspecies and Distribution.
C. p. venustus Fischer & Reichenow, 1884 - Rift Valley soda-lakes on border of Kenya and Tanzania.
C. p. pallidus Strickland, 1852 - S Africa, on coast from SW Angola to Mozambique, and inland in N Namibia, N Botswana and CN South Africa.

Descriptive notes. 15 cm; nominate 28-44 g, *venustus* 20-37 g. Proportionally long legs; black frontal bar, eyestripe and lores and chestnut band on forecrown joined to breast band; upper edge of breast band sometimes black. Female lacks black. No seasonal variation. Juvenile lacks chestnut and black; frontal bar and breast band greyish, latter usually broken; upperparts with whitish fringes. Race *venustus* smaller, with relatively larger bill and darker, browner upperparts.

Habitat. Prefers salt-pans, alkaline lakes and coastal lagoons and estuaries; habitat often of ephemeral nature; rarely occurs in freshwater habitats.

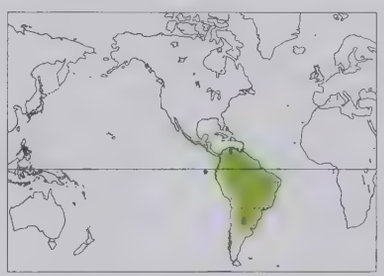
Food and Feeding. Feeds on insects and small crustaceans along the water's edge. Very active in early morning, in Kenya feeding until 09:00 hours, sometimes until 12:00 hours. Occurs singly, in pairs or in flocks of up to 50-60 birds.

Breeding. Laying Apr-Oct in E Africa, at end of rains and afterwards; Sept in Mozambique; Jul in Namibia; Mar-May and Sept-Jan, mostly Nov-Dec, in South Africa. Monogamous; solitary and territorial; 70 nests recorded along edges of single salt-pan. Nest situated on calcareous soil, mudflat or stony slope, within 50 m of water; shallow scrape, lined with small stones, grass, fish bones and small snail shells. Usually 2 eggs, sometimes 1, laid at 2-4 day intervals; possibly double-brooded; incubation by both parents, apparently by female during day and by male in evening, probably starting when clutch complete; incubation and fledging periods unknown. Chick has grey upperparts mixed with black markings and black lines down centre of crown and back; underparts white. Oldest bird recorded 11 years, 6 months.

Movements. Probably partial migrant and nomadic; makes local movements when breeding habitat dries up. In E Africa, moves up and down Rift Valley, with peak numbers in Jul-Sept at L Manyara. After breeding season, some inland birds disperse to coast to mix with sedentary coastal populations, e.g. in Namibia, where large numbers occur in Dec-Jan.

Status and Conservation. Not globally threatened. No population estimates available. Total of c. 5200 birds counted on coast of S Africa, mostly in Namibia; abundant to very abundant in E Africa; locally common to rare inland.

Bibliography. Blaker (1966), Britton, P.L. (1980), Brooke (1984a), Clancey (1962, 1985), Cunningham-van Someren (1971), Dowsett & Forbes-Watson (1993), Ellis (1971), Fraser (1969), Ginn *et al.* (1989), Harvey (1994), Jeffery & Liversidge (1951), Little (1966), Mackworth-Praed & Grant (1957, 1962), McLachlan & Jeffery (1949), Maclean (1993), Morgan-Davies (1960b), Perry (1975), Pinto (1983), Pollard (1980), Reynolds (1975a), Richards (1980), Robinson & Robinson (1951), Short *et al.* (1990), Snow (1978), van Someren (1956), Taylor, P.B. (1982b, 1983), Tree (1980a), Urban *et al.* (1986), Winterbottom (1963).



49. Collared Plover

Charadrius collaris

French: Pluvier d'Azara **German**: Schlankschnabel-Regenpfeifer **Spanish**: Chorlitejo de Azara
Other common names: Azara's Sandplover

Taxonomy *Charadrius collaris* Vieillot, 1818, Paraguay.
Shorter-winged population occurring from Mexico to N Brazil is by some authors considered subspecies *gracilis*. Monotypic.

Distribution. WC Mexico through Central America to W Colombia and W Ecuador, and E of Andes S to N Argentina; C Chile.

Descriptive notes. 14-15 cm; 26-31 g. Differs from most similar species by rather narrow black breast band; black frontal bar and lores; upperpart feathers have chestnut fringes; pale chestnut on central crown. Resembles *C. alexandrinus* but always lacks dark stripe behind eye; upperparts darker and browner; bill relatively long and thin; legs yellowish. Female generally very similar to male, but chestnut can be less extensive and black areas are sometimes brownish. No seasonal variation. Juvenile has no breast band, but has tawny brown lateral patches; no black on head; buff fringes on upperparts.

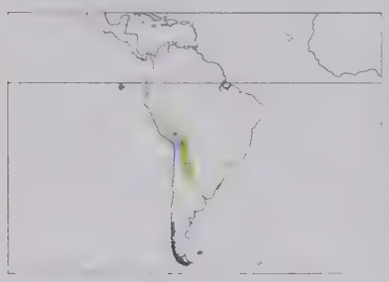
Habitat. Sandy coastal beaches, inland and estuarine wetlands, riverbanks and ponds; also open sandy savannas.

Food and Feeding. Little studied; (water) beetles and their larvae, dragonflies, fly larvae, ants; on intertidal flats, takes polychaete worms, small crustaceans, such as isopods, decapods and crabs, small gastropods; also seeds. Outside breeding season feeds solitarily, in pairs or in small loose flocks. Forages independent of tidal cycle, using intertidal flats at low tide, but beaches and nearby gravelly or short-grass areas at high tide.

Breeding. Breeding season varies with latitude: Nov-Dec in W Mexico; nest with eggs in Aug in S Colombia, another in Sept in Brazil; birds with young in Chile in Jan. Four nests reported, all with 2 eggs.

Movements. Sedentary. In Chile, said to be commoner Apr-Sept, outside breeding season, although no reports of movements. In South America, seems to be commoner on ocean beaches in austral winter than in summer. At Bay of Panama arrives on beaches in parties of 6 birds, from early to late Sept, departing middle to end of Feb.

Status and Conservation. Not globally threatened. No population estimates available, but apparently very common in E South America. Range is expanding on coast of Chile.



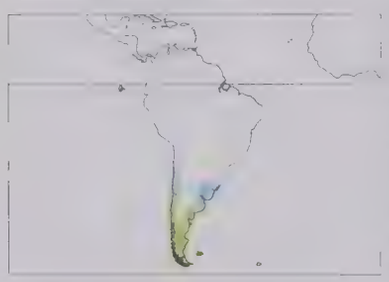
Bibliography. Belton (1984), Beltzer (1986b, 1991), Canevari *et al.* (1991), Contreras *et al.* (1990), Fjeldså & Krabbe (1990), Haverschmidt (1968), Haverschmidt & Mees (1995), Hayes & Fox (1991), Hilty & Brown (1986), Howell & Webb (1994, 1995a), Johnson (1965b), Klimaitis & Moschione (1984), Meyer de Schauensee & Phelps (1978), Monroe (1968), Oyarzo & Ruiz (1983), de la Peña (1981a, 1992), Ridgely & Gwynne (1989), Scott & Carbonell (1986), Sick (1985c, 1993), Slud (1964), Snyder (1966), Stiles & Skutch (1989), Strauch & Abele (1979), Tostain *et al.* (1992), Vilina & Droully (1990), Vooren & Chiaradia (1990), Wetmore (1965), Widrig (1980, 1983a), Yovanovich (1995).

50. Puna Plover

Charadrius alticola

French: Pluvier du puna **German**: Punaregenpfeifer **Spanish**: Chorlitejo Andino
Other common names: Puna Two-banded Plover

Taxonomy. *Ægialitis alticola* Berlepsch & Stolzmann, 1902, Ingapirca, Junín, Peru.
Sometimes considered a subspecies of *C. falklandicus*. Monotypic.
Distribution. *Puna* zone of high Andes, from C Peru through NE Chile and W Bolivia to NW Argentina.



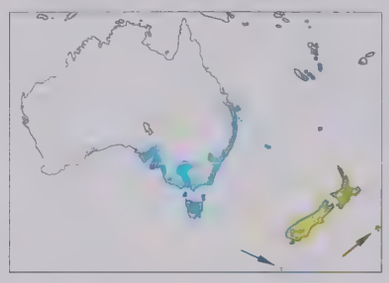
Descriptive notes. 16·5-17·5 cm. Compact plover with "neckless" appearance; black legs and bill, white face; large white forehead demarcated by black frontal bar joined to black lateral breast patches by thin black stripe behind eye; much of crown, hindneck and breast band pale chestnut. Female can be much duller; can have greyish breast band, and brownish patches in black areas. Non-breeding adult sometimes loses black and chestnut, and has obscure breast patches. Juvenile lacks black and chestnut; no lateral breast patches, and very faint breast band; less white-faced look. Birds from Catamarca, N Argentina, are pale and almost lack breast band.
Habitat. High plateau regions with wide expanses of rather firm clay or mud; partly flooded, strongly grazed grassland around salt and freshwater lakes; mainly at 3000-4500 m, but also occurs even higher.
Food and Feeding. Very little information available, but food includes small crustaceans. Outside breeding season usually feeds in loose parties.
Breeding. Laying mainly Sept-Oct, rarely Jan. Solitary. Nest situated on short, matted grass. Chick buffy white with black speckles above.
Movements. Probably mainly sedentary, but at least part of population regularly descends to Pacific coast, where reported from Ica and Tacna (S Peru), particularly in Jun-Oct; on coast observed in parties of up to 30 birds.
Status and Conservation. Not globally threatened. No population estimates available; rather common in S & C parts of range, e.g. on S shores of L Titicaca.
Bibliography. Blake (1977), Canevari *et al.* (1991), Fjeldså & Krabbe (1990), Graves (1981), Hellmayr & Conover (1948), Hoy (1967), Hughes, R.A. (1984), Johnson (1965b), Koepcke (1970), Meyer de Schauensee (1982), Narosky & Yzurieta (1987), Olrog (1984), Parker *et al.* (1982), de la Peña (1992), Remsen & Traylor (1989), Scott & Carbonell (1986)

51. Two-banded Plover

Charadrius falklandicus

French: Pluvier des Falkland **German**: Falkland-Regenpfeifer **Spanish**: Chorlitejo Malvinero
Other common names: Double-banded/Patagonian Two-banded Plover, Patagonian Sandplover

Taxonomy. *Charadrius falklandicus* Latham, 1790, Port Egmont, Falkland Islands.
Has been considered conspecific with *C. alticola*. Population of Falkland Is has been suggested as meriting a separate subspecies, on basis of high frequency of broken upper breast band. Monotypic.
Distribution. C & S Chile and Argentina; locally in S Brazil; Falkland Is. Winters N to N Chile, Uruguay and S Brazil.



Descriptive notes. 17-18·5 cm; 62-72 g. Slightly larger and longer-billed than *C. alticola*; white forehead and lores, black frontal bar; crown and hindneck pale chestnut; two black breast bands, the upper one frequently broken, especially in Falkland Is birds. Female has rufous on head duller; black areas brownish; upper breast band flecked white. Non-breeding adult has black replaced by grey, and chestnut by grey-brown. Juvenile like non-breeding adult, but breast bands brown with buff fringes and face darker; clear buff fringes on upperpart feathers.
Habitat. Gravelly and stony sea shores; also sandy beaches, wet savannas and short-grass borders with patches of sand or gravel, near streams and freshwater or brackish ponds in lowlands. In non-breeding season, also occurs on intertidal mudflats. Mostly coastal, but breeds up to 1200 m on Andean foothills in Santa Cruz, S Argentina.
Food and Feeding. Known to take small invertebrates. Feeds along edges of surf, on beds of rotting kelp, on short grass and around edges of freshwater pools.
Breeding. Laying Sept-Dec, sometimes later in upland habitats. Solitary. 3 eggs. Very tame on breeding grounds. Chick pale buff with black speckles and lines above.
Movements. Most birds migrate N in non-breeding season, although some still found on most of breeding range except extreme S. On Pacific coast, reaches Antofagasta, N Chile; from Patagonia reaches Uruguay and Rio Grande do Sul, SE Brazil. Seems faithful to wintering sites. Falkland Is population sedentary, only moving short distance outside season. During non-breeding season loosely social, occasionally in flocks of 150 or more.
Status and Conservation. Not globally threatened. Population estimated at 10,000-100,000 birds. Numbers seem to be stable, but very little information available. In Rio Grande do Sul, SE Brazil, breeding on coast at Lagoa do Peixe suspected in 1972, proved in 1986.
Bibliography. Antas (1988), Belton (1984), Blake (1977), Canevari *et al.* (1991), Clark (1986), Fjeldså & Krabbe (1990), Forrester (1993), Hellmayr & Conover (1948), Humphrey *et al.* (1970), Johnson (1965b), Meyer de Schauensee (1982), Myers (1980c), Myers & Myers (1979), Narosky & Yzurieta (1987), Olrog (1984), de la Peña (1992), Pinto (1964), Resende & Leeuwenberg (1989), Ruschi (1979), Scott & Carbonell (1986), Sick (1985c, 1993), Vooren & Chiaradia (1990), Woods (1988).

52. Double-banded Plover

Charadrius bicinctus

French: Pluvier à double collier **Spanish**: Chorlitejo Bicinchado
German: Doppelband-Regenpfeifer
Other common names: Banded Double-banded Dotterel

Taxonomy. *Charadrius bicinctus* Jardine and Selby, 1827, New South Wales.
Two subspecies recognized.
Subspecies and Distribution.
C. b. bicinctus Jardine & Selby, 1827 - New Zealand and Chatham Is; winters to S & E Australia, Tasmania, Norfolk I and Lord Howe I, New Caledonia, Vanuatu and Fiji.
C. b. exilis Falla, 1978 - Auckland Is.

Descriptive notes. 18-21 cm; nominate 47-76 g, *exilis* 78-89 g (4 birds); wingspan 37-42 cm. Small, chubby, upright plover; narrow upper breast band black, broad lower breast band chestnut; thin black frontal bar above white forehead; white chin, throat and lower cheeks. Female can have black areas brownish, and lower breast band brown of variable intensity. Non-breeding adult lacks black and chestnut; breast bands reduced to grey lateral patches; clear buff supercilium. Juvenile like non-breeding adult, but has very obscure greyish breast bands; upperparts have whitish buff fringes; recalls juvenile *C. mongolus*, but smaller, less grey and with thinner bill. Race *exilis* plumper, heavier and longer-legged; female has warmer brown upperparts, but duller breast bands.
Habitat. Usually breeds inland on dry, open, firm banks of sand, gravel or shingle in wide rivers; at high altitudes in New Zealand, in dry montane habitats with short vegetation; also coastal beaches, pasture, ploughed land, gravel, quarries and moorland. Outside breeding season, on wide variety of coastal and freshwater wetlands, seldom far inland, for instance occurring on estuaries, lagoons, swamps, beaches, salt-lakes and salt-works; also salt-marshes, grassland and pasture. Outside breeding season roosts in flocks on traditional sites, especially in inaccessible areas at night, e.g. islets, headlands and protected beaches.
Food and Feeding. Molluscs, insects (e.g. larvae of chironomids and other flies and beetles, also caterpillars), crustaceans (e.g. isopods and small crabs), marine worms and spiders; sometimes seeds and berries, eaten especially by chicks. Feeds on vegetated shingle beds, mudflats, salt-marshes, closely cropped pasture, tilled ground; occasionally probes in soft ground. During breeding season, non-breeders and failed breeders feed in flocks on nearby pastures. Diurnal and nocturnal forager; outside breeding season sometimes forages in small loose groups, but others defend territories on wintering ground; breeding birds on Auckland Is move to beaches at night to feed.
Breeding. Laying Aug-Dec in lowlands; mid-Sept (or mid-Aug) to mid-Dec, mostly Oct, in higher areas. Seasonally monogamous, sometimes into second year. High nest-site fidelity and natal philopatry, especially in males. Male produces loud clicking sound with wings during territorial flight display. Solitary and territorial; sometimes clustered with nests mainly 100-150 m apart. Nest is scrape on bare ground with prostrate vegetation, almost unlined or lined with varying amounts of stones and pieces of vegetation and dung, which are also added during incubation. Usually 3 eggs (2-4), laid at intervals of under 60 to 120 hours; up to three replacement clutches; double-brooding rare; incubation 25-28 days, by both parents, female most of day and male possibly most of night. Chicks have two colour morphs, not related to geographical distribution or sex, rarely with intermediates: gold morph has crown and upperparts speckled buff and black-brown with some black-brown blotches, hindneck collar off-white to cream; grey morph has buff of gold morph replaced by grey. Fledging 5-6 weeks; young tended by both parents until 2 weeks after fledging. First breeding at 1 year old. Hatching success 10-44%; eggs and young can be taken by various predators, or trampled by sheep and cattle; predation severest after sudden decline in rabbit numbers or where stoats present; predation rates lowest on broad shingle fans and river islands. Oldest ringed bird over 12 years.
Movements. Nominate is partially migratory, the only plover that migrates from New Zealand to Australia; birds breeding inland or at high altitudes, above about 600 m, almost entirely migratory, migrating to N New Zealand, E & S Australia and Tasmania, or further afield; destination varies regionally. Coastal breeders mostly sedentary. In race *exilis*, probably only part of population makes local movements, moving to tidal shores of Enderby I in winter, while others may remain on territories. Migration starts Oct-Nov, when birds leave territories, and start flocking in Dec-Jan (-Apr), forming flocks of up to 150 birds; most departures for Australia occur Feb-Mar, usually from staging areas on E & S coasts of South I; birds moving to North I depart Jan-Mar. Highly site-faithful on wintering grounds, some birds defending feeding territories. Returns to breeding grounds Aug to early Sept; 1 year olds appear to return later than older birds.
Status and Conservation. Not globally threatened. Widespread in New Zealand; total population estimated at 50,000 birds, of which estimated 30,000 winter in Australia, and more than 4000 on Tasmania. Race *exilis* currently numbers 730 birds; population decreased in 19th century due to introduction of cats and pigs; numbers increasing since early 1970's, when total was 100-200 birds. Species is favoured by conversion of shrubland into pasture, but flood mitigation and planting of willows and other trees have decreased amount of available nesting habitat. Introduced predators prey on significant proportion of eggs and chicks.

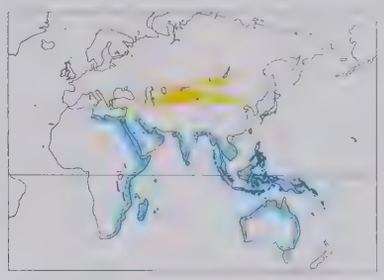
53. Lesser Sandplover

Charadrius mongolus

French: Pluvier de Mongolie **German**: Mongolenregenpfeifer **Spanish**: Chorlitejo Mongol Chico
Other common names: Mongolian Plover/Sandplover/Dotterel/Sand-dotterel

Taxonomy. *Charadrius mongolus* Pallas, 1776, salt-lakes towards Mongolian border = Kulusutay, probably on Onon River, Siberia.
C Asian and Himalayan populations form megasubspecies, *atrifrons*. Five subspecies normally recognized.
Subspecies and Distribution.
C. m. pamirensis Richmond, 1896 - W Tien Shan, Pamirs and Karakoram to W Kunlun Shan; winters S & E Africa to W India.
C. m. atrifrons Wagler, 1829 - Himalayas and S Tibet; winters India to Sumatra.
C. m. schaeferi Meyer de Schauensee, 1938 - E Tibet N to S Mongolia; winters Thailand to Greater Sundas.
C. m. mongolus Pallas, 1776 - inland E Siberia and Russian Far East; winters Taiwan to Australia.
C. m. stegmanni Portenko, 1939 - Kolymskiy, Kamchatka, N Kuril Is and Commander Is N to Chukotskiy Peninsula; winters S Ryukyu Is and Taiwan to Australia.



Descriptive notes. 18-21 cm; 39-110 g; wingspan 45-58 cm. Black eyepatch, broad rufous red breast band and hindneck collar; legs typically dark grey. Very similar to *C. leschenaultii* in all plumages, but smaller, with shorter legs, shorter and thinner bill and rounder head. Female like male but black on head browner, no black line on forehead, rufous parts duller, and no dark upper border to breast band. Non-breeding adult lacks black and chestnut; grey-brown upperparts with pale fringes; large grey lateral breast patches. Juvenile resembles non-breeding adult with buff fringes on upperparts; face, supercilium and breast patches with some buff. Nominate and race *stegmanni* have blackish upper border to breast band, and forehead white, bisected by thin black line; other races have forehead black, sometimes with a few white patches.
Habitat. In breeding season, occurs above or beyond tree-line, mainly in mountains at altitudes up to 5500 m in Ladakh and Sikkim; barren valleys and basins, elevated tundra and mountain steppes, mainly near water (e.g. bogs), on moist but well drained gravelly, rocky or sandy, sparsely vegetated surfaces, including salt-pans, patches of detritus, and in some areas dry edges of salt-marshes and places used by cattle herds; also at sea-level on sand dunes or on shingle, but at lower altitudes does not generally on cultivated or swampy terrain or lakesides until after breeding season. During non-breeding season strictly coastal, frequently tidal mudflats, sandy beaches and estuaries; occasionally airfields.
Food and Feeding. Rather few data available. In non-breeding habitats, takes insects; crustaceans, such as crabs and amphipods; molluscs, particularly bivalves; and polychaete worms. In breeding areas many beetles, and also fly larvae. Limbless bodies of crabs swallowed whole; stalks worms in their holes. May wade up to breast in water. Feeds solitarily or in scattered flocks, often mixed with other waders, including *C. leschenaultii*, on mudflats, salt-pans and salt-marsh, rarely at water's edge. Sometimes forages at night.
Breeding. Laying generally late May to mid-Jun, but from mid-May in *pamirensis*. Density of *pamirensis* c. 1 pair/km²; rarely 3-12 nests only 100 m apart. Unique grating call or display song, "trit-it-it-it-turkhweeoo", lasting 1 second. Nest is scrape or cattle footprint in bare sand or shingle, sometimes besides bushes or big stones, in Far East among lichens and *Drias*; lining of vegetation, small stones and debris accumulates during incubation. Usually 3 eggs, sometimes 2; may lay replacement clutches; single-brooded; incubation 22-24 days, female often starts incubating first egg; chick grey-buff above, mottled with black on crown, grey-buff hindneck collar, underparts white, greyish buff at sides; fledging 30-35 days; in most cases only males tend chicks, but sometimes both parents. Foxes can apparently cause high mortality. Breeds first probably at 2 years old. Oldest ringed bird at least 20½ years.
Movements. Migratory. Four groups definable, migrating to different winter quarters, ranging from coasts of S Africa through S Asia to Australia, using staging areas in between on both ways, e.g. SE Asia and, on northward migration, Japan; occasional winterer in small numbers in Japan. Race *stegmanni* leaves breeding grounds late Jul to late Sept, females first, juveniles latest. Many E Siberian birds migrate coastally, but large numbers of *mongolus* pass overland through Transbaikalia and Manchuria; marked southward movement down E coast of Australia in Aug-Nov. C Asian populations probably migrate directly to S Asian coasts. In Siberia, flocks form early Jul and depart early Aug to early Sept, adults first; arrive in India, S Arabia and E Africa early Aug to mid-Sept. Race *atrifrons* starts moving N in late Feb; main departures Apr; northern breeding grounds reoccupied by mid-Apr to mid-May; *stegmanni* late May to early Jun. Some non-breeders remain on wintering grounds. Casual in NW Alaska, where has bred.
Status and Conservation. Not globally threatened. Population of *pamirensis* estimated to at minimum of 30,000 birds, with 28,000 estimated wintering along Saudi Arabian Gulf coast; *atrifrons* minimum 100,000 birds; and *schaeferi* 25,000-100,000 birds; in winter in E Asia and Australasia, probably 25,000-100,000 birds of races *mongolus* and *stegmanni*, of which c. 20,000 in Australia. In winter, is commonest wader on coasts of Pakistan and India; locally common to abundant from Ethiopia to Tanzania, with thousands in Kenya.

54. Greater Sandplover

Charadrius leschenaultii

French: Pluvier de Leschenault **German**: Wüstenregenpfeifer **Spanish**: Chorlitejo Mongol Grande
Other common names: Great/Large/Large-billed/Geoffroy's (Sand) Plover/Dotterel

Taxonomy. *Charadrius Leschenaultii* Lesson, 1826, Pondicherry, India.
Three subspecies recognized.
Subspecies and Distribution.
C. l. columbinus Wagler, 1829 - Turkey, Syria, Jordan, Armenia, Azerbaijan and S Afghanistan; winters Red Sea, Gulf of Aden and SE Mediterranean.
C. l. crassirostris (Severtsov, 1873) - Transcaspia to SE Kazakhstan; winters in E & SE Africa.
C. l. leschenaultii Lesson, 1826 - W China (Dzungaria), S Mongolia (N Gobi Desert), S Siberia (Tuvinskaya) and Altai Mts; winters Australasia.

Descriptive notes. 22-25 cm; 55-121 g; wingspan 53-60 cm. Medium-sized plover; larger than *C. mongolus*, with larger, broader head, larger bill, longer legs and somewhat paler upperparts; legs usually paller greyish green, but rather variable. Male has narrower and more sharply demarcated rufous breast band than *C. mongolus*. Female has black on head dark grey-brown, no dark stripe on forehead, less extensive chestnut coloration on breast band. Plumages of non-breeding adult and juvenile very similar to those of *C. mongolus*. Races generally very similar, differing in bill shape and colour, both of breeding adult and of juvenile; *columbinus* extensively rufous on back and also on upper flanks.
Habitat. During breeding season predominantly found in deserts or semi-deserts, at lower altitudes than *C. mongolus*, although still up to 3000 m; in open, uncultivated and treeless areas with bare, dry surface, usually near water; in Turkey, also on heavily grazed saline steppe. During non-breeding season, mainly found on coast, on sheltered sandy, shelly or muddy beaches and estuaries, with large intertidal mudflats or sandbanks; also reefs, rocky islands and dunes; occasionally salt-lakes and brackish swamps; usually roosts on sandbanks and spits.
Food and Feeding. Mainly beetles, also molluscs (e.g. snails), worms, crustaceans (e.g. shrimps and crabs), other insects and their larvae (e.g. termites, midges and ants), and occasionally lizards. Recorded wading and foot-trembling. Feeds on mud or sand on intertidal mudflats, salt-marsh, shores of lakes and rivers and pastures. Often in feeding flocks of 2-50 birds, up to 1000 when roosting, commonly mixed with *C. mongolus*.
Breeding. Laying Apr-May in C Asia, late Apr to late May in Turkey; unfledged chicks in late Jun in Armenia. Solitary. Nest is shallow scrape in ground, variably lined with plant fragments, situated in the open or among low vegetation. Usually 3 eggs (2-4); single-brooded, but replacement clutches laid after egg loss; incubation by both parents for at least 24 days, probably starting with last egg; chick has crown, back and band down leg pale cream or straw yellow, marked with black spots and lines, eyeline, forehead and sides of head black, and hindneck collar and underparts white; tended by both parents, with brood often split between them; fledging at least 30 days; age of independence unknown. First breeds when 2 years old. Oldest ringed bird at least 10 years.
Movements. Migratory. Winters on shores of Australasia and Indian Ocean, but relation between breeding and non-breeding quarters poorly known. Probably migrates in broad front non-stop to non-breeding areas; some birds follow coast and occasionally large flocks are seen on passage, typically mixed with *C. mongolus*. Apparently, strong fidelity to non-breeding sites. Flocks form after breeding season between mid-Jul and early Aug, 1 month earlier in *columbinus*; abundant in S China and Hong Kong late Jul to Nov; arrives Australia mid-Aug, S Asia and Sudan to Tanzania late Aug to Sept, adults and immatures before juveniles. Body mass peaks in early Apr in Australia. Starts moving N from SE Asia in late Feb, peaking Mar to early Apr, and reaches breeding grounds from mid-Mar, most Apr-May. Departs E Africa and S Asia mid-Apr to early May. Some wintering birds, probably most non-adults, remain in wintering areas during breeding season.
Status and Conservation. Not globally threatened. Population of race *columbinus* probably numbers under 10,000 breeding birds, with 100-1000 pairs in Turkey and up to 150 in Jordan; *crassirostris* 65,000 birds, of which 10,000-25,000 in Sudan, 15,000 in Kenya and 5000-10,000 on Persian Gulf and in Baluchistan; race *leschenaultii* c. 99,000 birds wintering in E and SE Asia and Australia (74,000 birds), and probably 25,000-100,000 birds in SC Asia, with species abundant in India and Pakistan; c. 8000 birds estimated on Saudi Arabian Gulf coast. In Turkey, threatened by loss of wetlands and bordering fallow steppe through drainage and water extraction for irrigation. Status in Azerbaijan uncertain: species rarely recorded, but known to have bred.
Bibliography. 55. Caspian Plover

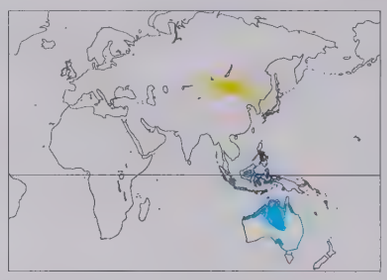
Charadrius asiaticus

French: Pluvier asiatique **German**: Wermutregenpfeifer **Spanish**: Chorlitejo asiático Chico
Other common names: Caspian Sandplover, Lesser Oriental Plover

Taxonomy. *Charadrius asiaticus* Pallas, 1773, salt-lakes of the South Tartar Steppes.
Sometimes placed in genus *Eupoda*. Forms superspecies with *C. veredus*, and possibly with *C. montanus*; formerly treated as conspecific with *C. veredus*. Monotypic.
Distribution. W, N & E Caspian Sea E to L Alakol and L Zaysan, E Kazakhstan, and extreme NW Xinjiang, NW China. Winters in E & S Africa.



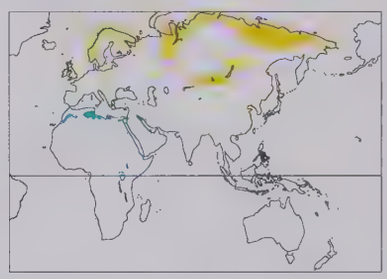
Descriptive notes. 18-20 cm; 60-91 g; wingspan 55-61 cm. Slim, upright plover, with clear white supercilium, forehead and throat; brown crown and upperparts; breast band rusty red or chestnut, with black line on border with white belly; white flashes on upperwing, underwing-coverts white; legs vary between pinkish yellow, greyish green and pale grey or brown. Resembles closely related *C. veredus*, but neck and legs slightly shorter, while *C. veredus* lacks white flashes on upperwing, and has underwing-coverts brown; taller and less compact than *C. mongolus* or *C. leschenaultii*. Female has breast grey-brown without black edge; sometimes has a few chestnut feathers tipped white; head and throat less white. Non-breeding adult has greyish brown breast band; face, forehead and throat pale buffish, upperparts with rufous-buff edges, when fresh. Juvenile like non-breeding adult, with clear rufous and buff fringes to upperpart feathers.
Habitat. Breeds in lowland desert and desert steppe, preferably in salt-pans and on saline soil, often subject to seasonal flooding, near water among sparse shrub vegetation. Concentrations after breeding on banks of lakes and rivers, and water-holes trampled by cattle. In Africa, occurs on recently burnt or heavily grazed grassland and dry floodplains, often far from water; sometimes on bare cultivated ground, coastal dunes (Somalia), airfields and golf courses; probably attracted by insects on animal droppings.
Food and Feeding. Few data available. Primarily insects and their larvae. In breeding season mainly takes beetles, also ants, grasshoppers, bugs, caterpillars and fly larvae; occasionally plant material, e.g. grass seeds. During non-breeding season, beetles, termites and grasshoppers, also small snails; observed hunting for insects in town garbage heaps and cow dung.
Breeding. Laying Apr to late Jun. Mating system uncertain, monogamous pair-bond reported. Song-flight may be heard until midnight on moonlit nights. Territorial, nesting singly or in small, loose groups of 10-25 pairs, at least 50-60 m apart. Adults will feed in small flocks outside territory, leaving eggs and (apparently) young unattended. Nest is shallow scrape, sparsely lined with plant material and debris, on ground in the open or among low vegetation. 3 eggs; probably single-brooded with replacements laid after egg loss; incubated by both parents, only female at night, period unknown; chick has crown, back and band down leg pale cream, marked with black spots, forming lines on crown, back and forewings, while forehead, sides of head, hindneck collar and underparts are white; tended by both parents; fledging at least 30 days; families with young tend to assemble in moist places or river bars; family groups possibly persist into non-breeding season. Age of first breeding probably 2 years.
Movements. Migratory. Usually moves in small flocks of 5-12 birds, sometimes up to 30. Flocks form after breeding, gradually merging for migration during Aug; migrates S Aug-Oct; return migration mid Mar to early May. Stop-over sites in Iran, Iraq, Arabian Peninsula, Red Sea, and perhaps Gulf of Aden, but probably overflies Middle East region during autumn migration; migrates in broad front to and from NE Africa; arrives NE Africa from middle to late Aug; main arrivals in non-breeding areas Sept-Oct, averaging later S of equator. On migration, common to very abundant in Ethiopia (peak Aug-Sept), Somalia and coasts of Kenya and Tanzania; within Africa, gradually moves S in nomadic fashion following local dry seasons, in flocks of 5-20 birds, sometimes moving at night. Main wintering sites are upland plains of SW Kenya and N Tanzania, and Botswana, N & E Namibia and N South Africa. Departure from S Africa late Feb to early Mar, E & SE Africa late Mar to early Apr, arriving Turkmenistan and Kazakhstan from late Mar to early Apr. During non-breeding season, usually in small flocks of up to several hundreds.
Status and Conservation. Not globally threatened. Total population probably numbers 10,000-100,000 birds. Estimated 100-500 pairs in European Russia, where population reckoned to have declined considerably; populations in core of range thought to be fairly stable. Estimated 5000-10,000 winter in Sudan; locally very abundant in Kenya and Tanzania; common in Namibia, uncommon elsewhere in S Africa. Main threat is destruction of natural steppe and grassland, mainly due to overgrazing and conversion to intensive agricultural practices, especially within European part of range.
Bibliography. Ali & Ripley (1980), Ballot *et al.* (1981), Beaman (1994), Benson & Benson (1975), Campbell, L. (1972), Claassen & Claassen (1991), Cramp & Simmons (1983), Dowsett & Forbes-Watson (1993), Elliot (1956), Étchécopar & Hüe (1964, 1978), Evans (1994), Flint *et al.* (1984), Ginn *et al.* (1989), Goodman *et al.* (1989), Harvey (1972), Hüe & Étchécopar (1970), Kashkarov & Ostapenko (1990), Kazmierczak *et al.* (1992), Keijl (1994b), Knystautas (1993), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Nielsen (1971), Nielsen & Colston (1984), Oreel (1984, 1986), Paz (1987), Pellow (1990), Pinto (1983), Poslavsky (1978), Shirihai (1996), Short *et al.* (1990), Taylor, P.B. (1983), Urban *et al.* (1986).

56. Oriental Plover

Charadrius veredus

French: Pluvier oriental **German**: Steppenregenpfeifer **Spanish**: Chorlito Asiático Grande
Other common names: Asiatic/Eastern/Oriental Dotterel/Sandplover, Greater Oriental Plover

Taxonomy. *Charadrius veredus* Gould, 1848, northern Australia.
Sometimes placed in genus *Eupoda*. Formerly considered conspecific with *C. asiaticus*; probably best considered to form superspecies with *C. asiaticus*, and possibly with *C. montanus*. Monotypic.
Distribution. S Siberia (Tuvinskaya and S Transbaikalia) through W, N & E Mongolia to extreme NE China (N Inner Mongolia and NW Manchuria). Winters from Greater Sundas to NW & NC Australia, sparsely in S.
Descriptive notes. 22-25 cm; c. 95 g; wingspan 46-53 cm. Elegant plover, with creamy white head and neck, and brown hindcrown; rufous red breast band with black lower edge; legs yellowish or pinkish. Legs and neck relatively longer than in *C. asiaticus*. Female has pale brownish breast band without black border; more brown on head with whitish supercilium, forehead, chin and throat. Non-breeding adult resembles breeding female, but breast band more diffuse and face and neck more buff or pale brown; new feathers on upperparts show clear rufous or warm buff fringes. Juvenile as non-breeding adult, with larger and paler buff fringes on upperparts.



Habitat. Arid inland areas, especially stony flats and alongside rivers and salt or freshwater lakes. During non-breeding season, occurs on dry open grasslands and sparsely vegetated inland plains, interspersed with dry bare ground; also clay-pans, playing fields, lawns, cattle camps, recently burnt fields, bare margins of wetlands, mudflats and sandbanks; often far from water. May roost on beaches during the day.
Food and Feeding. Few data available. Mainly beetles, also other insects, such as termites, grasshoppers and bugs; snails and seeds. Feeds in loose, small parties or flocks of hundreds; often with other waders and waterbirds. At Eighty Mile Beach, NW Australia, feeds at night and roosts during day.
Breeding. Season Apr-Jul. Solitary breeder. Only females tend brood. No further information available.
Movements. Migratory. Departs from breeding grounds in Jul, males first. Main non-breeding grounds in NW & NC Australia; passage migrant in small numbers through Korea, Japan, Hong Kong, Philippines, Micronesia and SE Asia, Sept-Dec; migrant through E China Aug-Sept and Mar-Apr, where very abundant in Yangtze Valley; arrives Australia mid-Sept to Oct. Scarcity of records between China and non-breeding grounds suggests non-stop flights between these two zones; recorded rather rarely in Indonesia. In Australia, shows erratic movements, apparently moving in response to rainfall and temperature; occurrence in coastal areas often associated with droughts or heatwaves. Birds may depart for Asia directly from inland areas, without visiting coast; leaves NW Australia Feb-Apr, perhaps mostly mid-Mar; present C Mongolia, immediately S of breeding grounds, from late Apr.
Status and Conservation. Not globally threatened. Total population estimated at 44,000 birds, of which 40,000 winter in Australia, with important sites at: Port Hedland Saltworks, with maximum of 29,900 birds; Eighty Mile Beach with maximum of 18,400 birds; and Roebuck Bay maximum 8700 birds. Total of 14,000 birds counted on 12·5 km of Eighty Mile Beach in Mar 1993. In Australia, species not immediately threatened due to occupation of sparsely settled areas; no information on trends in breeding zone, but human pressure generally reckoned to be relatively low.
Bibliography. Ali & Ripley (1980), Beaman (1994), Bigg (1981), Brazil (1991), Christian *et al.* (1992a), Close (1982), Coates (1985), Cox (1988b), Edgar (1968), Étchécopar & Hüe (1978), Flint *et al.* (1984), Knystautas (1993), Kozlova (1975), Lane & Davies (1987), Larkins & McGill (1978), MacKinnon & Phillipps (1993), Marchant & Higgins (1993), van Marle & Voous (1988), McCrie (1984), McKenzie *et al.* (1956), Meyer de Schauensee (1984), Morton *et al.* (1990), Nielsen (1971), Ostapenko *et al.* (1980), Pedler (1982a), Scott (1989), Smythies (1981), Warakagoda (1994), Watkins (1993), White & Bruce (1986).

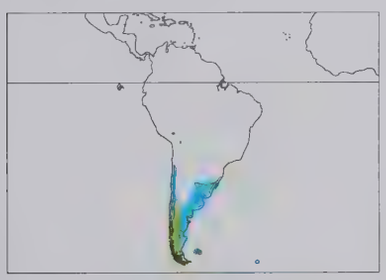
57. Eurasian Dotterel

Charadrius morinellus

French: Pluvier guignard **German**: Mornellregenpfeifer **Spanish**: Chorlito Carambolo
Other common names: Dotterel

Taxonomy. *Charadrius Morinellus* Linnaeus, 1758, Sweden.
Often placed in genus *Eudromias*, but possibly quite closely related to some or all of *C. asiaticus*, *C. veredus*, *C. modestus* and *C. montanus*. Monotypic.
Distribution. N Britain through Scandinavia and N Siberia to Chukotskiy Peninsula, and NE Kazakhstan and NW China (NW Xinjiang) E through S Siberia and N Mongolia to SE Russia; irregularly in Pyrenees, Alps, Carpathians, and also sporadically elsewhere in Europe, Caucasus and NW Alaska. Winters in N Africa and Middle East E to W Iran.

Descriptive notes. 20-22 cm; male 86-116 g, female 99-142 g; wingspan 57-64 cm. Bulky plover, with reversed sexual dimorphism in size and plumage; unmistakable in breeding dress; long white supercilia meet in "V" on nape; narrow white breast band separates grey throat and upperbreast from bright chestnut lower breast. Female more brightly coloured than male, with blacker crown and belly; breast band sharper than in male. Non-breeding adult lacks bright colours, and has supercilia brownish buff; upperparts fringed buff or sandy; pale white breast band, pale grey-brown breast with dull white bar; belly white. Juvenile shows greater contrast than non-breeding adult, with darker feathers and brighter fringes, and more buff on underparts.
Habitat. Breeds on extensive open, flat uplands, mountain ridges and plateaux, with sparse vegetation of moss, short grass or lichens and bare patches of rock, in Arctic tundra and Arctic-alpine zone; not particularly near water. On migration, stages in exposed areas with some short vegetation, heathland, fallow or ploughed land, often returning to same sites annually. Non-breeding grounds less known, but include stony steppe, ploughed farmlands, semi-desert, including marginal cultivation and shrubby steppe.
Food and Feeding. Insects, mostly beetles and Diptera larvae, also adult Diptera, larvae of butterflies and moths, grasshoppers, crickets, earwigs and ants, and spiders; occasionally snails, earthworms, especially in ploughed fields, and regularly some leaves, seeds, berries and flowers. Chicks have similar diet. Sometimes feeds by foot-trembling. May associate with cattle in some areas. Diurnal and nocturnal forager, primarily diurnal at southern breeding grounds.
Breeding. Laying mid-May to early Jul in Scotland, mid-May to early Jun in C Norway, from mid-Jun in Sweden, Finnmark and Taymyr. Seasonally monogamous, serially polyandrous and occasionally polygynous, depending on local sex ratios. Mating can take place on arenas. Sex roles reversed. No site fidelity apparent. Solitary, but where suitable habitat is restricted breeds in loose neighbourhood groups of 2-5 pairs; nests 200 m to several kilometres apart; density 4-6 birds/km² in NC Siberia, maximum density 8-10 pairs/km² and 17 pairs/km² recorded in Lappland. Usually feeds outside territory on neutral grounds; non-breeding and off-duty breeding birds often roost communally at night on feeding grounds. Nest in short vegetation or on bare gravel or soil; shallow scrape, lined with moss, lichens or leaves. 3 eggs, occasionally 2, laid at 30-36 hour intervals; in case of polyandry female produces second clutch c. 5-11 days or more after completion of first, and sometimes a third clutch; polygynous male usually has 2 mates simultaneously, occasionally 3, sometimes 2 clutches in 1 nest;



up to 2 replacement clutches. Incubation 23-29 days, starting with penultimate egg, (almost) entirely by male; in second or third clutches of polyandrous female, she participates more in incubation; chick blotched cinnamon, white and black, with off-white nape, broad supercilium and underparts; tended by male; fledging 25-30 days; young probably stay with male parent during migration and for some time in winter quarters. First breeding at 2 years old. Breeding success 162 fledglings per 427 breeding birds in N Scotland; hatching success 81% in Lappland; fledging success 72%. Important causes of failure are severe weather, especially sleet, snow and heavy rain, and predation.
Movements. Migratory. Migrates in broad front across Europe, staging at a few, often traditional, sites. Many birds probably migrate non-stop, especially in autumn. On autumn migration females usually precede juveniles and males by 2-4 weeks, and also tend to return first to breeding grounds. Birds depart from Scottish Highlands first half Aug, Siberia from late Aug to early Sept; passage W Europe mid-Aug to late Sept; some birds stage in Alps at altitude of 2000-3000 m or on crest of Jura Mts at 1600 m; many stage to moult in N Caspian region, migrating further S until early Nov; birds arrive in winter grounds from early Sept. Spring migration begins late Feb to Mar, passing W Europe mid-Apr to mid-May and Ukraine mid-Mar to late Apr; returns to breeding grounds in Scotland early May, S Scandinavia middle to late May, and Lappland and N Russia late May to mid-Jun. Despite vast and discontinuous breeding range no indication of subspeciation; this is in accordance both with limited faithfulness to breeding sites, which may be due to mixing in winter quarters, and with erratic breeding in Europe. During migration sometimes in flocks of 20-80 birds, but usually of 3-6.
Status and Conservation. Not globally threatened. Total breeding population in Europe 36,500 breeding pairs, with 28,000 in Norway (1981), 7500 in Sweden (1984), 800 in Finland (1986) and in excess of 550 pairs in Britain (1988), but decreasing; Asia 10,000-100,000 birds. In 19th century bred in Poland and Czech Republic and Slovakia. In Finland, significant decline in 1940's and since 1970's; cause for recent decline might be heavy persecution in N Africa; amelioration of climate in breeding area may also be significant factor. Numbers declined in Britain in late 19th century due to hunting and egg-collecting.

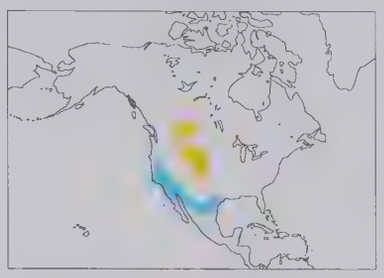
58. **Rufous-chested Plover**

Charadrius modestus

French: Pluvier d'Urville **German**: Rotbrust-Regenpfeifer **Spanish**: Chorlito Chileno
Other common names: Rufous-chested Dotterel, Chilean/White/Winter Plover

Taxonomy. *Charadrius modestus* Lichtenstein, 1823, Montevideo, Uruguay.
Occasionally placed in genus *Zonibyx*. No subspecies recognized, although birds from Falkland Is have longer wings and tarsi. Monotypic.
Distribution. S South America in SC & S Chile and WC & S Argentina and Falkland Is. Winters N to N Chile and SE Brazil.



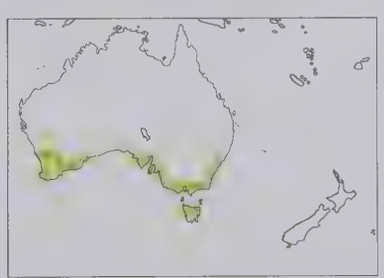
Descriptive notes. 19-22 cm; 71-94 g. Bright white supercilia meet on forehead; face, cheeks and throat ash grey, breast rufous red with broad black lower edge; belly white. Female tends to be slightly duller. In non-breeding adult, rufous and grey replaced with pale brown; feathers of upperparts with bright fringes and supercilia creamy. Juvenile as non-breeding adult, but upperparts and breast darker brown with clear buff fringes.
Habitat. Breeds mainly on inland short grassland, from coast up to altitude of 2000 m on windy inland foothills; sometimes boggy lowlands or dry stony areas around upland lakes; also coastal shingle, high parts of bogs and heaths. Outside breeding season occurs on flooded grassland, eroded inland grassland, marshes, streams, mudflats, beaches and rocky shores.
Food and Feeding. Insects, insect larvae, crustaceans, molluscs and some plant material (e.g. algae). Near water, forages at water's edge, where territory of 10-100 m often defended. Outside breeding season forages in small parties, of up to 100 birds or more; often together with *C. falklandicus*.
Breeding. Eggs Oct-Nov, rarely Jan; laying in Falkland Is late Sept to mid-Jan, with peak in Oct. Solitary. Nest placed in the open; in Falkland Is among stands of ferns and diddle-dee (*Empetrum*), providing cover. Usually 2 eggs, sometimes 3; incubated by both parents; chick golden buff, conspicuously marked with black dots and lines, nape rufous.
Movements. Migratory to resident; southernmost breeders migrate N in Mar-Apr and return Aug-Sept; some remain close to breeding grounds, even on Tierra del Fuego; most birds from Falkland Is migrate to mainland after breeding, but unknown proportion resident. Apparently faithful to wintering sites. Gathers in post-breeding flocks prior to northward migration.
Status and Conservation. Not globally threatened. Population size not known, but species generally reckoned to be not uncommon. Occupation of zones with relatively limited human impact suggests species likely to be secure at present; no threats identified.
Bibliography. Antas (1988), Belton (1984), Blake (1977), Canevari *et al.* (1991), Carstairs (1989), Clark (1986), Fjeldså & Krabbe (1990), Forrester (1993), Hellmayr & Conover (1948), Humphrey *et al.* (1970), Johnson (1965b), Meyer de Schauensee (1982), Narosky & Yzurieta (1987), Olrog (1984), de la Peña (1992), Pinto (1964), Scott & Carbonell (1986), Sick (1985c, 1993), Vooren & Chiaradia (1990), Woods (1988).

59. **Mountain Plover**

Charadrius montanus

French: Pluvier montagnard **German**: Bergregenpfeifer **Spanish**: Chorlito Llanero

Taxonomy. *Charadrius montanus* J. K. Townsend, 1837, central tableland of the Rocky Mountains = near Sweetwater River, Wyoming.
Sometimes placed in genus *Eupoda*. On occasion considered to belong to superspecies of *C. asiaticus* and *C. veredus*. Monotypic.
Distribution. Great Plains and plateau of E Colorado, in C North America. Winters from C California to Baja California and E to S Texas and NE Mexico.



Descriptive notes. 21-23·5 cm; 67-112 g. Bright white forehead and supercilium, black frontal bar and black lores; never has black on breast; underparts white, washed buff on sides; relatively long pale yellowish brown legs. Somewhat similar to non-breeding *Pluvialis dominica*, alongside which sometimes occurs, but smaller, with less spotted plumage and white underwing. Sexes alike. Non-breeding adult has pale brown crown and lores, and darker breast patches, which may be connected; upperparts have rufous fringes. Juvenile like non-breeding adult, but upperparts and breast darker brown; buff supercilium; broader and brighter buff fringes on upperparts.
Habitat. Nests in disturbed upland short-grass prairie. After breeding season occurs in semi-desert and on dry agricultural land or heavily grazed rangelands; shows strong preference for alkaline flats, but these have almost disappeared from range. Often found in association with colonial fossorial mammals, e.g. kangaroo rats (*Dipodomys*) and prairie dogs (*Cynomys*). Often roosts on burnt fields at night; roost-site is commonly in shallow depression, typically hoofprint, with bird's eyes just above the surface. Despite scientific and vernacular names, not a mountain species.
Food and Feeding. Grassland insects, mainly grasshoppers, also crickets, beetles and flies. Feeds on disturbed insects in recently cultivated fields. During winter, typically remains only for few days at any site. Gregarious, in loose flocks of up to several hundred, especially in winter.
Breeding. Season late Apr to Jul. At least some males site-faithful, but virtually all young disperse to other areas. Monogamous, polyandrous and probably polygynous in different cases. Territorial, often feeding outside territory, in neutral area; on average, nests 140 m apart. Nests on short-grass prairies, particularly in association with blue grama grass communities; nest is shallow scrape on bare ground between plants in loamy soil, sometimes including plant material and debris, which are accumulated during incubation. Usually 3 eggs (2-4), laid at intervals of 1-6 days; incubation 28-31 days, starting when clutch complete, performed by male alone; female often leaves first clutch to male, and lays second clutch which she incubates herself, or, in case of polyandry, is incubated by a second male; female may start third clutch; chick creamy buff above with conspicuous black spots, underparts buffy white; fledging 33-36 days. 20-65% of nests successful; nests failure caused by predation, storms and trampling by cattle. Winter survival 95%.
Movements. Migratory. On breeding grounds, flocks form from mid-Jun onwards; present in inland wintering areas chiefly from early Nov to mid-Mar; main wintering area is Central Valley of California; arrives in flocks on breeding grounds in Colorado by late Mar to Apr, probably after non-stop flight from wintering areas; migratory routes unknown.
Status and Conservation. VULNERABLE. Proposed for Endangered status (1995). Population decreasing: before 1900 species was an abundant and important gamebird, but by c. 1970 numbers had fallen to 200,000-300,000 birds; between 1960 and 1991, dramatic decline of 63%; in 1994, population estimated at only 5000-10,000 birds. Much of breeding area lost due to increased vegetation height as a result of planting "tame" grasses and excessive declines in populations of grazers, especially bison (*Bison bison*) and prairie dogs; alternatively, lost to cereal production; wintering areas also suffer from lack of grazers; decline may be explained completely by disking, to control weeds, or planting during the nesting and early chick phases. Currently, two sites of major importance: Pawnee National Grassland, Colorado, and Charles M. Russell National Wildlife Refuge, Montana.

60. **Hooded Plover**

Charadrius rubricollis

French: Pluvier à camail **German**: Kappenregenpfeifer **Spanish**: Chorlito Encapuchado
Other common names: Hooded Dotterel

Taxonomy. *Charadrius rubricollis* Gmelin, 1789, Adventure Bay, Tasmania.
Recently placed by some authors in genus *Thinornis* with *C. novaeseelandiae* (see page 385). Monotypic.
Distribution. S Australia and Tasmania.

Descriptive notes. 19-23 cm; 79-110 g; wingspan 36-44 cm. Short-legged plover with neckless appearance; black head and broad white neck collar; upperparts grey bordered black on neck, extending into small black patch at side of breast; deep red eye-ring; bill orange-red at base, with black tip; dull orange-pink legs. Sexes alike. No seasonal variation. Juvenile as adult, but hindneck, crown and breast patches pale grey-brown mottled whitish buff; chin and throat whitish; upperparts pale brown-grey with pale fringes; bill blackish with flesh coloured base and eye-ring paler.
Habitat. Mainly found on broad, sandy ocean beaches, occasionally near rocky or sand-covered reefs, estuaries, inlets and saline and freshwater lakes and lagoons close to coast. Breeds in sparsely vegetated sand dunes backing onto beach, between high water mark and base of dunes, often with much seaweed spread around, or, especially in Western Australia, round margins of lakes.
Food and Feeding. Amphipods, isopods, polychaetes, bivalves, gastropods, crabs, insects (e.g. dragonflies, beetles and flies) and seeds. Feeds busily along water's edge on prey left behind by receding waves during low to mid-tide. At high tide forages among seaweed and debris of beachcast; on rocks, forages in wave-wash or spray zone; at lagoons and lakes, forages on dry or moist substrates or in

shallow water. Diurnal and nocturnal; feeding mostly tactile at night, involving continuous pecking. During non-breeding season forages in loose, small flocks of 10-40 birds, up to large flocks, occasionally of several hundred.
Breeding. Eggs found Aug-Mar, or later due to replacement and second clutches. Monogamous, often over several years. Solitary and territorial, with nests often kilometres apart, but also as little as 18 m apart; density 0·2-2 pairs/km; high degree of site fidelity; possible breeding association with Australian Pied Oystercatchers (*Haematopus longirostris*). Nests in sand, in the open; nest is scrape, unlined or lined with pebbles, seaweed, sticks and shell or stone fragments, and sometimes encircled with such material. 2-3 eggs, occasionally 4, probably laid at 1-4 day intervals; replacement clutch may be laid; incubation 27-31 days, by both parents, starting once clutch complete; chick has sandy brown upperparts mottled with black, white nape with black band extending to just below eye and white underparts; both parents tend chicks until fledging; fledging 32-36 days. May breed at 1 year old. Hatching success 17-31%; 0·1 young fledged per pair; causes of nest failure are flooding, human disturbance, destruction by vehicles, trampling by livestock and predation.
Movements. Essentially sedentary, showing erratic movements; inland breeders move to coastal lakes after breeding season; in SE Australia, some flocking occurs during non-breeding season, and at some breeding sites birds absent or sparse during Apr-Aug, suggesting at least local movements; also moves inland, e.g. to salt-lakes immediately behind beach, and may fly to offshore islands, c. 20-70 km away.
Status and Conservation. VULNERABLE. Population probably numbers at least 5000 individuals, of which 1730 on Tasmania. Small W population probably secure, but range contracting on coast and around salt-lakes in S Western Australia. In E Australia, human disturbance through recreational activities on beaches has probably contributed to decline of species; incubating birds readily leave eggs due to disturbance, and scavengers are attracted to human activities. Many nests may be crushed by 4-wheel-drive vehicles, e.g. 81% of nests at the Coorong in 1985-86; in some areas, predation by foxes and Silver Gulls (*Larus novaehollandiae*) and trampling of nests by livestock are major causes of nest failure; young can be killed by vehicles when hiding in wheel ruts.

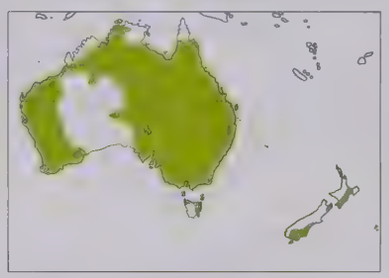
61. **Shore Plover**

Charadrius novaeseelandiae

French: Pluvier de Nouvelle-Zélande **Spanish**: Chorlitejo de las Chatham
German: Chathamregenpfeifer
Other common names: New Zealand/Shore Dotterel/Plover

Taxonomy. *Charadrius novæ-Seelandiæ* Gmelin, 1789, Queen Charlotte Sound, South Island, New Zealand. Often placed in genus *Thinornis*, in recent years increasingly with *C. rubricollis*, but limits and validity of genus *Thinornis* remain debatable, so both species probably best retained in *Charadrius* for present (see page 385). Monotypic.
Distribution. Rangatira I (South-east I) of Chatham Is.

Descriptive notes. c. 20 cm; 52-69 g. Distinctive small, chubby plover, with proportions not unlike *Arenaria interpres*; black head, except for grey-brown crown encircled by white band; orbital ring orange to red; short, thick orange legs. Female similar to male, but black of head replaced with dusky brown; more black on bill tip. No seasonal variation. Juvenile has mainly white face with dark brown eyestripe and crown; brown lateral breast patches; upperparts more clearly scaled; bill mainly black, pale orbital ring and legs. Calls higher-pitched in females than in males, and in juveniles than in adults.
Habitat. Rocky shores with extensive wave-cut platforms containing shallow tidal pools, sometimes covered with barnacles, limpets or patches of algae; also adjacent boulder-strewn beaches and less often nearby barren salt-meadows with turf-like and halophytic vegetation. Formerly occurred on estuarine mudflats and sand-spits on mainland New Zealand. Breeds on beaches among high piles of boulders and on inland salt-meadows with mats of herbaceous plants or clumps of lignum.
Food and Feeding. Small crustaceans (e.g. copepods), spiders, gastropods, bivalves and insects of rocky shores; takes Hemiptera, caterpillars and larvae on salt-meadows. Sometimes feeds by foot-trembling. Active diurnally and nocturnally, depending on tide. Feeds at low tide, at edges of shallow tidal pools and on wet rocks, bare or with beds of barnacles or algae. Outside breeding season, often forages in small flocks of up to 15 birds.
Breeding. Laying mid-Oct to Dec; breeding synchronized amongst pairs in same area. Monogamous on long-term basis. Defends home range, including nest-site; also defends area for chick-rearing and, to varying extent, feeding area. Congregations form in suitable habitat, where nests may be only few metres apart; shows high degree of site fidelity. Nests in cavities among boulders or under rocks, logs, tree-roots, etc., on salt-meadows; nest is cup-shaped scrape in sand and grit, substantial in wetter sites, where made of roots and dead grass, lined with plant material, occasionally feathers, shells and pebbles. Some pairs may remain in breeding home range for most of year. 3 eggs, sometimes 2, laid at 1-2 day intervals; single-brooded, but replacement clutches are laid, incubation c. 28 days, by both parents, but more by female; chick has upperparts mottled with off-white, buff, pale brown and black-brown spots, lacks white hindneck collar, underparts tawny white; tended by both parents, but more intensively by female; fledging 29-63 days; young independent 4-36 days after fledging. Most birds breed first at 3 years old. Hatching success 83%, of which 7-43% fledge, i.e. 0·5-0·8 young/pair. Mass failure of beach-breeders may occur through storm surges, washing away eggs or chicks; other causes of failure include predation by Silver Gulls (*Larus novaehollandiae*) and Brown Skuas (*Catharacta antarctica*). Average longevity 6 years, maximum at least 17 years.
Movements. Sedentary; local movements of small flocks in non-breeding season. Juveniles very mobile immediately after independence, visiting other suitable habitats, but usually returning eventually to natal shore. Birds return to breeding territories May-Jul, females often preceding males.
Status and Conservation. ENDANGERED. Total population in 1993 was c. 130 birds, including 43-44 breeding pairs; numbers stable since 1969, probably constrained by shortage of suitable habitat. Formerly occurred on North I and South I and adjacent islands of New Zealand, but was already very rare, or even extinct, in 19th century; this decline was probably due to predation by introduced rodents and feral cats; no records on mainland New Zealand after 1888. Probably once occurred on all islands of Chatham group, but extirpated on Pitt I and Mangere I by introduced predators. Between 1890 and 1910, hundreds were collected on Rangatira I for sale as scientific specimens. Populations declined on Rangatira I after removal of sheep in 1958, resulting in deterioration of formerly suitable habitats, but numbers seem to have recovered and stabilized. In 1970 and 1971, adult and immature birds were unsuccessfully reintroduced to Mangere I, soon making their way back to Rangatira I. Very low numbers and tiny distribution make species extremely vulnerable to rapid extinction, e.g. if mammalian predators were to reach Rangatira.
Bibliography. Bell (1974), Chambers (1989), Collar & Andrew (1988), Collar *et al.* (1994), Davis (1987, 1994a, 1994b), Dowding & Kennedy (1993), Falla *et al.* (1981), Ferguson-Lees & Faull (1992), Flack (1976), Fleming (1939b), King (1978/79), Marchant & Higgins (1993), Phillips (1977, 1980), Robertson (1985), Rosair (1995d), Sibson (1982), Soper (1976), Williams (1975), Williams & Given (1981).



Genus *ELSEYORNIS* Mathews, 1914

62. **Black-fronted Dotterel**

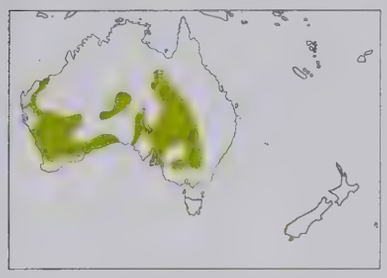
Elseyornis melanops

French: Pluvier à face noire **German**: Schwarzstirn-Regenpfeifer **Spanish**: Chorlitejo Frentinegro
Other common names: Black-fronted Plover

Taxonomy. *Charadrius melanops* Vieillot, 1818, New South Wales.
Often included in genus *Charadrius*. Monotypic.
Distribution. Australia, Tasmania and New Zealand.

Descriptive notes. 16-18 cm; 27-42 g; wingspan 33-35 cm. Strikingly coloured, slim plover; black eyestripe and lores continuing onto forecrown; white supercilia join on nape; red bill with black tip; purplish patch on upper scapulars; black V-shaped breast band; rump and uppertail-coverts dark brown to chestnut with broad buff fringes; black stripes on undertail-coverts; pinkish or pale orange legs; in flight mainly white from below. Sexes alike. No seasonal variation. Juvenile has buffy cream forehead and crown, dark brown eyestripe and buff supercilium; upperparts with buff and brown fringes, no chestnut on rump; obscure breast band; bill brown to grey-black; orbital ring often absent; legs pink-brown.
Habitat. Bare or sparsely vegetated margins of wetlands, freshwater or sometimes brackish, on areas with mud, firm ground or gravel, including swamps, lakes, pools, water-holes, springs; also man-made habitats, including reservoirs, farm dams, tanks and even roadside ditches; often round receding floodwaters. In New Zealand, mainly on shingle or gravel beds of shallow, braided rivers, and on nearby farmland when rivers flood; also ditches beside roads and margins of wetlands; in arid regions, sometimes near saline water.
Food and Feeding. Water snails, crustaceans, earthworms and insects, such as crickets, grasshoppers, flies, ants, water beetles and larvae, occasionally seeds. Forages diurnally, on mud at edge of water; occasionally in shallow water. On hard substrates, taps and pecks. When foraging, usually solitary or in pairs, also in family groups.
Breeding. Season Sept-Feb in Australia, Aug-Mar in New Zealand, but can occur earlier or later owing to variable conditions, e.g. of rain and temperature. Monogamous, at least sometimes for more than one season. Solitary, with territory also used for feeding; site-faithful. Nest placed on open stony ground, often on banks of sand, gravel, pebbles or shingle, and sometimes besides or on gravel roads; nest is scrape or depression, unlined or lined with pebbles, plant material and debris. 3 eggs, sometimes 2, laid at intervals of 2 days; double-brooded and may lay up to two replacement clutches; incubation 22-26 days, by both parents; chick buff above, speckled and blotched black, with white collar and black along sides of back, underparts white; tended by both parents; fledging 23-40 days; young of first brood remain with parents until incubation of second brood starts, or until second brood hatched; young of second brood remain with parents for at least 8 weeks. Hatching success 61% in Australia, fledging success 32-67% in New Zealand. Broods may fail through predation by feral cats and foxes, human disturbance, flooding or trampling by cattle.
Movements. Poorly known in Australia, but apparently mainly sedentary; sedentary in New Zealand. Flocks of non-breeding birds at some sites in Australia suggest possible movements, but no large-scale movements apparent. In New Zealand, flocking occurs at favoured sites away from river, especially Apr-Jul, with flocks of up to 175 birds. Vagrant to India: single old record.
Status and Conservation. Not globally threatened. Has recently expanded range due to development of new suitable habitat resulting from construction of artificial wetlands, such as farm dams and sewage ponds. Now most widespread wader of Australia with total population of at least 19,000 birds, but almost certainly more. Colonized New Zealand from Australia, starting in Hawke's Bay in late 1950's, and has since expanded; in 1992, population of c. 1600 birds, but much suitable habitat on South I not yet occupied.
Bibliography. Andrew (1975), Barlow (1989), Barter (1991a), Blakers *et al.* (1984), Chambers (1989), Child (1982), Child & Child (1984), Christian *et al.* (1992a), Falla *et al.* (1981), Flegg & Madge (1995), Heather (1973, 1977), Lane & Davies (1987), Lindsey (1992), Macdonald (1988), Maclean (1977), Marchant & Higgins (1993), Phillips (1980), Pizzey & Doyle (1980), Pringle (1987), Robertson (1985), Schodde & Tidemann (1986), Schulz (1990), Sibson *et al.* (1972), Simpson & Day (1994), Slater (1987), Slater *et al.* (1989), Tarburton (1989), Trounson (1987).

Genus *PELTOHYAS* Sharpe, 1896



63. **Inland Dotterel**

Peltohyas australis

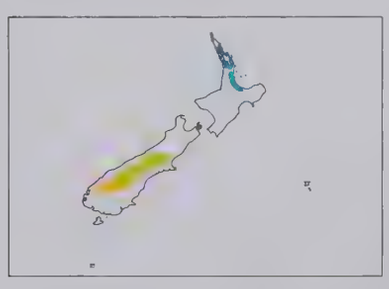
French: Pluvier australien **German**: Gürtelregenpfeifer **Spanish**: Chorlito Australiano

Other common names: Australian Dotterel/Courser, Desert Plover

Taxonomy. *Eudromias Australis* Gould, 1841, interior Australia.
Relationships uncertain, and somewhat controversial: formerly considered to belong to family Glareolidae, where was listed closest to genus *Rhinoptilus*; also in past, on occasion placed in genus *Eudromias*; recent biochemical studies suggest genus might possibly be merged with *Charadrius*. Race *whitlocki* has been proposed for birds in C & SW Australia, but doubtfully valid. Monotypic.
Distribution. SW, SC & EC Australia.

Descriptive notes. 19-23 cm; 64-107 g; wingspan 43-47 cm. Very distinctive black vertical eye-bar continuing onto crown; Y-shaped breast band continues onto hindneck; pale chestnut underparts, with dark chestnut lower edge and white lower belly; thin whitish eye-ring; underwing conspicuously rich rufous buff. Sexes alike. No seasonal variation. Juvenile like adult but generally duller, showing traces of dark face and collar.
Habitat. Mainly inland in flat, open, arid habitat with sparse growth of 20-40 cm tall salt-bush, blue-bush or samphire, often with bare patches of clay, including gibber plains, gravel flats, clay-pans and gilgais; at extremes of range, extends to coastal regions and into grasslands; often on gravel roads or airstrips at night; also heavily grazed pasture, and clearings opened in mallee vegetation for agriculture and ploughed land.
Food and Feeding. Seeds, leaves, insects (e.g. earwigs, crickets, beetles, termites, ants and larvae), and spiders. Mainly inactive during day, although very tolerant of high temperatures; feeds among shrubs in daytime; at night, feeds on dirt roads; tends to be herbivorous during day and insectivorous at night. Makes vigorous biting, pecking and pulling actions to procure pieces of plants up to 15 mm in diameter. Usually forages in small flocks of up to 20 birds, occasionally up to 50-400, but seems to feed solitarily at night.
Breeding. Not well known. Breeds at any time of year, responding to rains. Probably monogamous. Solitary or in small, loose colonies of up to 6 pairs. Nests on bare stony or sandy ground; nest is shallow scrape or depression, unlined or lined with small stones, plant material and debris. 3 eggs, sometimes 2, laid at daily intervals; incubation 26-30 days, probably by both parents, but mainly female; when leaving nest, e.g. if disturbed, adult rapidly covers eggs with soil and debris; chick has pale pinkish buff to cream upperparts with brown blotches, underparts off-white to cream; young tended by both parents. Fledging period and age of independence unknown. Eggs and young sometimes taken by foxes.
Movements. Little known. Dispersive, perhaps moving S in spring and N in summer; appears to be nomadic in Victoria. Movements probably dependent on rains and drought, and may be initiated by drought inland; recorded appearing before or after rains, but also during drought, and departing after heavy rains.
Status and Conservation. Not globally threatened. Total population estimated at 14,000 birds. No information available on population trends or impact of changes to vegetation caused by grazing in pastoral areas. Extensive distribution within many areas of relatively limited human impact suggests species likely to be fairly secure.
Bibliography. Blakers *et al.* (1984), Bock (1964), Bryant (1940a), Christian *et al.* (1992a), Emison *et al.* (1987), Flegg & Madge (1995), Lane & Davies (1987), Lindsey (1992), Macdonald (1988), Maclean (1973, 1976b), Marchant & Higgins (1993), McNamara (1980), Pizzey & Doyle (1980), Pringle (1987), Schodde & Tidemann (1986), Simpson & Day (1994), Slater *et al.* (1989), Trounson (1987).

Genus *ANARHYNCHUS*



Quoy & Gaimard, 1830

64. **Wrybill**

Anarhynchus frontalis

French: Pluvier anarhynque **German**: Schiefschnabel **Spanish**: Chorlitejo Piquituerto
Other common names: Wry-billed Plover

Taxonomy. *Anarhynchus frontalis*, Quoy and Gaimard, 1830, Hauraki Gulf, North Island, New Zealand.
Genus very close to *Charadrius*, and perhaps not justifiably distinct; species has been linked particularly with *C. bicinctus*. Monotypic.
Distribution. New Zealand; breeds in C South I; winters in N North I.

Descriptive notes. 20-21 cm; 43-71 g. Rather plump, greyish plover with conspicuous long bill curved to the right; male has black frontal bar and breast band. Female has duller, browner and narrower breast band and lacks black frontal bar. Non-breeding adult has breast band lacking or faint; no frontal bar. Juvenile as non-breeding adult, but has grey patches at sides of breast instead of breast band; feathers of upperparts have narrow dark subterminal bands, and narrow white fringes.
Habitat. Breeds inland on large braided rivers, occupying large bare beds of shingle and sand, with preference for large, glacier-fed rivers, fast-flowing water and dynamic shingle banks, which will not easily become overgrown with weeds; occasionally in smaller, less braided, slower-running rivers. Outside breeding season found in shallow estuaries, on sheltered coasts with large tidal mudflats, and lagoons with soft silty or muddy substrate. Occasionally in ploughed paddocks, reclaimed salt-marsh or muddy margins of small mountain lakes and ponds.
Food and Feeding. During breeding season takes aquatic invertebrates, including flatworms, annelids, gastropods, mites, spiders, and eggs, larvae, pupae and adults of various types of insect; also fish and their eggs. Uses curved bill to probe and sweep under stones, especially for catching mayflies (see page 388). In non-breeding areas, polychaete worms, small bivalves, crustaceans, beetles and Diptera larvae. During breeding season feeds at shallow riffles, pools and backwaters, on shingle banks and, when rivers flood, also among washed up debris; at non-breeding grounds pecks, probes and scythes on soft mud of mudflats, often at edge of receding tide. Diurnally active; in winter, night or day, depending on tide. Highly gregarious during non-breeding season, frequently in hundreds or thousands, often feeding together with other small waders.
Breeding. Laying late Aug to late Oct, with second clutch late Oct to late Dec. Monogamous on long-term basis. Solitary; holds vigorously defended territory in which nests and feeds, but also feeds in undefended areas; nests 400 m or more apart, rarely as close as 40 m. Highly site-faithful and high degree of natal philopatry in juveniles, immatures and adults. Nest in sand among shingle of large, smooth, rounded stones (often 1-2 cm in diameter) commonly sheltered by large stone or piece of wood; shallow scrape lined with small pebbles. 2 eggs, laid at intervals usually of less than 48 hours; double-brooded, and may lay replacement clutch; incubation 30-36 days, by both parents, but more by female, starting once clutch complete; chick has pale, uniform, off-white to grey upperparts, with indistinct grey-black flecking, white underparts; tended by both parents; fledging 35-37 days; independent immediately after fledging. Breeds first at 2-3 years old. Hatching success 77%, fledging success 38%, i.e. 0·79 young/pair. 10% of laid eggs (47% of failed eggs) flooded, 1% of laid eggs (4%) predated. Average longevity 5·4 years; oldest recorded bird at least 12 years old.
Movements. Migratory. Moves from breeding grounds in C South I to mudflats of estuaries and harbours on N end of North I. Leaves rivers late Dec to early Feb; juveniles of first nest depart before parents finish second nest. Migrates via E coast of South I and W coast of North I, probably usually in single flight; juveniles arrive in winter quarters late Dec to early Jan, and most adults mid-Jan to Feb; highest numbers present on N coast May-Jul; adults show high degree of site fidelity to wintering and roosting sites. Most birds leave wintering sites in Aug; second-year non-breeders leave half way through breeding season and some, mainly first-year birds, spend summer in North I. Uses stopover sites on return migration, and arrives at river mouths late-Aug to Sept.
Status and Conservation. VULNERABLE. Hunted up to 1940; after hunting ceased, population increased, but stabilized by early 1960's, with c. 5000 birds. In 1994, total of 5111 birds counted. Now only breeds on 26 river beds E of Southern Alps, but only numerous on 10 of these. Nesting and roosting habitats, especially in lowlands, deteriorate through invasion of exotic weeds, such as broom (*Cytisus scoparius*) and whin or gorse (*Ulex europaeus*), caused by reduction of seasonal flushing of riverbeds as consequence of water abstraction. Further development, including hydro-electric schemes, threatens long-term survival of total population. Since floods are main causes of breeding failure, flood mitigation may have positive effects on breeding success; however, construction of dams also destroys nesting habitat, due to permanent flooding.

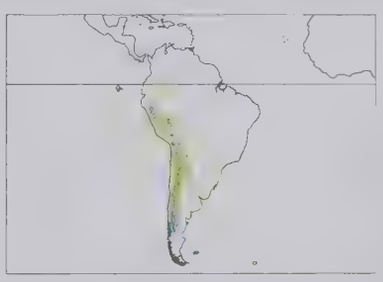
Genus *PHEGORNIS*



G. R. Gray, 1846

65. **Diademed Plover**

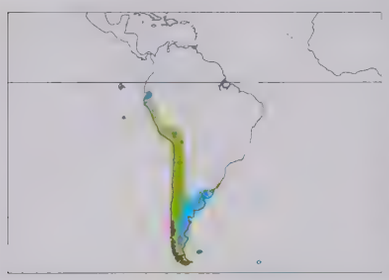
Phegornis mitchellii

French: Pluvier des Andes **German**: Diademregenpfeifer **Spanish**: Chorlitejo Cordillerano
Other common names: (Diademed) Sandpiper-plover, Mitchell's Plover

Taxonomy. *Leptopus (Leptodactylus) Mitchellii* Fraser, 1845, Chile, probably in the province of Colchagua.
Affinities obscure. Monotypic.
Distribution. Andes from NC Peru through N Chile and W Bolivia to SC Chile and SC Argentina.

Descriptive notes. 16·5-19 cm; 28-46 g. Very distinctive small, compact plover with long, thin, slightly dropping bill, recalling those of *Calidris*; black head with white supercilia meeting on forecrown; grey upperparts, dark chestnut hindneck collar; underparts white with fine black bars; short, rounded wings; short, undulating flight, as in some passerine birds. Sexes alike. No seasonal variation. Juvenile has grey head with obscure supercilia; dark brown upperparts with dark buff fringes, paler underparts with less clear barring.
Habitat. *Puna* zone, on waterlogged mossy tundra and bogs with matted cushion-plant vegetation, especially *Distichia* bogs; also gravel or grass on river plains and near lakes. Breeds at altitude of 4000-5000 m; in S, descends to 2000 m in winter.
Food and Feeding. No information available on diet. Feeds in hidden spots, in eroded holes and creeks in bogs. Probes vertically with bill, and also picks prey off aquatic plants. Alone or in pairs, rarely more together.
Breeding. Laying Oct-Dec in Chile, Jan in Bolivia. Breeds in *puna* zone of high Andes, nesting at low densities. No further information available.
Movements. In southernmost parts of range, birds from highest ground descend to lower altitudes in Mar, after breeding season, but remains at relatively high altitudes; return to breeding areas in Oct. Possibly limited northward migration up Andes in austral autumn, and southward movement in spring.
Status and Conservation. Not globally threatened. Currently considered near-threatened. Very poorly known. Population size unknown. Uncommonly recorded, but easily overlooked. Occupation of bleak zone at high altitude suggests species may be relatively secure, at least in parts of range, but paucity of data calls for caution; nowhere known to be common, and may be rare and local throughout.
Bibliography. Blake (1977), Canevari *et al.* (1991), Fjeldså & Krabbe (1990), Hellmayr & Conover (1948), Howell & Webb (1995a, 1995b), Johnson (1964a, 1965b, 1972), Koepcke (1970), Meyer de Schauensee (1966, 1982), Narosky & Yzurieta (1987), Olrog (1984), Parker *et al.* (1982), de la Peña (1992), Pierce (1990b), Remsen & Traylor (1989), Rosair (1995a), Scott & Carbonell (1986), Zusi & Jehl (1970).

Genus *OREOPHOLUS*



Jardine & Selby, 1835

66. **Tawny-throated Dotterel**

Oreopholus ruficollis

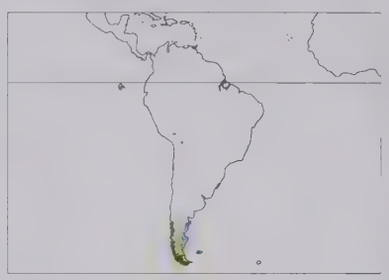
French: Pluvier oréophile **German**: Orangekehl-Regenpfeifer **Spanish**: Chorlito Cabezón
Other common names: Slender-billed Plover

Taxonomy. *Charadrius ruficollis* Wagler, 1829, Canelones, Uruguay.
Sometimes placed in genus *Eudromias*. Two subspecies recognized.
Subspecies and Distribution.
O. r. pallidus Carriker, 1935 - coastal N Peru.
O. r. ruficollis (Wagler, 1829) - coastal C Peru S through W Bolivia, Chile and W & NC Argentina to Tierra del Fuego; non-breeding N to S Ecuador and E to E Argentina and SE Brazil.

Descriptive notes. 25-29 cm; 120-154 g. Fairly upright plover with long, slender bill; striking plumage, mainly rich buff with heavily striped back, feathers with dark streaks and broad sandy to rufous fringes; chin white, throat orange-tawny, neck and breast grey; small, but prominent black patch on belly; legs dull pink;. in flight, underwing contrastingly white. Sexes alike. No seasonal variation. Juvenile has buff throat; feathers of upperparts have blackish centre and much narrower buff fringes; underparts paler and belly patch brown; legs grey. Race *pallidus* paler, and smaller than nominate.
Habitat. Mainly windy semi-arid ridges of open heathlands and overgrazed *puna* grassland up to 3500-4600 m, or sandy areas with sparse vegetation; seasonally on coastal plains and irrigated parts of the coastal desert in C Peru. On migration, also on fields and meadows in lowlands.
Food and Feeding. Very little known; one young bird had remains of beetles and grit in its stomach. Outside breeding season, often gathers in loose flocks of 10-30 birds, up to 100, for feeding; when disturbed, bird stands upright and turns striped back to observer, thereby presenting disruptive camouflage.
Breeding. Little known. Eggs Jun-Jan in race *pallidus*. Eggs apparently found generally Jun-Sept, but later towards S; two clutches Nov-Dec on island off NC Chile, where birds paired Sept-Nov; incubated nest found on Isla Grande, Tierra del Fuego, in Nov and a young bird in Dec. Race *pallidus* nests on sandy and nearly vegetation-free *lomas* zone near sea-level; one nest of nominate on top of clump of tussock grass, another surrounded by variegated pebbles arranged in concentric patterns. 4 eggs (4 nests); chick cinnamon, intricately patterned with black lines and zones of dense white "powder-puffs"; chicks of race *pallidus* very pale.
Movements. Poorly known; *pallidus* possibly resident in N Peru; nominate probably sedentary in parts of range, but migratory elsewhere. Birds breeding in high Andes migrate to lower altitudes after breeding season; those from southernmost areas mostly migrate N in Mar-Apr to Ecuador, and SE Brazil, Uruguay and E Argentina, returning late Aug to Sept. Absent from islands off NC Chile and adjacent mainland Feb-May.
Status and Conservation. Not globally threatened. No estimates of population, but species considered to be generally common in most parts of extensive range. Hunting in Chile and Argentina during autumn migration has apparently resulted in marked decreases, although no figures available.
Bibliography. Belton (1984), Blake (1977), Canevari *et al.* (1991), Clark (1986), Fjeldså & Krabbe (1990), Forrester (1993), Hellmayr & Conover (1948), Humphrey *et al.* (1970), Johnson (1965b), Klimaitis & Moschione (1987), Koepcke (1970), Meyer de Schauensee (1966, 1982), Myers (1980c), Narosky & Yzurieta (1987), Olrog (1984), Parker *et al.* (1982), de la Peña (1992), Remsen & Traylor (1989), Ruschi (1979), Scott & Carbonell (1986), Sick (1985c, 1993), Vilina & Teillier (1990).

Subfamily PLUVIANELLINAE

Genus *PLUVIANELLUS*



G. R. Gray, 1846

67. **Magellanic Plover**

Pluvianellus socialis

French: Pluvianelle magellanique **German**: Magellanregenpfeifer **Spanish**: Chorlito de Magallanes

Taxonomy. *Pluvianellus socialis* G. R. Gray, 1846, Straits of Magellan.
Relationships unclear and somewhat controversial: shows several unique features, and sometimes considered to form separate monospecific family, Pluvianellidae (see page 386); possibly related to sheathbills (Chionidae). Monotypic.
Distribution. Extreme S Chile and S Argentina. Winters N to Valdés Peninsula, SC Argentina.

Descriptive notes. 19·5-21·5 cm; male 79-102 g, female 70-87 g. Pale grey turnstone-like wader, with very short legs; soft grey upperparts and breast; lower breast with brown tinge; rest of underparts, throat and chin white; bill has pinkish patches at base of culmen and lower mandible, usually indistinct; pinkish red iris and legs. Sexes alike. No seasonal variation. Juvenile has upperparts spotted and fringed with white and buffish white; breast streaked; legs yellow, iris orange-grey.
Habitat. During breeding season, occurs in highlands, at open shores of freshwater or brackish lakes andalso at shallow pools in steppe-like regions. Outside breeding season, found on coast, mostly in sheltered bays, lagoons and river mouths.
Food and Feeding. During breeding season takes tiny arthropods; chironomid larvae apparently form staple food in winter. Pecks food from surface, turns over stones, shells and debris to find food, and may occasionally scratch or dig into sand for food using powerful legs, behaviour unique among waders; very active and fast-running. Outside breeding season, forages in small flocks.
Breeding. Laying probably early Sept to mid-Nov. Solitary, with strongly defended territories; additional feeding territory defended, sometimes well away from nest. Nests on wide clay or pebble shores of clear or clayey lakes with unstable water levels; nest is exposed scrape lined with gravel, situated very close to water. 2 eggs; incubated by both parents, period unknown; chick finely mottled ochraceous and dusky with some white down tips; newly-hatched chicks very weak, and fed by parents, apparently sometimes by their regurgitating food from their well developed crop, unique among waders (see page 388); fledging 28-30 days; young may be fed for 10 days more. The weaker chick, usually the second-hatched one, normally dies due to starvation.
Movements. Resident, dispersive and migratory. After breeding season, birds move to coast and some move relatively short distance N to Valdés Peninsula, SC Argentina. Small numbers may remain in wintering areas during breeding season. Generally arrives on breeding grounds by late Aug to early Sept.
Status and Conservation. Not globally threatened. Currently considered near-threatened. Total population may not exceed 1500 birds; estimate from 1990 suggests no more than 1000 birds in lowlands, where main breeding grounds in region of Straits of Magellan, with few birds in N & E Tierra del Fuego; a few hundred birds at 700-1200 m up to upland plateaux in inland Santa Cruz, S Argentina.
Bibliography. Blake (1977), Canevari *et al.* (1991), Clark (1986), Cracraft (1981), Fjeldså & Krabbe (1990), Hellmayr & Conover (1948), Humphrey *et al.* (1970), Jehl (1975a, 1975b), Johnson (1965b), Meyer de Schauensee (1966, 1982), Narosky & Yzurieta (1987), Narosky *et al.* (1993), Olrog (1984), de la Peña (1992), Pierce (1990a), Scott & Carbonell (1986).

Class AVES

Order CHARADRIIFORMES

Suborder CHARADRII

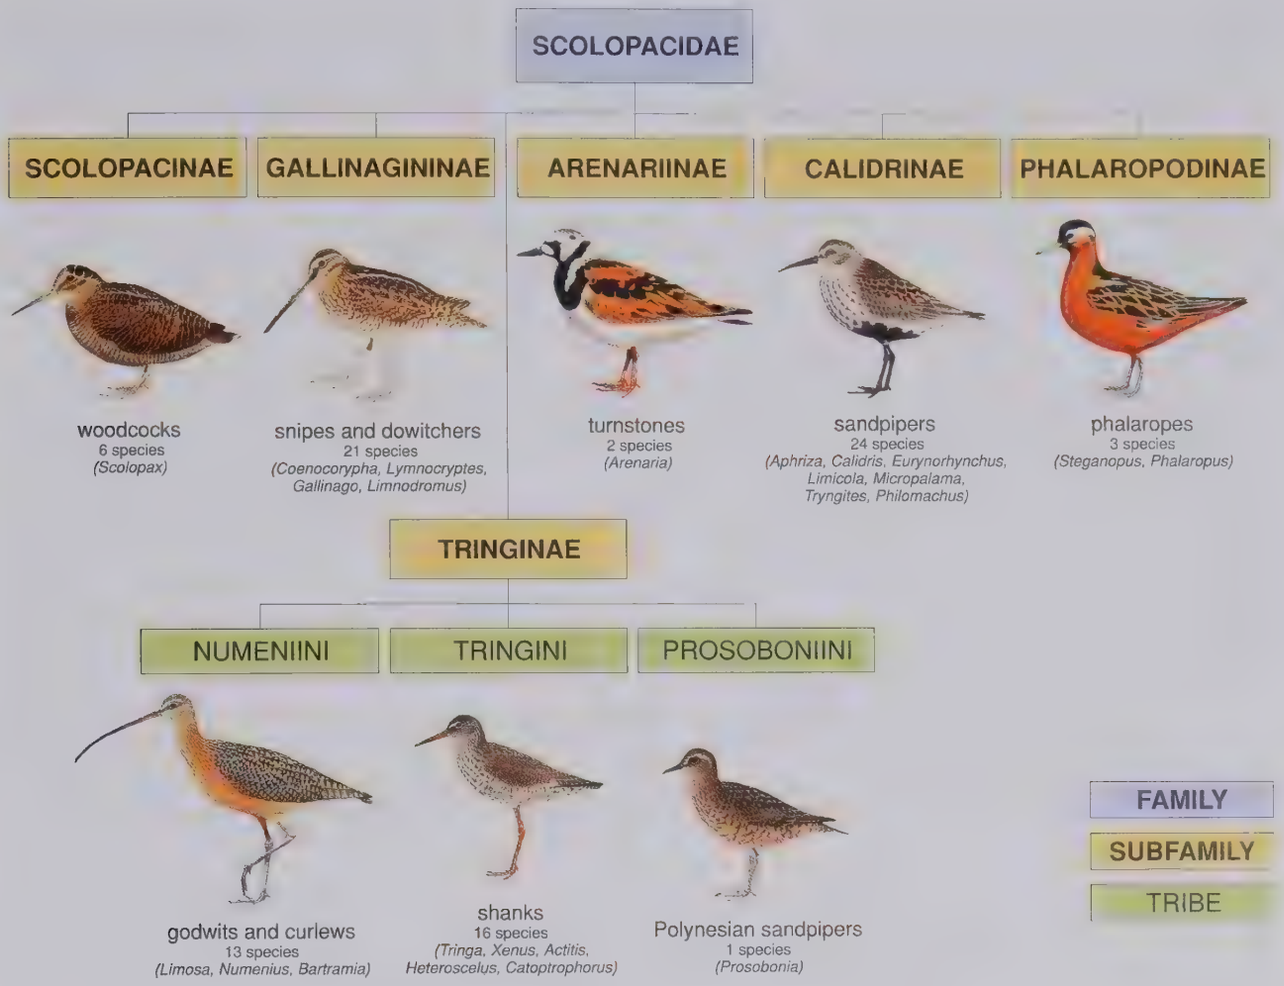
Family SCOLOPACIDAE (SNIPES, SANDPIPERS AND PHALAROPES)

- Small to medium-sized waders with short to long legs; bill often long and may be straight, decurved or slightly recurved.
- 12-66 cm.

- All regions except Antarctic; most species breed in Northern Hemisphere and are highly migratory.
- Mainly coastal and on inland wetlands; breeds in open steppe, grassland, marsh, tundra, scrubland and even forest.
- 24 genera, 86 species, 134 taxa.
- 10 species threatened; 2 species and 1 subspecies extinct since 1600.

Systematics

The snipes, sandpipers and phalaropes of the Scolopacidae comprise a highly diverse family of birds that apparently arose in the early Tertiary, probably in the late Eocene, 40 million years ago. Their exact relationship with the plover family (Charadriidae) is still disputed, with most recent authors arguing that the two families are not sister groups, as has often been assumed in the past. Despite the great morphological and behavioural diversity within the Scolopacidae, modern morphological and biochemical evidence strongly suggests that the traditionally recognized members of this family do indeed derive from a common ancestor. This ancestor may also have given rise to the jacanas (Jacanidae) and the painted-snipes (Rostratulidae), according to the osteological studies of J. G. Strauch and the follow-up reanalyses of P. C. Chu and M. Björklund. Jacanas and painted-snipes may thus be derived sandpipers. This view is not corroborated by the DNA-DNA hybridization studies of C. G. Sibley and J. E. Ahlquist, which suggest that the jacanas along with the painted-snipes in one lineage, and the seedsnipes (Thinocoridae) in another, are the two most closely related outgroups to a monophyletic scolopacid family.



Snipes, sandpipers and phalaropes appear to be the result of an extraordinarily explosive evolution in the early Tertiary, after a great wave of extinctions at the end of the Cretaceous. This radiation is likely to have taken place in the late Eocene. From this period some fossil material of scolopacid waders is available, possibly representing the genera *Limosa* (godwits) and *Tringa* (shanks). If the Scolopacidae have diversified over a relatively short time period, there was little time between speciation events for neutral genetic changes to build up. For this reason it may be difficult or impossible, even with advanced molecular genetic techniques, to establish with any certainty the pattern of internal relationships within the family. However, using these same techniques, T. P. Birt and A. J. Baker have concluded that morphologically and behaviourally outlying taxa such as woodcocks (*Scolopax*), turnstones (*Arenaria*) and phalaropes (*Phalaropus*, *Steganopus*) appear to be unambiguously nested within the Scolopacidae. The phalaropes have frequently been placed in a separate family of their own.

The family Scolopacidae can usefully be divided into six subfamilies, with the recognition of Scolopacinae (woodcocks), Gallinagininae (snipes), Tringinae (shanks and allies), Arenariinae (turnstones), Calidrinae (sandpipers) and Phalaropodinae (phalaropes); in turn, Tringinae is usually further subdivided into three tribes, Numeniini (godwits and curlews), Tringini (shanks) and Prosoboniini (Polynesian sandpipers). Four of these subfamilies, Scolopacinae, Arenariinae, Calidrinae and Phalaropodinae, are almost certainly monophyletic. Apart from a possible merger of woodcocks and snipes into a single subfamily of snipe-like species (Gallinagininae), which would appear to be defensible on the basis of the latest biochemical evidence, the exact position of the three dowitchers (*Limnodromus*) remains unresolved. Most previous authors have listed them with the snipes, but others have placed them with the tringine sandpipers; there is something to be said for both views, but further study is unquestionably required. Tringinae is, in any case,

A notable difference between the Scolopacidae and the Charadriidae is that almost all members of the former have a hind toe, which enables them to perch in trees. Some members of the Tringinae will even nest in trees, in the wooded marshy habitats of the northern taiga belt, where they may make use of old thrush nests. Breeding tringines are very secretive, and finding their nests can be a major challenge; it is far easier to locate a vigilant breeder perched in the top of a conifer, like this Spotted Redshank.

[*Tringa erythropus*. Photo: Gordon Langsbury/ Bruce Coleman]

Subdivision of the Scolopacidae.

[Figure: Francesc Jutglar & Etel Vilaró]

most likely to be a polyphyletic assemblage. Recent work suggests that the "shank" genera *Tringa*, *Xenus*, *Heteroscelus*, *Actitis* and *Catoptrophorus* may be closely related to the phalaropes, and that this lineage may be a sister group to the woodcocks and snipes. The godwits (*Limosa*) and the curlews (*Numenius*, *Bartramia*) appear to be two independent taxa, quite unrelated to the rest of the Tringinae, possibly branching off at the base of the scolopacid family. The position of the Tuamotu Sandpiper (*Prosobonia cancellata*) and its two extinct relatives (see Status and Conservation) remains uncertain, particularly in view of a lack of modern phylogenetic studies. On the basis of the morphological studies by R. L. Zusi and J. R. Jehl, which suggested a closer relationship with the Tringini than with the curlews or calidrine sandpipers, *Prosobonia* is positioned as a separate tribe among the Tringinae.

Within the lineage of phalaropes, Wilson's Phalarope (*Steganopus tricolor*) appears to be the sister taxon to the closely related species pair of the Red-necked (*Phalaropus lobatus*) and Red Phalaropes (*Phalaropus fulicaria*). Within the Calidrinae, there is little doubt that the morphologically and behaviourally exceptional genera *Aphriza*, *Eurynorhynchus*, *Limicola*, *Micropalama*, *Tryngites* and *Philomachus* are all closely related to the "true" sandpipers of *Calidris*. In fact, some of these genera may be more closely related to many of the *Calidris* species, than some members of *Calidris* are to each other. If this suggestion were correct, *Calidris* would not be considered a monophyletic genus. For example, the Curlew Sandpiper (*Calidris ferruginea*), on the one hand, and the Great Knot (*Calidris tenuirostris*) and the Red Knot (*Calidris canutus*), on the other, may each provide lineages quite separate from the other calidrines. Modern molecular genetic studies have supported the suggestion of J. R. Jehl, based on morphological and natural history arguments, that the Surfbird (*Aphriza virgata*) is very closely related to the knots. It is retained in a monotypic genus because of its bill, which in contrast to all other calidrines is not rhynchokinetic, meaning that a Surfbird is unable to bend the lower portion of its upper mandible. For the same reason, the Spoon-billed Sandpiper (*Eurynorhynchus pygmeus*) with a unique spoon-like bill, has a separate genus of its own despite a close overall resemblance to the Red-necked Stint (*Calidris ruficollis*). The systematics of sandpipers is ripe for a thorough revision, including the application of the latest biochemical and theoretical techniques.

The Long-billed (*Limnodromus scolopaceus*) and Short-billed Dowitchers (*Limnodromus griseus*) were considered conspecific until F. A. Pitelka showed in 1950 how different they actually are. Apart from differences in morphology and vocalizations, their habitat choices in the non-breeding season are very distinctive. Long-billed Dowitchers mainly use freshwater habitats, whereas Short-billed Dowitchers are confined to coastal, saltwater areas, a type of habitat that they have in common with Asian Dowitchers (*Limnodromus semipalmatus*). In spite of their close resemblance, the divergence of the mitochondrial DNA of the Long-billed and Short-billed Dowitchers is greater than that of many other avian species pairs. On the basis of widely used rates of hereditary change, or molecular clocks, J. C. Avise and R. M. Zink arrive at a crude estimate of the time since separation of 4 million years. This estimate can be compared with a figure of 4-6 million years for the separation of the lineage of Red Knots from the other calidrines estimated by A. J. Baker. These two estimates of the age of present day species can be contrasted with the supposed time of the original diversification of the Scolopacidae in the early Tertiary, almost 10 times as long ago. It would be exciting to use comprehensive information on molecular genetic divergence and calibrated molecular clocks to estimate periods of stasis and radiation in this fascinating and diverse family of birds.

In spite of the fact that most scolopacid waders nowadays breed in boreal to Arctic environments, the family seems to have evolved in the early Tertiary, when the world's climate was warm. The first cold period occurred about 10 million years ago, and

As a rule, shorebirds do not swim, but wade. The three phalarope species provide the exception to this rule, as this Red-necked Phalarope demonstrates. With their thick duck-like downy plumage they are able to remain on the water without becoming waterlogged. With their lobed toes and basally webbed feet, phalaropes are able to move rapidly on the water, twisting and turning. They feed on small planktonic prey items that occur near the water surface. These can be transported to the mouth in water droplets which move upwards between the lower and upper mandibles at great speed, due to capillary force.

[*Phalaropus lobatus*, Great Basin Desert, California, USA. Photo: Barbara Gerlach/ DRK]

from then onwards the region of cold moved south. By the end of the Pliocene, only 1·5 million years ago, the climate became similar to that of today, with polar ice caps and a circumpolar belt of tundra. Subsequently, during the Pleistocene epoch, there was an alternation of ice ages and interglacial periods, the first ice age reaching a peak about 500,000 years ago and the last about 18,000 years ago. With southward and northward invasions and retreats of the ice sheets, all the wader habitats continuously shifted dramatically in both geographical position and extent. Several authors, including S. Larson and W. G. Hale, have speculated on the role that these climate changes, through their effects on the distribution of suitable habitats, may have played in the evolution of species and subspecies of scolopacid waders, but these early attempts were strongly constrained by the absence of assays of genetic population structure and estimates of divergence times.

Until a few years ago, the only way to examine the genetic, subspecific, population structure of extant species was by the study, on the basis of museum material, of morphological characters, usually the size of external dimensions such as bill or wing length or the details of moult and plumage coloration. For example, in Rock Sandpipers (*Calidris ptilocnemis*), confined to the Bering Strait region during breeding, four subspecies were described in this way. In contrast, the closely related Purple Sandpiper (*Calidris maritima*) of the North American and European Arctic regions did not appear to show much substructuring, a finding that has now been backed up by allozyme studies. Reasonable congruence between classic museum studies and modern molecular genetic assays was also obtained by P. W. Wenink and associates for the population genetic structuring of the world's Dunlins (*Calidris alpina*). Of the six examined subspecies, five could be retraced in data of mitochondrial DNA variation. Time estimates of the origin of these groups based on sequence divergences suggest that there was repeated fragmentation of Dunlin populations during the late Pleistocene, from about 200,000 years ago onwards. The extant subspecies of Dunlins seem to originate from these old climatic events, a scenario that is quite different from that of the origin of five morphologically distinguished subspecies of Red Knots. Using the same methodology, these races are estimated to be in the order of 10,000 years old. If this were true, the present day world distribution and migration routes of Red Knots evolved from a small bottleneck population that survived during the retreat of the last great northern ice caps.

Recently there have been heated debates about the taxonomic status of a few aberrant *Calidris* individuals that were irregularly observed in Australia, and occasionally elsewhere. These birds, named Cox's Sandpiper ("*Calidris paramelanotos*") and Cooper's Sandpiper ("*Calidris cooperi*") by those that believed them to be distinct species, are now considered hybrids between the Curlew Sandpiper on the one hand, and respectively the Pectoral (*Calidris melanotos*) and Sharp-tailed Sandpipers (*Calidris acuminata*) on the other. In the case of a Cox's Sandpiper, molecular genetic analyses showed that the mitochondrial DNA was identical with that of Curlew Sandpipers. Since mitochondrial DNA is maternally inherited, the mother must have been a Curlew Sandpiper that most probably mated with a Pectoral Sandpiper male. Outside Australia, putative hybrids between other *Calidris* pairs have been reported: Curlew Sandpiper with White-rumped Sandpiper (*Calidris fuscicollis*); Dunlin with Sanderling (*Calidris alba*); Dunlin with Purple Sandpiper; Baird's Sandpiper (*Calidris bairdii*) with Buff-breasted Sandpiper (*Tryngites subruficollis*); and Little Stint (*Calidris minuta*) with Temminck's Stint (*Calidris temminckii*).

Considering the size and internal diversity of the family, there is relatively little disagreement as to which forms should be treated as species; this is clearly connected with the notable fact that of the total of 86 species as many as 64 are considered monotypic. The main area of doubt at the species level lies in the snipe genus *Gallinago*, which contains some of the least known of all scolopacids. Similarly, generic limits are almost universally agreed upon, although a few authors recognize slightly broader versions of the genera *Tringa* and *Calidris*. For many years the typical snipes were classified in the genus *Capella*, as opposed to *Gallinago*, but rather than a taxonomic issue this change reflects one of nomenclature: *Capella* Frenzel 1801 pre-dated *Gallinago* Koch 1816; however, the name *Gallinago* is actually attributable to Brisson 1760, and thus has priority.

The number of species recognized may be on the point of increasing! Until recently, the only species of woodcock known from the Philippines was the temperate breeding Eurasian Wood-

Compared with members of the plover family, the typical scolopacid wader is noted for its smaller eyes, more slender head, and longer, thinner bill. The bill tends to contain a very high density of tactile receptors towards the tip, these being closely linked with the more tactile, less visual, foraging style of the Scolopacidae. Body shape, size and general design are rather more varied in this family, and its members occupy a greater range of ecological niches than the Charadriidae, while it is also diverse in terms of reproductive systems. The sandpiper group, including all species but the snipes and woodcocks and the phalaropes, is a particularly varied assemblage. It contains small to large birds with legs ranging from medium length to very long. There is notable diversity in the bill, which ranges from short to extremely long and narrow, and may be slightly recurved or markedly decurved. This graceful Marsh Sandpiper shows the typical long legs after which the "shanks" are named, and the long, straight bill, characteristically needle-thin in this most attractive species.

[*Tringa stagnatilis*, Al Ansab Lagoons, Oman. Photo: Hanne & Jens Eriksen/Aquila]

Although most of these Common Redshanks roosting at high tide have their eyes covered with the white nictitating membrane, a few are keeping a watchful eye on their environment. They have good reason to do so, since many are taken by raptors during the non-breeding season. Juvenile and adult birds appear to make different habitat choices with regard to predation risk. Young Common Redshanks, outcompeted from musselbeds by adults, feed in high-risk areas of salt-marsh, where the food supply is, however, better. Only 10% of them survives the raptor predation throughout the winter.

[*Tringa totanus*, Little Eye Dee estuary, Britain. Photo: Alan Hartley/ Oxford Scientific Films]

cock (*Scolopax rusticola*), which turns up as a rare winter visitor in the north. However, on the southern island of Mindanao birds have recently been observed performing regular roding display flights, sure proof of breeding on the island. R. S. Kennedy is currently in the process of comparing specimens and vocalizations with the available material for the nearest populations of Eurasian Woodcocks in Japan, and also for the Sulawesi Woodcock (*Scolopax celebensis*). At the time of going to press the outcome is still uncertain, but it appears quite likely that this form will be described as a species new to science.

Morphological Aspects

The Scolopacidae are small to medium-sized birds. On dry land they can walk and run and on water they can swim, but many species are at their best when wading in shallow water. Compared to plovers (Charadriidae), they have smaller eyes and more slender heads. With their longer, thinner bills they are geared to a more tactile, less visual, foraging style than plovers. Their bill tips contain particularly high densities of tactile receptors. The Scolopacidae show a much greater variety of body forms and occupy a greater range of ecological niches than the Charadriidae. Three eco-morphological groups can roughly be distinguished: the snipe, sandpiper and phalarope groups.

The snipe group contains small to medium-sized birds with long legs and very long bills. These long bills have been the origin of vernacular names in many languages. For example, the English name "snipe" is derived from "snite" or "snout", later transformed into "snipe". All snipes, and the closely related woodcocks, are earthy brown with longitudinal brown or buffy stripes, which provides excellent camouflage in the bogs, marshes and forests where they live. The sandpiper group, containing all species except the snipes and their allies and the phalaropes, are small to large birds characterized by medium to very long legs and short to very long and narrow bills which may be slightly upcurved or prominently downcurved. All species show countershading, with darker browns and greys above and paler underparts; some species show rufous or black underparts during the breeding season. The third group, the pelagic-living phalaropes, are small, roundish but elegant birds with relatively heavy duck-like plumages of the same general coloration as in the sandpipers, and with medium-length, narrow bills. Their legs are rather short, the tarsi laterally compressed, and the feet show small webs between "scalloped" toes. These coot-like feet with lobed toes have given them their name: the word *Phalaropus* is derived from the Greek words for "coot", *phalaris*, and "foot", *pous*. The Semipalmated (*Calidris pusilla*), Western (*Calidris mauri*) and Stilt Sandpipers (*Micropalama himantopus*), the Willet (*Catoptrophorus semipalmatus*), Nordmann's Greenshank (*Tringa guttifer*) and the Terek Sandpiper (*Xenus cinereus*), the dowitchers and the godwits all have partly webbed feet too, and the *Tringa* species have a small web between the outer toes, but the remaining scolopacid waders show no webs. Nearly all Scolopacidae have three long front toes and a small hind toe. As an adaptation to running on sandy beaches, which are firmer than most other substrates, Sanderlings differ from all other scolopacids in that they lack the hind toe.

Scolopacid waders show their greatest variability in the relative length and shape of their bills. Bill length relative to head length varies by a factor of seven, from more than 3 in the Far Eastern (*Numenius madagascariensis*) and Long-billed Curlews (*Numenius americanus*) to 0·45 in the Tuamotu Sandpiper, and bills may be straight, slightly upcurved or downcurved. With the Surfbird and the turnstones as clear exceptions, the tip of the bill of most scolopacids is slightly swollen and its horny sheath is internally honeycombed with hexagonal cells. These cavities are filled with tiny receptor organs, including Herbst's Corpuscles that measure pressure and Grandry's Corpuscles that measure shear, to which sensory fibres are attached. In addition, the brains of the Scolopacidae show an expansion of the frontal and brainstem area that is absent in the Charadriidae. This expansion is innervated by the receptor-rich bill tip. The neural modifications and enlargements make scolopacid waders very effective in the tactile detection of buried prey.

The great variation in bill types is not only interesting but also instructive, since the diversification in bill morphology goes hand in hand with the diversification of food resources and habitats used. Although a single species may show more than one feeding style, indicating the flexibility and scope for behavioural and morphological evolution, four general feeding styles can be distinguished; the first is pecking with occasional probing, mostly

As soon as food becomes a defensible resource and flock-feeding unnecessary, individual waders are liable to establish feeding territories. This tends to be the case particularly when the birds are foraging by means of visual techniques. These two non-breeding Black-tailed Godwits are involved in a "mandibular clash" over a profitable piece of wetland.

[*Limosa limosa*, India. Photo: David Hosking/ FLPA]

used by species that live in rather dry inland habitats and along fringe habitats, such as water-lines, including the genera *Bartramia*, *Actitis*, *Heteroscelus*, *Catoptrophorus*, some *Tringa*, *Arenaria* and probably *Prosobonia*; the second is probing of soft soils and intertidal flats, the common mode shown by all snipes and woodcocks and the majority of the sandpiper group; the third is running with the bill submerged chasing fish, a mode used by *Tringa*; and the fourth, rapid pecking of tiny prey from a water layer, is practised by the phalaropes and some *Calidris*. The motor arrangements of the skulls of scolopacid waders are sophisticated and include the capability of bending to bend the lower part of the upper mandible without opening the entire bill. This is called rhynchokinesis and allows a fine manipulation of the bill tip during deep probes and thus the capture of buried prey.

Once captured in the bill tip, prey items must be transported to the mouth. There are three possible ways to do so. Prey can be "glued" to the tongue and carried upward, as in most relatively short-billed sandpipers. In the longer-billed scolopacids, prey must be more extensively manipulated: capture is followed by throw and fetch movements that bring the prey higher in the bill until "glue" and tongue-carrying can take over to complete the movement towards the mouth. This method is used by species that have tongues shorter than their bills. Third, the feeding on tiny drifting invertebrate prey brings its own problems and solutions. Because water is incompressible, the movement of a bill tip through the water layer will displace water and with it the tiny prey items that a wader may have visually detected and aims to capture. Phalaropes, and probably many calidrine sandpipers too, have been shown by M. Rubega and B. S. Obst to solve this problem by "capturing" a small quantity of water that contains the tiny prey. Capillary forces then move the water droplet mouthwards between the mandibles as these are slightly opened. Transport is very rapid, sometimes taking as little as 1/100 second to complete. When the water droplet with the prey reaches the mouth, the jaws are abruptly closed so that the water is squeezed out and can be shaken off the bill. In this way the ingestion of osmotically stressful salt water is avoided.

It may seem impossible to bring such a great variety of scolopacid species under a common heading with regard to bill and skull morphology and feeding habits. However, their seemingly extravagant morphological and behavioural variability illustrates a wide and rapid radiation that may well originate from a single basic design. According to the research by G. A. Zweers and co-workers, the whole trophic diversification, the whole range of current feeding mechanisms of the Scolopacidae, can be considered to represent varying degrees of specialization derived from a single common pecking mechanism originally displayed by a short-billed plover-like shorebird. This pecking mechanism has been modified to the different pecking, probing and prey-transport styles of snipes, sandpipers and phalaropes, changes that came along with morphological adjustments to maximize particular ways of penetration, detection, inspection and handling of prey items. This includes the evolution of sensory organs and brain capacity to detect buried cryptic prey items by remote-touch mechanisms. A common form of feeding behaviour, that of making pecks and shallow probes, is still shown by all members of the Scolopacidae, no matter their morphological and behavioural specializations. This is likely to be an only slightly modified version of that original pecking mechanism.

The decurved bills of curlews and Curlew Sandpipers and the slightly upcurved bills of godwits and Terek Sandpipers have generated considerable speculation and dispute in ornithological literature. A straight bill is more suitable mechanically for rapid thrusting in the substrate. This shape has the lightest construction, avoids local concentration of mechanical stress and requires minimal effort during penetration. When probing into small openings, in complex burrow systems, between stones or amongst branches, a decurved bill allows the bird to reach more of the space behind the entrance than a straight bill. A decurved bill is also advantageous for the intact removal of long and soft-bodied prey from mudflats, yields a larger touch-area when moved around in soft substrates and provides a better initial positioning to grasp a prey item from a surface. However, curvature weakens the construction, and decurved bills require structural reinforcements. These bony structures take up most of the bill cavity and require a great reduction in the size of the tongue. As a consequence, curlews must remove prey from the substrate before they can swallow it. It must be transported to the mouth by head-jerking and a co-ordinated opening and shutting of the mandibles. In contrast, snipes and woodcocks with long straight bills have an open bill cavity and a long tongue. By a combination of a rapid series of retractions of the rhynchokinetic upper jaw tip

Large mixed flocks are typical of the Scolopacidae, especially during migration and in winter. At all times of the year, but especially during migration, food supplies tend to be of paramount importance, and huge numbers of waders will gather at particularly high quality refuelling sites. These splendid Red Knots were photographed at one such site in Delaware Bay, USA, in the company of Ruddy Turnstones (Arenaria interpres) *and Sanderlings* (Calidris alba).

[*Calidris canutus rufa*, Reed's Beach, New Jersey, USA. Photo: Joe McDonald/ Animals Animals]

and by tongue action, they are able to transport prey inside the bill while it is still inserted in the substrate. Godwits show a certain degree of bill reinforcement and tongue reduction, and are only in some circumstances able to ingest prey without taking the bill from the substrate. In summary, shorebird species that predominantly forage by probing in small holes and crevices have the most curved bills, whereas species that probe in the firmest substrates will have relatively straight bills.

This is not, however, the whole story. There are scolopacid waders with bills that are out of the normal range by virtue of other characteristics than length or curvature, for example the turnstones. Superficially, their stout bills resemble those of plovers, and for this reason turnstones were in the past assigned to the Charadriidae. The turnstone bill is tough, deep at the base and strongly tapering. With this wedge-like instrument the birds can search for invertebrate prey by probing under, and then overturning, quite heavy stones and pieces of seaweed. This turning behaviour has also lead to an exceptionally strong neck musculature. Spoon-billed Sandpipers, small calidrine waders with plumage and external and internal morphology strongly reminiscent of Red-necked Stints, carry spatulate bills much like those of spoonbills (*Platalea*). The spoon-like expansion of the bill tip has enormously increased the number of Herbst's Corpuscles and also the size of the tactile surface applied to the sediment. This should greatly enhance the tactile detection of the tiny prey that Spoon-billed Sandpipers are known to feed on, and perhaps aid their capture. The spatulate bill may be most effective when the bird makes rapid sideways sweeps through the upper layer of the preferred soft sediments and shallow water with the mandibles slightly apart, just as in feeding spoonbills. The Broad-billed Sandpiper (*Limicola falcinellus*) has a bill that is broad over much of its length and is also packed with tactile receptor organs at the tip; it is used for sustained vertical probing rather than for pecking, and may be especially suited for the efficient capture and ingestion of quite large buried polychaete worms in soft sediments.

That visual prey detection is less important for most scolopacid waders than it is for plovers is reflected by other aspects of their respective morphologies as well. Not only are the eyes of scolopacid waders smaller than those of plovers, but the retinal density of rods (useful for detection under poor light conditions) is lower, and that of cones (for visual acuity in daylight and for colour discrimination) is relatively higher. In snipes and woodcocks the eyes are placed laterally and so high in the skull that the brain case is positioned below, rather than behind, the eyes. There is almost no skull structure in front or behind the eyes, and, as a consequence, the ear openings are placed directly below the eyes. This arrangement gives the snipes comprehensive visual coverage of the hemisphere above them and total panoramic vision in a near horizontal plane, as shown in a detailed study of Eurasian Woodcocks by G. R. Martin. There is no blind area behind the head except at or below the horizontal. This panoramic vision is achieved at the expense of binocular depth vision, since the binocular field is only 12° at its widest, upwards from the head and perpendicular to the line of the bill. The binocular field is only 4° wide horizontally in the forward plane. That the bill tip falls just outside the visual field is no problem for birds that find their prey entirely by tactile and chemical cues. Like most other waders, snipes and woodcocks feed, roost and nest exclusively on the ground so that they are always vulnerable to both aerial and terrestrial predators. Freed from the constraint that vision is essential for prey location, their visual field appears primarily adapted for efficient and effective surveillance.

The guts of scolopacid waders are all quite uniform in relative size and shape. Moving towards the tail end of the bird, the oesophagus is followed by the glandular stomach or proventriculus, the "muscular stomach" or gizzard, the small intestine, and the large intestine. A pair of small caeca, possibly fulfilling a role in the bacterial digestion of fibrous material, can be found attached to the large intestine. Compared to the plovers of similar size and diet, the length of the intestine and the caeca is shorter. The glandular stomach of most scolopacid waders is also small, and can not contain much stored food. The gizzard shows quite large variations in relative size between species, much of which can be explained by the way in which it is used. Species that feed mainly on hard-shelled mollusc prey, such as Purple Sandpipers, Red and Great Knots and Surfbirds, have large muscular stomachs. These species ingest their prey whole and must crack and crush the food items before digestion in the intestine. In these species undigested shell fragments are discarded, compacted as firm and calcium-rich droppings, via the intestines. A closely related sandpiper species like the Dunlin feeds only infrequently on small bivalves, and ejects almost all shell fragments as regurgitated pellets. Pellets are routinely produced by many other species of Scolopacidae as well, especially when they feed on chitin-rich arthropods such as insects and crustaceans. A phenomenon that has received scant attention in the literature is the fact that several scolopacid waders eject the lining of their gizzards at particular times of the year. These linings, small yellowish bags, have been found in great numbers on roost-sites of northward migrating Whimbrels (*Numenius phaeopus*). In dissected shorebirds of a wide variety of species, linings are regu-

larly separate from the muscular stomach wall. Such "moults" of the gizzard may prevent the build-up of stomach parasites.

Although mollusc-eating waders have relatively large gizzards, the size is not constant within a species or even within an individual bird. The gizzard varies depending on the work requirement, in other words the type and volume of food ingested. When eating soft arthropods that require no crushing, on Arctic tundra during the breeding season for example, gizzards of Red and Great Knots are greatly reduced in size. This flexibility is also paramount in other parts of a shorebird. For example, during fat storage in preparation for long distance flights, the size of the different organs involved in the digestion, absorption and internal transport of nutrients, namely the stomach, intestine, liver and kidneys, is temporarily increased considerably. Before take-off for the migratory journey these organs may again be broken down so that part of the released nutritional components can be used for a rapid build up over the last few days of the critical parts of a flight machine, the breast muscles and the heart.

In male waders on their way to the breeding grounds, the reproductive glands, the testes, have already increased in size at stopover areas. In contrast, the equivalent organs of females, the ovaries, usually begin full development after arrival on the breeding grounds, but then they become much heavier than the testes. Among calidrine sandpipers, monogamous species have a smaller testis size than non-monogamous species. Polygamous male sandpipers may be selected to mate with as many different females as possible, and this leads to sperm competition between males. A higher demand for sperm, a greater "work-load", will then select for larger organs, larger testicles, just as it does for any part of the shorebird body. The Ruff (*Philomachus pugnax*) in breeding condition has the biggest testes of all scolopacid waders, which contribute almost 5% to their body mass and thus weigh much more than their brains. The Scolopacidae differ from other shorebird families in their sperm. Whereas in the rest of the charadriiforms sperm cells are simple straight rods with tails, those of scolopacid waders are spiral in form. J. G. van Rhijn has suggested that this may also relate to sperm competition, with spiral sperm cells having higher motility and thus an edge over simpler forms during the race to reach the unfertilized egg first.

Particularly flexible little organs are the pair of salt glands, carried on the upper part of the head between the eyes. Salt glands excrete excess salt directly from the blood plasma as a concentrated saline fluid into the nasal cavity, from where it is discarded by fast sideways bill sweeps. Snipes and woodcocks, which occur almost exclusively in freshwater habitats, have no salt glands. The salt glands of sandpipers frequenting freshwater habitats are tiny. Scolopacids that live along the seashore generally show large salt glands, and the largest are found in bivalve-eating sandpipers that ingest their prey whole, such as Red Knots. These sandpipers can not avoid ingesting salt water since bivalve flesh is isotonic with seawater and since it is contained in pure form between the valves. For this reason the salt glands of Red Knots are relatively large, even larger than those of Wilson's Phalaropes that live on highly saline lakes. As discussed above, phalaropes squeeze out the salt water surrounding their planktonic prey before ingesting the prey. Yet, when Red Knots live without sea water for some time, as they do on their tundra breeding grounds, their salt glands become small. They are regrown upon a renewed encounter with sea water, during southward migration. In scolopacid waders occupying marine and saline habitats the size of the salt glands is thus finely tuned to the amount of ingested saltwater that needs to be processed, and to the volume of osmotically free (fresh) water that is required for evaporative, cooling, purposes.

Whereas the salt glands are the smallest functional organs of a scolopacid wader, the breast muscles are certainly the largest. The strong sternum has a prominent ventral keel, and on both sides lie a pair of muscles, the large flight muscle *pectoralis*, which generates the power for the downstroke, and the much smaller *supracoracoideus* muscle, which powers the upstroke of the wings. The breast muscles usually comprise about a quarter of the fat-free mass of shorebirds. This heavy flying gear is partly compensated for by the lightness of the bones. Although the dimensions of the skeletal attachment area of snipes and woodcocks is similar to that of the other scolopacid waders, the breast muscles are relatively heavy. This is correlated with the rather different wing morphology of woodcocks and snipes.

While the great majority of shorebirds are long distance migrants with long and pointed, high-speed, wings bearing a minimum of drag, the woodcocks, and to a lesser degree the snipes and the *Actitis* sandpipers, have more rounded wings. The rather elliptical shape of woodcock wings is designed for navigation

Once or twice a day, waders of the foreshore congregate on safe high-lying flats when the tides cover their intertidal feeding areas. At the period of high tide, waders can rest, preen and bathe, whereas all feeding has to be carried out at low tide. High tide is also the time when flocks aggregate, and there may be information exchange about the birds' inclination to migrate onwards or about the quality of different feeding locations.

Typically for "meadowbirds", this wary Upland Sandpiper uses a fence post to oversee its territory. A prairie grassland species, the Upland Sandiper experienced massive declines a century ago, due to the cultivation of its preferred habitat. It suffered even more when farmers started to lay down poison, killing large numbers, in the belief that the species ate their grain. In fact, these sandpipers consume wireworms, grasshoppers and other potential grassland pests.

[*Bartramia longicauda*, North Dakota, USA. Photo: Wayne Lynch/DRK]

among tree limbs. Most woodcock species do not carry out long distance migrations and lack the speed of shorebirds of open spaces. Instead, they have perfected a rocketing take-off in case of disturbance. Like little helicopters they can disappear straight up through the branches. The Common Sandpiper (*Actitis hypoleucos*) of the Old World and the Spotted Sandpiper (*Actitis macularia*) of the New, combine rounded wings with a special "buzzy" flight technique in which wingbeats are shallow and spasmodic. During level flight, usually low over the water, each wingbeat is curtailed just below the horizontal so that the wings do not get wet, and there are short glides on down-bowed wings between series of flickering shallow wingbeats. During their long migratory flights between their temperate breeding areas and tropical wintering areas, the rounded wings and peculiar flight style give Common and Spotted Sandpipers rather low flight speeds. These are in the order of 30-40 km/h rather than the 60-70 km/h of long-winged family members. The adaptive value of their wing morphology and wingstroke patterns only becomes apparent when potential predators, such as hawks, show up, upon which *Actitis* sandpipers immediately dive under water and swim with the help of the feet and wings to safety among rocks or vegetation along the shore. E. O. Willis has proposed that diving and swimming under water, starting from the buzzy flight low over the water, allow this genus to use water courses in closed habitats, such as tropical rivers and mangroves, to a much greater extent than other sandpipers. This author also suggests that their dives to safety provide a good analogy to the aerial glides of flying fish.

Scolopacid waders, much more than plovers, show intraspecific variation in size, with respect to both geography and sex. As an example of the first phenomenon, the wing length of Common Redshanks (*Tringa totanus*) breeding in warmer climatic zones is shorter than that of conspecifics breeding in colder areas. This may be regarded as a nice example of Bergmann's Rule, which states that in colder climates warm-blooded animals should be larger in order to reduce relative heat loss by a smaller surface area/volume ratio. A weird contrasting congeneric pair of longitudinal size differences within a species is provided by Black-tailed (*Limosa limosa*) and Bar-tailed Godwits (*Limosa lapponica*): in this case, towards the east there is a cline of decreasing body size in Black-tailed Godwits, while there is one of increasing size in Bar-tailed Godwits. This has the confusing effect on worldwide birdwatchers that in western Europe Black-tailed Godwits are larger than Bar-tailed Godwits, but that in South-east Asia and Australia this is reversed. No easy explanatory "rule" is at hand here.

The Scolopacidae provide some of the best examples of pronounced sexual size dimorphism in birds. Indeed, the family contains some species in which males are larger, but also many in which the reverse is true. Male Ruffs are almost 25% larger than the females, called Reeves, in all linear dimensions. In other promiscuous sandpipers such as the Pectoral and Sharp-tailed Sandpipers, males are also quite considerably larger than females. In contrast, male knots, godwits, curlews and phalaropes are consistently smaller than the females. Amongst the woodcocks, snipes and tringines, the sexes are usually of equal size. Most published evolutionary interpretations of the sexual size dimorphism of scolopacid waders have emphasized the correlation with mating system and parental role division. In species that show a physically competitive lekking system the males are larger, with the notable exception of the Great Snipe (*Gallinago media*). In lekking species females carry full responsibility for breeding and rearing the chicks. Conversely, in species where females are larger, males take on the greater share of parental care. P. E. Jönsson and T. Alerstam have argued that a smaller body size is adaptive for the care-taking sex, since smaller individuals require less energy to maintain themselves. In addition, the short bills, with dimensions that mirror those of the chicks to an extent, are better adapted for foraging in typical chick-rearing habitats and are therefore advantageous when attending broods.

The flight-feathers and tail feathers of scolopacid waders are replaced once a year. Usually these feathers are moulted when the breeding plumage is also replaced. In most cases moult commences after arrival on the wintering grounds, but it can also occur earlier in the year. In this regard scolopacid waders seem quite flexible. In Dunlins there are breeding populations that already start flight-feather moult on the breeding grounds, while other populations only begin their moult after having arrived in their winter quarters. The primaries are moulted from the "wrist" outwards, the secondaries inwards. The moult of the secondaries, the tertials and the tail feathers starts when the primaries are half way done. Wing moult is usually completed in one continuous period of 2-4 months, but several inland-staging waders, such as Black-tailed Godwits and Ruffs, renew only the inner 3-6 flight-feathers in Europe and finish this moult later in the year on the African wintering areas. In scolopacid waders wintering along the eastern shores of the Atlantic Ocean, wing moult in northerly areas is completed faster and earlier in the year than in southerly areas. In western Europe shorebirds have completed their wing moult by late October, but the cline continues over the equator into southern Africa, where shorebirds in wing moult may be encountered into the month of February of the next calendar year.

During the non-breeding season the plumage of scolopacid waders is uniformly dull, usually with the belly paler and the back darker. In many of the species this changes during the breeding season, when the belly may turn from pale grey to dark rusty red or black, and when the back may be decorated with finely coloured scapulars with colours matching those of the breast and belly plumage. Red Knots, Curlew Sandpipers, Bar-tailed Godwits and Red Phalaropes develop rusty red bellies, brighter in males of the first three species, and in females of the last. In phalaropes, the males are the "choosing" sex that take care of all parental duties except, of course, egg-laying, and the duller plum-

Resting but wary at high tide, this Western Sandpiper is one of the several million that use the Copper River Delta as their major staging site on the way north to their breeding grounds in Alaska and on the Chukotskiy Peninsula. Unlike many other Calidris *species, this sandpiper does not migrate in long, non-stop flights, but instead moves northward in rather short stretches of about 600 km from one stopover site to the next up the American Pacific coast. When sleeping, scolopacids typically stand on one leg, and tuck the head and bill into the feathers on the back; both of these habits are particularly useful in cold weather, as a great deal of heat can be lost through the extremities. Having once adopted this posture, birds appear loath to alter it, and can often be seen hopping about on one leg.*

[*Calidris mauri*, Copper River Delta, Alaska. Photo: Kim Heacox/DRK]

A long decurved bill is a great asset when it comes to catching crabs, mudprawns and mudskippers buried in muddy and sandy substrates. It also comes in handy when feathers of the upperparts require preening, as this female Long-billed Curlew illustrates. At some 17 cm long, this bill is one of the very longest to be found in the family Scolopacidae.

[*Numenius americanus*, Coronado, California, USA. Photo: A. & E. Morris/ Birds As Art]

age may provide better camouflage, as is usually the case for females in other sandpiper species. In Great Knots, the back plumage during breeding resembles that of the closely related Red Knots, but the breast becomes blackish instead of rusty red. In another relative, the Surfbird, the plumage of the back shows a change very similar to that in the two knots, whereas the belly plumage becomes spotted, as in the Great Knot. Similarly, Spotted Sandpipers, Nordmann's Greenshanks and Slender-billed Curlews (*Numenius tenuirostris*) may develop dark spotted breasts in the breeding season. Among the smaller calidrines, only the Dunlin develops a real dark breast and belly patch, and the Rock Sandpiper a blackish brown patch. Most other calidrines show more intense hues on their backs and breasts only, with the exception of the male Pectoral Sandpiper which has a dark blackish brown throat and breast in breeding plumage. These longish dark feathers cover a breast sac, a prominent pendulous organ filled with fat and lymph. The sac is extended during display flights and with it the displaying male produces impressive hooting sounds.

The most bizarre and wonderful breeding plumage shown by any scolopacid wader is formed by the ruffs, tufts and scapulars of male Ruffs. A fully-grown ruff comprises a ring of long colourful feathers around the base of the head and neck and on the upper breast. It can be spread out as a wide, eye-catching collar but can also be carried, not quite invisibly, close to the skin. The head tufts consist of shorter feathers but these too can be erected. Together these specialized feathers, worn for about 2-3 months in late spring and summer, produce a very expressive aspect. Ruff- and tuft-feathers come in a range of hues, from white to red to brown to black, and a variety of patterns, from none, to specks and stripes to flecks. Their hues and patterns are combined in innumerable ways. As if this were not extravagant enough, males have the face bare and covered with yellow, orange or reddish wattles. In stark contrast, the Reeves are dull, brownish-plumaged, standard calidrine sandpipers. The adaptive significance of the impressive plumage variability of male Ruffs is not clear, although there exists one robust correlation with behaviour. Non-fighting males, those that do not defend little areas on an arena, have very pale or white tufts and ruffs. Another case of plumage variation is provided by the Ruddy Turnstone (*Arenaria interpres*), where males in particular have facial patterns which are especially striking during the breeding season. The pattern of the mask of an individual remains the same from year to year. On the basis of a series of ingenious experiments with fibreglass turnstone-decoys resembling territorial neighbours, D. P. Whitfield concluded that in Ruddy Turnstones plumage variation serves the function of individual recognition.

The intense coloration of some of the breeding plumages of scolopacid waders may, however, serve other functions too. Before their northward departure from West Africa to their Siberian breeding areas, Bar-tailed Godwits have more or less completed the moult into a rusty red breeding plumage. During their main stopover period in the Netherlands some of the Bar-tailed Godwits, males as well as females, nevertheless start a second contour feather moult. Moulting individuals are not only the ones with the brightest coloration, but also those that are heaviest at that time of year; during migration, fatter is better! Moulting individuals also carry fewer intestinal parasites and have a better blood profile, for instance with higher counts of red blood cells. Thus, individual Bar-tailed Godwits that can afford to upgrade their plumage during a stopover, in spite of the stress of rapid fuel storage, signal their own quality as healthy, well performing long distance migrants. Bright breeding plumages may therefore represent the products of sexual selection for quality traits. Incidentally, the bristles of Bristle-thighed Curlews (*Numenius tahitiensis*), which are actually barbless feather shafts, serve no known function, not even a sexual one.

The snipes have little to show in terms of sexual or seasonal body plumage variations, but they have something else: special tail feathers. Whereas most other scolopacids have 12 tail feathers, snipes commonly have as many as 16, with numbers ranging from 14 to 26 in different species. The outer tail feathers of snipes are different and of a stronger build than the inner tail feathers. With a narrow outer vane and a broader inner vane they look rather like outermost primaries. Connected to the body with special muscles, these feathers can be pointed outwards. During the plunge-dive of aerial displays, flight speed is high enough to make these feathers vibrate, thus producing the winnowing sounds that snipes are famous for. Any minor disarrangement of these specialized outer tail feathers can alter the sound of the bleat. When L. M. Tuck slightly clipped the tip of one of the outer rectrices, or notched its webbing, he could distinguish the bleating sound produced by that manipulated individual Common Snipe (*Gallinago gallinago*). During the dives the quivering of the wings interrupts the air flow, and this causes the tremulous quality of the bleating sound. In spite of their strong build, the outer tail feathers become so worn that they may be moulted twice each year. In this way the winnowing sound of a displaying snipe may be as much of a quality signal as the belly plumage colour of a Bar-tailed Godwit.

Like virtually all waders, Jack Snipes live in close contact with water. The uropygial gland, situated at the base of the tail feathers, produces oily waxes that are used in order to ensure the waterproofing of the plumage, a most important part of feather care. The oil is distributed over the feathers by means of rapid bill movements. The smallest of the snipes, this species is also the only one that lacks the characteristic central crown stripe, but it does have a well marked double supercilium.

[*Lymnocryptes minimus*, Al Ansab Lagoons, Oman. Photo: Hanne & Jens Eriksen/Aquila]

Great Snipes come together on ground-based leks and do not have the remarkable display flights shown by their congeners, but their tails nonetheless play a striking signalling role as well. The amount of white on the outer tail feathers is greater in males than in females. The white is displayed by males on the lek, where they fan out their tails in an upright posture. According to J. Höglund and co-workers, females prefer males with the whitest tails, including those with experimentally enlarged white areas. A large area of white on the tail feathers may act as a quality signal because white feather keratin is weaker than pigmented keratin and such tails are thus more difficult to maintain intact.

Another story connected with tails and signalling is the remarkable number of white rumps in scolopacid waders. These eye-catching white surfaces may be plain or broken by a dark mid-line or by transverse bars. T. Stawarczyk, who found that the aggression between shorebird species with dissimilar rump patterns was more frequent than between similarly rumped sandpipers, suggested that the colour pattern of the rump of sandpipers is a form of "social mimicry". White rumps would favour the formation and maintenance of multispecies feeding flocks during migration periods and in winter, and reduce the level of aggression between co-occurring individuals.

Hatchling scolopacid waders are characterized by very large legs. Their bills are still relatively small and show little of the eventual curvatures that can be so striking later in life. An exception is provided by hatchlings of the aberrant Spoon-billed Sandpipers. Their bills are dorsally flattened from the day of hatching. Although the bills of hatchlings are more rounded and shorter, at first sight they look like miniature versions of the spoon-like parental bills. The plumage of scolopacid chicks shows a great deal of variation between the taxa. The down of snipes is usually chestnut brown even on the underparts, with black bands on which complex patterns of "powder-puffs" are found. Powder-puffs are small, elongated white downy feathers with the appearance of minute snow flakes that may give excellent camouflage in particular habitats. The down of calidrine sandpipers and dowitchers is longer and looser, especially on the nape. It is whitish below and mainly greenish beige to rich brown above, with black notches and good numbers of powder-puffs. Powder-puffs are absent in woodcocks, turnstones, godwits, curlews, tringines and phalaropes, most of them breeding in more enclosed, marshy, scrubby or woody habitats than species with chicks that do have powder-puffs. Small chicks less than 10 days old have a bare patch on the neck where two thick blood vessels come close to the skin. Small wader chicks can not maintain a constant body temperature on their own and must be heated up regularly after spells of activity in the cold. The naked vascularized area functions as a heat exchanger which is pressed against the parents' naked brood patches during brooding sessions.

Habitat

The Scolopacidae live in an extremely wide range of habitats. They can be encountered in the form of a rare woodcock in the middle of a moist tropical forest, or of a Red or a Red-necked Phalarope far out on the open ocean. A great variety of sandpipers and similar species occur in grassland and scrubland, in taiga and tundra, and on mudflats and salinas. In spite of the variability, it is possible to recognize the common denominator of all these scolopacid habitats: their substrates are watery, wet or moist, and are usually penetrable by elongated sensitive bills. A few species, in particular Rock and Purple Sandpipers and Surfbirds, obey the wetness criterion but select hard substrates, rocky shores that carry good densities of marine invertebrate food items.

Overall, members of the Scolopacidae breed farther north than any other bird family, including the plovers. Most species breed in boreal, subarctic and Arctic regions, and only a few south of the temperate zone. In fact, only 11 of the 86 species breed at tropical latitudes, four of which are woodcock species living on forested islands, six are snipes, and the eleventh is the Tuamotu Sandpiper of the archipelago in the central Pacific of the same name. All the tropical species are residents, and most of them have very restricted ranges. Although travelling the world in the non-breeding season, several migrant calidrines also have fairly restricted breeding ranges. Spoon-billed Sandpipers breed in a small area of the Russian Far East. Western Sandpipers only breed around the Bering Strait, and Sharp-tailed Sandpipers breed on low Arctic tundra in easternmost Siberia. The Curlew Sandpiper occurs as a non-breeder over a very wide range, being commonly observed in much of Europe, Africa, Asia and Australia, yet the core of its breeding areas is limited to the Taymyr Peninsula and the New Siberian Islands, both in north-central Siberia. Scientists have no idea whether the small breeding ranges are a consequence of very precise habitat requirements during reproduction, requirements that are only fulfilled in small segments of the circumpolar tundra range, or whether these distributions reflect historical contingencies and constraints.

Almost all scolopacid waders breed in inland habitats, mostly in freshwater wetland systems. The clear exceptions are three north temperate breeding species of shank, the Common

Redshank, the Willet and Nordmann's Greenshank, all of which may breed on coastal salt-marshes and raise their chicks on the marsh and nearby intertidal flats. Considering that many scolopacid wader species are obligate coastal dwellers for the rest of the year, they not only fly large distances between breeding and wintering areas, but also show quite dramatic shifts in habitat and diet when moving towards and away from the breeding areas. A good example is provided by the Red Knot, a bird occurring worldwide, but only in coastal intertidal areas where it feeds in a probing manner on subsurface mollusc prey. Red Knots breed at the northernmost latitudes, on high Arctic tundra, where the frozen subsoil prevents seepage of the melted frosts to ensure the formation of ponds and pools. In spite of the many wet soils, Red Knots restrict foraging to moist or dry areas with sparse tundra vegetation, feeding on surface-dwelling arthropods and spiders detected by eye. Except just after arrival, during the breeding season Red Knots rarely probe. A complete ecological contrast is provided by the two *Actitis* sandpipers that migrate over quite large distances yet remain faithful to fairly similar, riparian habitats all year round, keeping to enclosed, forested waterways and ponds.

Shanks, several species of snipe and the western race of the Broad-billed Sandpiper, prefer wet wooded areas, especially during the breeding season. Many of them breed in the boreal and subarctic zones, in forested wetlands such as muskeg and taiga. Most calidrine sandpipers breed north of the taiga in the low to middle Arctic tundra zone, the majority thus remaining south of the breeding grounds of Red Knots, Sanderlings and Purple Sandpipers. These low and middle Arctic tundras are more productive than the tundra deserts of the high Arctic, and provide vast pastures of mosses, lichens, sedge grasses, sphagnum and dwarf willow. Snipes, dowitchers, godwits and curlews breed in marshes, and often also occur in man-made habitats such as meadows and cattle pastures at northern temperate latitudes. In all the northern wetlands mentioned, summer weather releases swarms of mosquitoes, flies, craneflies, caddisflies, aquatic midges, spiders and other small invertebrates. The migrating scolopacid waders take excellent reproductive advantage of the pronounced seasonal cycles of these animals.

During the northern winter, in the non-breeding season, many scolopacid waders are restricted to coastal intertidal habitats at tropical and both southern and northern temperate latitudes. Individuals of very few species, such as the Common Snipe, Eurasian Woodcock, Eurasian Curlew (*Numenius arquata*) and Green Sandpiper (*Tringa ochropus*), remain inland in the temperate zone during the northern winter. When the winter is severe, Eurasian Curlews move from the grasslands to the coast, and the others move south with the frost-line, each trying to keep to its own typical habitat type.

Many species, perhaps the majority, migrate south to winter in tropical non-tidal wetlands, including river deltas, floodplains, more permanent lake shores and lagoon areas close to the coast. An example of these important wintering habitats is provided by the floodplains and lagoon systems of West Africa. These areas depend on rainfall which is very seasonal and shows great variability from year to year. Normally, the main rains fall within the period March-July, followed by a short period of rains in September-November. In average years these wetlands are thus filled with water by the time the northern waders arrive in September-October. Since scolopacid waders exploit shallow water margins, the best habitat is available when the water tables drop during the course of the northern winter. Within such tropical lagoon systems, different species use different micro-habitats. In coastal lagoons in Ghana, for example, Little Stints, Ruddy Turnstones, and Common Sandpipers feed on the drying edges of the lagoons and the wet mudbanks. With their small body mass, only Little Stints can feed on algal beds that accumulate in stagnant lagoons or saline ponds. Curlew Sandpipers, Sanderlings and Wood Sandpipers (*Tringa glareola*) feed in the shallow water margins, and Marsh Sandpipers (*Tringa stagnatilis*), Common Greenshanks (*Tringa nebularia*), Spotted Redshanks (*Tringa erythropus*) and Black-tailed Godwits in slightly deeper water. The choice of water depth and substrate is a function of leg length and food availability. Deeper areas of the lagoon and recently flooded areas still devoid of prey items are not used by any scolopacid waders.

In Africa, species like the Ruff and the Black-tailed Godwit rely extensively on man-made habitats such as rice fields, where they feed on spilled rice and chironomid larvae. Seed- and insect-eating Ruffs also occur in dry grassland areas, as long as freshwater ponds are close by. Similar kinds of habitat are, or were, exploited by Buff-breasted Sandpipers and Eskimo Cur-

Away from their breeding areas Hudsonian Godwits are not very vocal, but "at home" in the North American Arctic, their loud and sustained alarm calls are used to confuse or scare away intruders, including humans. Their calls are among the loudest of all sounds made by waders. In the past, in some areas shorebirds calling noisily to defend their territories sometimes irritated hunters to such an extent that they were rewarded with a barrelful of shot for their pains.

[*Limosa haemastica*, Churchill, Manitoba, Canada.

The Red Knot usually feeds on shellfish which it ingests whole, crushing the shells in its powerful muscular gizzard. Sometimes this species relies on prey other than intertidal bivalves and snails, a famous example being its use of the abundant eggs of horseshoe crabs (Limulus polyphemus) *on the shores of Delaware Bay. At this major refuelling station, many knots have just completed one of the longest non-stop flights of the avian world, clocking in from southern Brazil. Even though the crab eggs are tiny, a high intake is ensured by the specialized "conveyer belt" system whereby several eggs are passed up the bill at once.*

[*Calidris canutus rufa*, New Jersey, USA. Photo: Arthur Morris]

lews (*Numenius borealis*) on the South American *pampas*, and by a close relative of the latter species, the Little Curlew (*Numenius minutus*), in New Guinea and northern Australia.

Coastal intertidal areas of sand and mudflats are frequented by a different assortment of scolopacid wader species than are the inland lagoon and grassland systems. Although some species, notably the Little Stint, Red-necked Stint, Sharp-tailed Sandpiper and Curlew Sandpiper appear as much at home on intertidal flats as in shallow lagoons, the tringine waders are relatively scarce in coastal areas. In contrast, Dunlins, Red and Great Knots, Bar-tailed Godwits, and a few selected shanks such as the Common Redshank and the Terek Sandpiper, are rarely seen off the coast. Intertidal areas derive their quality from the fact that at low water levels the sea bottom is exposed, and thereby all the marine organisms living there. Tidal flats are exposed on a regular basis, once or twice daily, in coastal regions where the tidal amplitude is larger than a few decimetres. However, along the shallow shores of enclosed seas such as the Baltic and the Black Sea, tidal amplitudes are minimal and flats only become exposed when wind drives the water away. In spite of their unpredictable availability, such wind-flats may harbour large densities of feeding *Calidris* and Broad-billed Sandpipers, especially in productive systems where there are alternative feeding areas depending on wind direction. The wind-flats of the Sivash in the Ukraine and the southern Baltic in Germany and Poland, with high polychaete and crustacean stocks, are intensively used as refuelling sites during northward and southward migration. A similar situation exists in shallow coastal lagoons in southern Brazil where wind exposes extensive flats used by Red Knots and Hudsonian Godwits (*Limosa haemastica*) during northward migration.

Depending on feeding style and prey choice, during low water periods different species prefer flats at different tidal heights and with different substrates. Asian and Short-billed Dowitchers, Broad-billed, Western and Semipalmated Sandpipers usually select muddy areas, whereas Bar-tailed and Hudsonian Godwits and Red Knots go for the more sandy parts of the intertidal flats. Species that hunt for crabs, notably the Whimbrel and the Terek Sandpiper, are traditionally found on the high parts of the intertidal zone since it is usually there that densities of burrowing crabs reach a peak.

Sandy substrates along the seashore, including various types of beaches, are the preferred habitat of Sanderlings. However, Sanderlings may also be found scavenging among the huts in shoreline fishing villages, a man-made habitat that they share with the scolopacid wader with the most catholic taste of all, the Ruddy Turnstone. Ruddy Turnstones may be found foraging in many other coastal habitat types, including beaches, salt-marshes, coastal meadows and rocky shores. Rock and Purple Sandpipers and Surfbirds almost uniquely occur on steep rocky shores. Along the Patagonian shores one finds an exceptional type of rocky habitat called *restinga*: this has the appearance of an intertidal mudflat but consists of flat areas of compacted siltstone. The patches of mussel on the *restinga* are harvested by scolopacid waders otherwise confined to soft intertidal substrates, especially White-rumped Sandpipers and Red Knots.

There exist clear differences in habitat selection between pairs of closely related species, and even between subspecies pairs. As an example of the first, of the two North American dowitcher species, the Short-billed lives in saltwater habitats, whereas the Long-billed inhabits freshwater marshes and avoids marine habitats. Bar-tailed Godwits live almost exclusively in coastal intertidal areas, in Europe as well as in Africa, whereas the Black-tailed Godwit in Africa only occurs inland, in rice fields, floodplains and freshwater lagoons. African-wintering Black-tailed Godwits belong to the subspecies *limosa*, which has a habitat choice that is quite different from that of the race *islandica* which breeds in Iceland; the latter winters on intertidal estuarine mudflats in western Europe. Such intraspecific variability also exists with respect to breeding habitats. Willets in north-western North America, for example, breed in coastal salt-marshes, whereas the population on the prairies occupies the shores of lakes and ponds with a wide range of salinities.

If the very strict habitat requirements shown by some species were known in sufficient detail, if such habitats were identifiable in the fossilized geomorphological record, and if reconstructions of past habitat distribution were carried out on sufficient scales, it would be possible to develop hypotheses of the past distribution of those species. Great efforts have been made to map the past distribution of ice-free tundra in the course of the Pleistocene climate cycles, and these habitat reconstructions have been used by ornithologists to speculate about the

To detect their buried prey, most scolopacids use a touch-sense located in their long bills. Several species have been shown to "feel" prey even at some distance from the bill tip. The Common Snipe is a typical example of such a tactile forager. Its bill tip is full of receptors, the so-called Herbst's Corpuscles, that can measure changes in pressure. These peripheral receptors are connected to specialized enlargements of the frontal brain area.

evolution and past breeding areas of tundra-breeding waders, such as the Red Knot, a seemingly obligate high Arctic tundra breeder, which, according to molecular genetic data, underwent a recent population bottleneck 15,000-10,000 years ago. According to the distribution of high Arctic tundra around this time, Red Knots could have bred either in the North Sea basin or in the Bering Strait area. Additional studies of the past distribution of intertidal wintering habitats may allow an evaluation of hypotheses on past migration routes, the "paleoflyways".

Having talked in general terms about breeding habitats, and in more specific terms about the feeding habitats used during the nonbreeding season, it is important to remember that scolopacid waders need to fulfil more functions than feeding. Most importantly, birds need water for bathing and preening, and a safe or a sheltered place for resting and sleeping. In many non-tidal areas all micro-habitats can be used for all functions, but in dry grassland areas scolopacid waders need freshwater ponds. In intertidal areas birds are forced to come together on hightide roosts. Visually-hunting species may additionally congregate at nighttime roosts, usually in shallow water or in mangroves. Scolopacid waders show a wide variation in their readiness to accept tree perches as high tide roosts. For example, in tropical areas Red Knots will never roost in mangroves or in a baobab tree, but Bar-tailed Godwits, Whimbrels and Semipalmated Sandpipers accept such sites with no difficulty whatsoever.

General Habits

The maintenance of a balanced energy budget, the avoidance of predators and parasites, and sex, provide the main components of a functional framework in which most of the general habits of scolopacid waders can be explained. Species-specific behavioural characteristics such as the teetering of tails, the buzzy display flights or the zig-zag escape flights, and more generally the choice of feeding and roosting sites, the degree of flocking and territoriality, and the daily rhythms of shorebirds are all evolutionarily trimmed by these factors.

Outside the breeding areas some scolopacid waders such as dowitchers and knots customarily forage in compact groups, almost shoulder to shoulder. Since they feed by tactile means on buried prey that have very limited means of escape once alarmed by the approaching avian predators, such shorebirds can afford to feed in dense flocks. At the other end of the spectrum are species like the Greater Yellowlegs (*Tringa melanoleuca*), Buff-breasted, Terek and Upland Sandpipers (*Bartramia longicauda*) that rely on eyesight for prey detection so that the presence of nearby conspecifics disturbs the prey and reduces intake rate. These waders scatter widely, or they may defend feeding territories. Several species, such as the Common Redshank, show considerable variation in the degree of flocking. When using visual stimuli to find prey they keep their distance and maintain territories, but when feeding on small buried gastropods, located by tactile means, they come together in flocks. Apart from woodcocks and snipes, flocking characterizes the majority of scolopacid waders during the non-breeding season. Phalaropes "dancing" on an ocean swell, sandpipers feeding on a mudflat, and shanks chasing fish in shallow water, all do it together in flocks.

As an example, in coastal lagoons in West Africa, most wintering scolopacid waders feed and roost in mixed-species flocks. Only Common Sandpipers live singly and mainly on their own, and a small proportion of the Wood Sandpiper population defends small, temporary feeding territories. Sizes of mixed-species flocks vary between two and almost 1000 individuals, with most birds feeding in flocks of 50 or more. Some flocks consist of dense aggregations of waders that all forage frantically, making seemingly orchestrated, synchronized movements together. In this way Common Greenshanks, Spotted Redshanks and Marsh Sandpipers drive shoals of fish to particularly shallow water, tire them out or confuse them, so that the catch is made easier.

Feeding in flocks may thus allow waders to enhance the catchability of fast-moving prey. Flocks may also serve the function of sharing information about good feeding sites. Although feeding flocks will always passively attract individual birds that have yet to find a good feeding location, scolopacid waders that make a living on cryptic and buried prey items "hidden" in "uninformative" habitats, may additionally employ active information sharing. A case in point is, again, the Red Knot, a species foraging in very large flocks in most coastal areas where it occurs. In the estuaries of western Europe, a wintering individual Red Knot experiences an average of several thousand flock-mates

For most scolopacids foraging on mudflats prey availability depends on the burrowing depth of benthic invertebrates, their own bill length and the height of the water covering the mudflat. Of course, the hungry wader must also show plenty of perseverance, as is exemplified by the frantic probing of this Marbled Godwit. The seasonal removal of large proportions of entire cohorts of prey species by migrating shorebirds is likely to leave its imprint on the life history strategies of the prey species. Thus, due to their own predation pressure, scolopacids may have lowered levels of prey availability, since the invertebrates concerned do their best to live out of reach of the waders.

[*Limosa fedoa fedoa*, San Diego, California, USA. Photo: Arthur Morris]

when feeding on buried bivalves and small gastropods. These prey occur patchily over intertidal flats that otherwise have a very uniform appearance, even at close range. To make it even more complicated for the predators, the availability of bivalves often changes. By burying themselves deeper or moving towards the surface of the sediment over a period of days, bivalve stocks can suddenly become unavailable or available. By living in large and wide-ranging flocks with many sensitive bills exploring the sediments, Red Knots are able efficiently to keep track of the best feeding sites.

Flocks also provide a defence mechanism against raptors and other potential predators. Even though some species such as snipes and woodcocks, Common and Spotted Sandpipers, and some tattlers are casual flockers at best, these species and most other scolopacid waders will cluster together in times of peril. A singular exception is provided by Solitary Sandpipers (*Tringa solitaria*). Living up to their name, even a group of Solitary Sandpipers will scatter upon taking flight. Flying together in flocks that make synchronized movements makes sense in most natural situations, since raptors seem daunted by the unity or just the plain bulk of a tight flock in the air. At many coastal sites all over the world, the appearance of a Peregrine Falcon (*Falco peregrinus*) will bring sandpipers together in a dense flock. Such flocks may ascend to heights of several hundred metres, outflying the raptor that is no longer able to make its impressive groundward stoops on the waders.

That thousands of birds flying together at high speeds are able to execute abrupt manoeuvres with precise co-ordination is a miracle in itself. By analysing high-speed film recordings of Dunlin flocks, W. K. Potts was able to demonstrate that a single bird may initiate the manoeuvre that spreads itself through the flock in a wave. The propagation of this wave begins rather slowly, but then increases to speeds that are three times higher than would be possible if the sandpipers were simply reacting to their immediate neighbours. This speed of propagation appears to be achieved in much the same way as in human chorus lines and in organized "waves" at North American sporting events. Individuals take note of the approaching wave and ensure that their own manoeuvre coincides with its arrival.

Feeding in flocks also has an element of information sharing in relation to predation. On the ground many watchful eyes help the detection of approaching raptors and ground predators; flock-feeding provides an early warning system. In Eurasian Curlews feeding on inland grassland, birds in larger flocks look up less often and have a greater food intake per unit foraging time. Studies by N. B. Metcalfe of Ruddy Turnstones and Purple Sandpipers feeding together on a Scottish rocky shore, show that vigilance increases when their view is obscured by boulders, even though they are better camouflaged in such places. Vigilance is reduced when birds can see a conspecific or an individual of a similar-sized species, but it is not shared with much larger species. In spring, before departure to the breeding grounds, adult Ruddy Turnstones have reduced levels of vigilance, but non-migratory juveniles have not. During this period the adults feed hard to store fuel fast, and for this reason appear to accept the increased risk of predation which results from a decrease in vigilance. A similar kind of trade-off between feeding rate and risk of predation is apparent in the choice that Common Redshanks, studied also in Scotland by W. Cresswell, have to make between a high-risk/high-intake area of salt-marsh and a low-risk/low-intake musselbed. The adult birds opt for the relatively unprofitable musselbed and evict juveniles to the dangerous salt-marsh, where over 90% are killed over a winter. Along beaches in California, Sanderlings give up their linear beach territories in winters when Merlins (*Falco columbarius*) are around. During such winters they forage only together, in the relative safety of flocks.

Several studies have proved that being in a flock is indeed safer for an individual wader. For example, feeding in flocks reduces the probability that an individual Common Redshank be killed by Sparrowhawks (*Accipiter nisus*) or Peregrines. Although raptors are more inclined to attack larger than smaller feeding flocks, attacks on small flocks are usually more successful. Larger flocks are safer because there is increased common vigilance, a greater degree of predator confusion and, quite simply, safety in numbers. Depending on the geography of the area, scolopacid waders run the highest risk of raptorial predation either at roosts or on the feeding grounds. On the Banc d'Arguin in Mauritania, where waders disperse widely over extensive tidal flats, three co-occurring species of falcon are most active at high tide, trying to catch the roosting waders by surprise. In habitats with smaller spatial scales, such as small enclosed estuaries, foraging waders can also be taken by sur-

Some types of prey are not only hard to find, but are even harder to ingest in one piece. Active, crawly polychaetes require specialized handling techniques and a considerable amount of patience in order to end up with successful swallowing. The broad, flat bill of the aptly named Broad-billed Sandpiper could well be an adaptation designed for the effective capture and ingestion of large polychaete worms.

[*Limicola falcinellus sibirica*, Australia.

prise during low water. At such sites hawks and falcons may kill up to 50% of the initial wintering population of scolopacid waders.

The question remains whether wader flocks are anonymous assemblages of individuals that just happen to group together in different ways on different days, or whether individuals in a flock know each other. Along Pacific beaches in California, J. P. Myers could only find random associations among the 700 wintering Sanderlings. He concluded that "Sanderlings have no friends". As a clear contrast, Ruddy Turnstones on a European wintering area have high site fidelity and forage regularly with as few as 50 other individuals in small flocks. In spite of the fact that they regularly come together in large roosting aggregations of several hundred birds, these Ruddy Turnstones show a clear social structure. That not all individual scolopacid waders knowing each other would necessarily regard themselves as "friends", is suggested by the discovery that wintering Ruddy Turnstones maintain rather strict dominance relationships on the feeding areas. Individuals low in rank pay a price by not being able to use the most profitable feeding techniques. The establishment of dominance hierarchies may involve much fighting, and unlike other scolopacid waders, Ruddy Turnstones have been known to kill each other.

Most of the small *Tringa* and the *Actitis* sandpipers routinely make frequent, restless up and down movements with the tail end of the body when they are standing "still". This nodding and bobbing is called teetering or tipping, and is also shown by dippers and wagtails, passerines that likewise often feed along water margins enclosed by high vegetation. The striking parallel of habit and habitat in species so unrelated has led to the suggestion that teetering makes shoreline birds blend into the lapping wavelets of river and pond and the play of light and shadow thus created on the shore. Since small shanks also teeter when the sun does not shine, this hypothesis is not very convincing. Teetering may be analogous to the tail-flicking behaviour of rails (see page 116). It may improve visual acuity, a better perception of distant prey or predators. Interestingly, such marsh-living birds have been noted to increase the rate of tail-flicking as they go further from protective cover, and also when they are orientated away from conspecifics or when predators are present. It has been suggested that by making themselves more conspicuous, teetering birds tell their potential predators that a profitable surprise attack is out of the question. No scolopacid wader species has yet been studied to see whether teetering could safely be interpreted as what is called a "pursuit-deterrent signal".

An alternative to signalling one's presence is for individual birds to stay out of sight. By flattening themselves against the ground, shorebirds are able to decrease or eliminate the shadow that could give them away, an effect which is enhanced when the wings are slightly spread so that the body tapers imperceptibly into the surroundings. Species such as the Pectoral, White-rumped and Least (*Calidris minutilla*) Sandpipers will crouch down on their tarsi behind reed stumps or lumps of mud. A disturbed Wandering Tattler (*Heteroscelus incanus*) has been seen to act much like a crocodile, disappearing completely into shallow water on a tidal mudflat; only its eyes and nostrils remained above the water surface. Snipes and woodcocks are famous for lying still until the final moment when they burst away from a dangerous intruder. Upon disturbance, Green and Solitary Sandpipers and especially snipes will fly up and move away in a zig-zag escape flight. This behaviour is shared with some other species of inland grassy mudflats such as Least and Pectoral Sandpipers, that will also zig-zag away, if flushed when alone.

During sleep, scolopacid waders usually stand on one leg with the head laid on the back pointing tailwards. The bill, where much heat is lost, may be tucked away among the scapular feathers. The frequent observation that roosting birds will hop one-legged for considerable distances when they are lightly disturbed on a roost, suggests that the one-legged stance is quite relaxing. Dunlins observed on particularly food-rich feeding areas in coastal Morocco, habitually hopped around feeding on one leg. Waders may roost during high water periods, spread out throughout the day or just at night. This depends on their feeding method, the pattern of prey availability and predator abundance. The roost-site may be an area of shallow water behind a reedbed, a high beach or sand spit, an open patch of sand or mud among tropical woodlands, or even the branches of mangroves. When not attached to a breeding territory, most of the migratory scolopacid waders have the habit of congregating on communal roosts at regular times. Roosting together may be a

consequence of a limited supply of safe roosting sites but may also serve biological functions comparable to those of feeding and flying flocks. High densities of birds shield each other from wind and cold, offer safety in numbers, enable the exchange of information about good feeding areas and, more generally, help the synchronization of daily and seasonal behaviour on the basis of information accumulated and shared by many different individuals.

In intertidal areas the feeding grounds are only available when the tide goes out. Scolopacid waders must use the low water periods to feed, and preen and sleep in the period around high water. Feeding may take place during day and night, but daylight feeding is preferred by most species. In a detailed study of the time budgets of waders on the Banc d'Arguin, Mauritania, in spring, A. M. Blomert and colleagues showed that even tactile feeders may spend less time foraging during night-time low waters than during daytime. They also demonstrated that scolopacid waders increase the fraction of total time spent feeding during the 4-6 weeks before their northward departure to the breeding grounds. This is accomplished by foraging throughout neap tides, when relatively unprofitable feeding areas remain available during high water periods, and by foraging more at night. In non-tidal coastal lagoons in Ghana, nocturnal feeding is common in many scolopacids. It is mostly used by species that detect their prey by touch. Visual surface-foragers feeding on small prey items, such as Wood and Common Sandpipers, spend over 75% of the daytime foraging. Several larger species including the Eurasian Curlew, Black-tailed Godwit and Common Greenshank, forage for less than 40% of the day. These and several other studies have shown that the fraction of time spent foraging is related to body size, with small waders spending far more time foraging than bigger birds. An additional factor is prey size, with species that eat small prey spending much more time feeding than species eating large prey, for example fish.

On the breeding grounds at the northernmost latitudes, the daily rhythms of scolopacid waders are quite different from those in the north and south temperate and tropical wintering areas. When the scolopacid waders are present in the Arctic, daylight is continuous. Upon arrival, exhausted after very long flights, they may sleep for half a day or so, but in the 6-8 weeks thereafter there is little time for rest. Incubating birds may take a nap, but overall, activity levels during the breeding period are extremely high. The details of daily rhythms vary with species and with the phase of the reproductive cycle. At temperate breeding grounds, diurnal rhythms of waders come closest to a "normal" 24 hour periodicity. For example, snipes show most display during twilight periods. Their bleating flights can best be heard during the early morning and the early evening, especially when the weather is clear.

Lumbricid earthworms commonly dominate the diet of the Eurasian Woodcock, since it generally resorts to other food items only when the soil is frozen and can not be penetrated by its long, pointed bill, or when the earthworms have crept out of reach in dry ground. Remarkably, this species is capable of consuming twice its own body weight in earthworms during a 24-hour period. While foraging is typically carried out by means of probing, the bird may also peck at the ground surface or rummage in the dead leaves.

Voice

In contrast to the tail-bleats of snipes, real wader songs sung during display-flights can be very melodious. A good example is the fluting of an Upland Sandpiper as it drifts over a sunny meadow in spring: first one hears some notes resembling the gurgling of water from a large bottle, then the loud "whip-whel-ee-you", long drawn out and weirdly thrilling. Then there is the "poor-me poor-me" of Red Knots ringing over snowfields and tundra, of which many authors have written that it is one of the loveliest of shorebird songs.

But the sounds of scolopacid waders have not always been appreciated by human observers. Black-tailed and Hudsonian Godwits with chicks, for example, have the habit of maddening human intruders to their territories with their loud, sustained alarm calling. Similarly, Lesser Yellowlegs (*Tringa flavipes*) respond to the presence of people with loud calls, chuckles, screams and yodels. Their larger relatives, Greater Yellowlegs, are so noisy that A. C. Bent reported that "many a yellowleg has been shot by an angry gunner as a reward for its exasperating loquacity". In the past, the Black Turnstone (*Arenaria melanocephala*), a noisy sentinel of the Pacific coast of North America, was often silenced for the same offence by hunters of sea otters.

There is a great difference between the vocal repertoire of woodcocks and snipes on the one hand, and that of the most other Scolopacidae on the other. Among the subfamily of snipes, Common Snipes advertise their presence from an elevation in the territory by a rapid "jick-jack" called "yakking". Except for the Great Snipe, all *Gallinago* species also display in the air during courtship, though aerial display is not restricted to the breeding season. Display-flights are accompanied by hooting, bleating, neighing or winnowing sounds that are widely believed to be non-vocal but made by the quivering tail feathers during high-speed aerial descents, but some of the sounds made during snipe display-flights may have a vocal origin. For instance, the courtship flights of Giant Snipes (*Gallinago undulata*) are like those of their smaller congeners but accompanied by trisyllabic sounds that are probably vocal. During their aerial display, Pintail Snipes (*Gallinago stenura*) combine the fizzing sounds of the tail feathers with several different vocal elements. The small Jack Snipe (*Lymnocryptes minimus*) makes distinctive sounds as it precipitously plunges downward from high in the sky. These sounds are reminiscent of the clopping made by galloping horses on hard ground, and since they are given from the ground as well as from the air, they are presumably vocal at least in part. Woodcock species make vocal beeps and purrs as they patrol their woodland territories during tree-top flights. However, during song flight American Woodcocks (*Scolopax minor*) additionally make twitterings that are produced by air passing between the three special attenuated outer primaries. In the sex-role reversed phalaropes, the number of vocalizations is relatively limited compared to most other scolopacid species. Phalaropes have no elaborate flight displays and songs. Among the sandpipers, the lekking Ruff and Buff-breasted Sandpiper must be reckoned the least vocal, even during the mating season. The highly decorated male Ruffs sometimes make indistinct nasal grumbling sounds on leks, in foraging flocks and during arrival at nocturnal roosts. Male Buff-breasted Sandpipers may utter similarly soft purrs as females fly over or leave a display area. Their quietness may help to avoid giving away the lek's position to ground-dwelling predators.

In order to advertise their presence and attract females, the males of the great majority of scolopacid waders perform aerial displays that are accompanied by vocalizations in the form of song. These displays usually have a complement enacted on the ground. Aspects of the ground displays, and the songs that go along with them, are carried out as pre-copulatory behaviour. In general, songs seem to be aimed to emphasize and enhance the visual signals made during aerial and ground displays. Even though the songs and vocalizations of many scolopacid waders remain undescribed to this day, the variation and complexity of known vocalizations is so great and so relatively poorly analysed, that for the present it defies an adequate summary description at the family level. Instead, it may be instructive to examine one fairly typical example of song flight of scolopacid waders in general and of calidrine sandpipers in particular, that of Broad-billed Sandpipers studied in the mosquito-ridden bogs of northern Sweden by B. W. Svensson. Males defend territories and attract mates by aerial display-flights at heights of 15-20 m. These consist of repeated alternations of brief episodes of wing-fluttering, and long descents during which the wings are held increasingly high above the body as the glide becomes steeper,

Members of the tribe Tringini do not usually catch their prey by probing, but instead use more visual techniques and, like plovers, run and snatch prey as soon as it comes into sight. When trying to catch small fish gathered in shoals in shallow water, several tringine waders show social foraging, during which they concentrate the prey into a small area by walking up together in rows. The Lesser Yellowlegs, however, is no communal fisher, each individual tending to chase its fish singly.

[*Tringa flavipes*, Long Island, New York, USA. Photo: Tom Vezo]

followed by rapid ascending flights. The staccato-like song during the glide is introduced by a brief chattering and followed by rhythmically repeated calls during the ascent and the horizontal early phase of the glide.

Aerial vocalizations are taken to an impressive extreme by Pectoral Sandpipers. The sounds and displays are described by J. P. Myers and were published in 1982 by *American Birds* as a unique combination of a sound-disk and a written article. Male Pectoral Sandpipers carry a breast-sac that is inflated during display flights low over the tundra. The sac is pumped up and down in the rhythm of the wingbeat, producing loud hooting, resonant, owl-like reverberations sounding like "oó-ah oó-ah oó-ah". Each syllable is separated by a moment's silence and is repeated 2-3 times per second for 10-15 seconds during a shallow descent towards a female standing on the tundra. After several such "bombing flights" low over the female, the male starts to approach her on the ground, making series of brief muted growls once every 1-2 seconds; these are sustained for several minutes if necessary. He then runs to her side, tail cocked, and if she stays he droops his wings, the breast-sac balloons down and starts to bounce, and with an escalated voice he utters a muted version of the aerial hoot against a background of growls. A copulation may follow shortly afterwards.

The singing of migratory waders may start in the staging areas, several days before take-off on the several thousand kilometre long flight to the breeding grounds. Such pre-departure vocal displays have been noticed in species as varied as the Short-billed Dowitcher, Bar-tailed Godwit, Western and Least Sandpipers, Dunlin and Red Knot. In several instances the vocalizations are accompanied by complete acts of ground or aerial display. Since it is likely that most long distance migrating wader species only pair up after arrival on the breeding territories, the functional significance of such early displays is unclear. It may be an uncontrolled expression of rising sexuality or it may function as a means of synchronizing the migratory behaviour of flocks.

At the start of long distance migration flights, waders assembling in flocks on the ground, or sorting out their initial flight formation in the air, may show intense calling. Some of the vocalizations refer to those made during flight displays, others are more reminiscent of contact calls. Although vocal intensity usually drops after the flight formation, often a V-formation or an echelon of 50-100 individuals, has been established, many species continue to make contact calls during their entire migration. On the basis of such calls, nocturnal migration intensity has been studied at various locations, for example on the island of Helgoland in the German Bight.

There are many other vocalizations that are important to scolopacid waders. Several are used in the subtle signalling that goes on between mates during the final stages of pair formation, before copulation and during nest-relief. There are special calls made during distraction displays, and there is an entire vocabulary of soft contact and loud alarm calls for the communication between parents and their chicks and vice versa. Within the parent-chick repertoire, a particular vocalization is made when the attending parent discovers a predator, nearby or still very far off. This makes chicks freeze on the spot, and this lasts until another call is made which signals that all is clear. When chicks are very young and still thermolabile, parent sandpipers make chuckling calls to collect them under the brood patch for warming-up. Similar soft and short contact calls are made by the foraging adults of many species that habitually feed in flocks, especially calidrine sandpipers. Another category of vocalizations consists of the harsh notes made during intra- and interspecific aggressive interactions. This includes frightening rattles uttered by Ruddy Turnstones during their hot aerial pursuits of intruders of their breeding territories. Similar rattles are made during interactions on the ground, and indeed during the rest of the year as well.

A final category of vocalization is the short calls commonly made by many scolopacid waders in the presence of hunting predators, especially on the non-breeding grounds. Such alarm calls may serve a function as warning signals to neighbouring relatives, as pursuit-deterrent signals that persuade hunting predators to move on, or as calls that incite and co-ordinate flocking. Waders feeding in close-knit flocks have softer alarm calls than species that tend to feed more widely dispersed. A detailed study of Common Redshanks indicated that their loud alarm calls are mainly directed at conspecifics, are used most in visually obstructed habitats, and that they result in the formation of flocks. In a tight flock the calling individual finds safety from hunting raptors, especially since callers are not more likely to be attacked than silent birds. Common Redshanks are less likely to give an alarm on attack by a Peregrine Falcon than by a Sparrowhawk:

This Ruddy Turnstone lives up to its name. With its wedge-like bill it lifts up stones and may also bulldoze away seaweed in its search for hiding invertebrates. This feeding technique requires not only a strong bill, but also strong muscles in the neck. Although specifically adaptated to rocky shore life, Ruddy Turnstones are well known for their highly opportunistic foraging habits, which frequently involve scavenging. Given half a chance, they will eat almost anything, including even soap washed up on the beach.

[*Arenaria interpres interpres*, Lake Constance, Vorarlberg, Austria. Photo: R. Kunz]

Little Stints normally feed by pecking very rapidly at tiny prey items, such as the larvae of dipteran flies and also small worms. They sometimes probe into the substrate, as this juvenile may have been doing, to judge from its tell-tale muddy bill. Little Stints can be highly gregarious, living in flocks of up to several thousand birds, but sometimes individuals will defend feeding territories and thus feed on their own. They are not usually shy and can be approached to within several metres by human observers.

[*Calidris minuta*, Taymyr Peninsula, Siberia. Photo: Jan van de Kam]

this makes sense since staying put is the best strategy to avoid the claws of falcons rather than hawks. Territory-holding adult Common Redshanks may incur long-term benefits by calling more than juveniles in the presence of resident Sparrowhawks, since calling birds reduce the profitability for the hawk of the territory area where the hawks' potential prey are repeatedly alarmed. That scolopacid waders subtly tailor both their vocal signals and their responses to the conditions they are in is also suggested by a study on Western Sandpipers that were exposed experimentally to alarm calls. Birds feeding closest to the salt-marsh, whence hunting raptors would be expected to start their surprise attacks, were most likely to fly away upon an alarm, even though they were farthest removed from the loudspeaker.

Food and Feeding

The great morphological radiation within the Scolopacidae reflects the fact that different species use different habitats and food types (see Morphological Aspects). In the course of evolutionary history over the last 40 million years each clade has pursued its favoured sort of excellence. Indeed, the very strict habitat requirements shown by some scolopacid wader species today are correlated with different sensory specializations that allow profitable and efficient exploitation of particular kinds of food. As a consequence the Scolopacidae, and the trophic resources on which they rely, have diversified to such an extent that it is difficult to see that an American Woodcock probing the turf of a thicket for lumbricid worms, Sanderlings on a beach in search of crustaceans exposed by the retreating surf and Red-necked Phalaropes darting and fluttering undaunted at the crests of breaking ocean waves, share a common ancestor, not even so very long ago.

Turnstones, with the stout tapering bills and strong neck musculature that make them expert overturners of stones and seaweed, sometimes seem to have turned into specialists of opportunistic foraging. Ruddy Turnstones will eat almost anything, and the list of things they have been observed to prey upon varies from soap, via gull excrements to human carcasses. So great is the variety that R. E. Gill wondered "what won't turnstones eat?" His feeding trials demonstrate that they indeed go for almost any edible item, but when a variety of foods is put on offer they have a preference for fresh fish and crustaceans. Ruddy Turnstones are also reputable egg predators, especially in colonies of Common (*Sterna hirundo*) and Arctic Terns (*Sterna paradisaea*) and Mew Gulls (*Larus canus*). In such sites they can additionally make off with food brought to the surviving larid hatchlings. The fact that turnstones have raided nests of Red Phalaropes suggests that even dispersed wader nests are not completely safe from them. In seabird colonies on small Pacific islands, Bristle-thighed Curlews may sneak eggs from beneath albatrosses as the latter briefly stand up to shuffle their feathers and resettle.

A Red Phalarope has once been seen to eat carrion in New York City, a form of behaviour that mirrors picking skin-lice and other crustaceans off surfaced whales, but phalaropes routinely obtain their food by a subtle scooping of small zooplanktonic animals from the upper layer of water. With swift pecks prey are captured within a water droplet, which is transported mouthwards by surface tension (see Morphological Aspects). During feeding, phalaropes often spin around rapidly, probably to bring deep prey closer to the water surface. During the breeding season, they feed on a great variety of arthropods, notably chironomid midges and spiders, which are collected from shallow water, or sometimes picked from relatively dry marsh or tundra. Non-breeding phalaropes congregate in productive water basins. These may be saline lakes with enormous blooms of brine-shrimps, areas of oceanic upwelling where high stocks of zooplankton are found, and areas of sea with surface swarms of euphausiid shrimps. Indeed, any oceanographic phenomenon that will concentrate zooplankton at the ocean surface will attract them. For example, Red and Red-necked Phalaropes like ocean slicks, lines of debris, algae and other floating objects accumulated on the zone of convergence between surface currents.

The phalaropes' way of transporting tiny prey items towards the mouth by moving water droplets may also be used by several small sandpiper species, for instance Western and Semipalmated Sandpipers. Outside the breeding season these birds feed on mudflats with soft upper layers of sediment. They feed by stitching, making rapid sewing movements with the bill, and do not take the bill out of the substrate to ingest individual prey items. Although the diet of most small sandpipers has hitherto eluded

Ingestion of hard-shelled prey items requires a strong muscular gizzard to crush the shells; the shell remains may then either be regurgitated as pellets or flushed through the intestine and voided as calcium-rich droppings. Some species are specialized mollusc-eaters, and go for shellfish as a rule. Others will take shellfish on occasion but are also well adapted to eating polychaetes and crustaceans. The Marbled Godwit, for example, has a varied diet combining bivalves with crustaceans, insects, annelids and leeches.

[*Limosa fedoa*, California, USA. Photo: Tom Vezo]

detailed description, the fact that amphipods, oligochaetes and small polychaete worms usually occur in high densities where small sandpipers concentrate their feeding suggests that these meiobenthic prey provide the bulk.

Small tringines, such as the Common, Spotted, Wood, Green and Solitary Sandpipers, are called sandpipers although they belong to the Tringinae. They are built as shanks, but their diet converges to a fair degree with that of small sandpipers. Small tringines eat a great taxonomic variety of small prey that are captured at the surface of water, wet sediments or shallow vegetation. Quite similar feeding habits are shown, but somewhat larger prey are taken, by Common Redshanks, Willets and probably Tuamotu Sandpipers. The large tringines such as the yellowlegs, Marsh Sandpiper, Common Greenshank and Spotted Redshank, and perhaps the rare Asian Nordmann's Greenshank too, provide the other extreme. They may feed on small invertebrates picked from surfaces, but during migration and on the wintering grounds they are also prone to operate in large flocks that make fairly synchronized movements to drive together, and feed on, pelagic schools of small fish in shallow water.

One tringine species is truly aberrant. This is the Terek Sandpiper that during migration and on the wintering grounds specializes in catching and eating small burrowing crabs. Since these crabs tend to be burrowed, for good reasons, at greater depths than where the slightly upcurved bill of Terek Sandpipers can reach, the crabs, when showing on the surface in order to feed or to court, can only be captured by surprise after short sprints on the part of the bird. In many coastal non-breeding areas, different species of curlew, notably the Whimbrel and Far Eastern Curlew, also concentrate their feeding on burrowing crabs. The profitable size of sentinel crabs fed upon by Far Eastern Curlews is much larger than the size of sand-bubbling crabs eaten by Terek Sandpipers, so much so, in fact, that in coastal areas of Southeast Asia and Australia where the three species occur together, Far Eastern Curlews do not even take notice of the small crabs favoured by Tereks, even though their relatively shallow burrows make them readily accessible to the curlews. A small curlew species like the Little Curlew lives mainly on arthropods other than crabs. Little Curlews, and Eskimo Curlews in the past, feed on the surface-living insect life of pastures, steppes and grasslands in their wintering areas in Australasia and South America respectively. Another curlew, the gravely threatened Slender-billed Curlew, may depend on the arthropods of temperate and Mediterranean steppe-like grasslands, but it can also feed on estuarine fauna.

Eurasian Curlews wintering on temperate and subtropical coastal wetlands in western Europe and West Africa, where crabs are not so abundant as in some tropical areas, feed on small bivalves and large polychaetes, in addition to the occasional shorecrab. Such a mixed diet is also typical of all the coastal wintering populations of godwits, whether the Marbled Godwits (*Limosa fedoa*) along the Pacific shorelines of California, the Hudsonian Godwits along the southern Atlantic shores in Patagonia, the Bar-tailed Godwits at the opposite side of the Atlantic in tropical West Africa, and in north-west Australia, or the Black-tailed Godwits in western Europe. Molluscs, especially bivalves and to a lesser extent the harder-shelled gastropods, dominate the diets of the clade of knots, including Surfbirds, Great Knots and Red Knots, and a few species of northerly wintering sandpiper, Rock Sandpipers in the Pacific Northwest and Purple Sandpipers in the Atlantic region. The two sandpipers and the Surfbirds have a preference for rocky shores, on which the small sandpipers also find much crustacean food between the mussel and algal beds. Red and Great Knots show a preference for bivalves buried in soft sediments.

The beach-combing Sanderlings make a living on small sandcrabs and similar crustaceans that live buried in sand in the wave-washed zone. These sandcrabs feed on small particles of organic material carried in the receding waves by sticking their antennae into the waves. Once the wave has washed back, the crabs withdraw their antennae and retreat beneath the surface. At the tail end of retreating waves just before the crabs retract, but when the water is shallow enough for access, they are most easily captured. This explains the Sanderlings' incessant running up and down in front of the waves. Sanderlings also take other invertebrates from sandy beaches, including isopods, amphipods, polychaete worms, and small bivalve molluscs. They also respond opportunistically to rich food resources such as fish drying in coastal villages. Another example is provided by the large quantities of eggs that horsheshoe crabs (*Limulus polyphemus*) deposit on the shores of Delaware Bay in May. This occurs just

as Sanderlings, Red Knots and Ruddy Turnstones are on their way north to the breeding grounds, and all three come together in great numbers to feed on this superabundant but temporary food resource, and store nutrients for further flight.

To detect small polychaetes and crustaceans buried in the sand, Sanderlings and related *Calidris* sandpipers possess a form of "remote sense". With the array of sensory receptors in the bill tips, Sanderlings have been shown to detect the vibrations of small polychaetes moving in the sand at distances of 2 cm from the bill tip. Red and Great Knots forage on soft intertidal sediments, and the hard-shelled molluscs that they are after do not usually move. Even so, Red Knots, with equally sophisticated sensory equipment in their bill tips, seem to have some sort of remote sense as well. Perhaps they detect the hard-shelled objects in soft sediments from the direction in which counter-pressure builds up as they push their bills in the substrate.

In coastal habitats, non-breeding Asian and Short-billed Dowitchers and Broad-billed Sandpipers constitute the typical polychaete-eaters; members of the ragworm family (Nereidae) are especially favoured. A different group of annelid worms fed upon by scolopacid waders are the lumbricids that provide much of the diet of woodcocks and snipes. Lumbricid worms are supplemented by insect larvae and adults, particularly beetles, which are captured by the birds' long rhynchokinetic bills on or in soft soils. American and Eurasian Woodcocks, and probably the other woodcock species too, habitually try to lure worms upward by trampling the ground with their feet, thus creating shallow funnel-shaped depressions. In difficult environmental conditions, for example when soils are frozen or covered with snow, woodcocks and snipes may rely to some degree on plant material such as seeds, buds and shoots.

Few scolopacid waders subsist on a purely vegetarian diet, but in southern Europe and tropical West Africa Ruffs and Black-tailed Godwits periodically eat only rice, mostly the grains spilled during the harvest; Ruffs may also take corn grains and ground nuts. On small dykes bordering rice fields in Guinea-Bissau, individual Black-tailed Godwits defend temporary feeding territories against conspecifics at heaps of harvested rice grains. In view of these rice-eating habits, in some Sahel countries Ruffs and Black-tailed Godwits are customarily considered pest species. Hudsonian Godwits are known to feed on aquatic vegetation in ponds along the coastlines of Hudson Bay and James Bay, and in the prairie provinces of Canada.

During late spring and early summer, when long distance migrating sandpipers arrive on their high Arctic tundra breeding grounds, where snow is just beginning to clear away and the summer cycle is just getting under way, the birds find themselves faced with rather lean feeding conditions. At this time many species that otherwise eat only animal food, may temporarily supplement their diet with seeds and shoots. It should be noted, however, that the stomach content analyses on which many diet studies of breeding waders are based must be biased in favour of plant food, simply because plant material is more difficult to digest and thus more likely to be encountered in stomachs; the most nutritious foods, the ones that are easiest to digest, do not show up. Nevertheless, even stubborn mollusc-eaters like Red Knots that turn to spiders and insects on the tundra, have been observed to pick and eat seeds and fresh horsetail shoots. Juvenile Red Knots were observed stripping seeds from grass stems using sideways sweeps of the bill during a short period in late summer on Ellesmere Island, Canada. Another example is provided by the rather similar Great Knot. In the summers of 1994 and 1995, P. S. Tomkovich discovered in north-eastern Siberia that adults, as well as large chicks, feed extensively on heather berries. Great Knots also eat the hard-shelled nuts of dwarf pine (*Pinus pumila*), which the birds find in the soil where they have been buried by Spotted Nutcrackers (*Nucifraga caryocatactes*); the nuts are crushed in the muscular stomachs of the Great Knots. Berries have also been the staple food of Eskimo Curlews during breeding, and especially during refuelling stops in Labrador, before their long flights south over the western Atlantic Ocean to South America. Similarly, southward migrating Whimbrels on Kamchatka and Sakhalin are called "berriers" by local hunters in view of their appetite for heather berries.

On the breeding grounds, the diet of adults of different species shows extensive overlap, which hints at relaxed competition in an environment that offers abundant resources during this time of year. Adults and their chicks both live on the spiders and insects that emerge over the summer, and their diet is fairly similar too. In most scolopacids, chicks gather their own food, and are merely brooded and guarded by one or both of their parents. The exception is provided by woodcocks and snipes, where parents bring lumbricid worms to their chicks. But even in these cases, the precocial young catch most of the food themselves, mainly in the form of small insects and worms. Before their first southward migration, scolopacid chicks are left on their own. How the ontogenetic development of food and habitat choice is steered by trial-and-error learning in combination with endogenously programmed instructions is a subject area that has not yet been studied in any wader species.

Whatever the developmental or ecological reasons behind it, there are sometimes clear-cut and repeatable differences between categories of a particular scolopacid species with regard to feeding techniques and diet. As an example, in Bar-tailed Godwits where the females are significantly larger than the males, females follow the waterline where they have highest success in catching polychaete worms. Males only forage on the exposed intertidal flats. This sexual segregation of feeding habitat has been observed in European estuaries and also in West Africa. The Ruddy Turnstone is the only scolopacid in which individuals have been observed to specialize in the use of particular feeding techniques. On a rocky shore in south-east Scotland wintering Ruddy Turnstones employ six different feeding techniques: flicking and bulldozing seaweed aside; probing; stone-turning; hammer-probing; digging; and surface-pecking. Females are more liable than males to turn over stones. Strikingly, high status birds resort more to the most profitable technique, flicking and bulldozing, than do birds with a low dominance status. Experimental temporary removal of dominant individuals suggests that the relative "weaklings" are in fact actively prevented by the "bullies" from using the best feeding techniques.

Successfully foraging scolopacid waders are predicted to select prey items that are profitable. Profitability is defined as the nutritional or energy equivalent divided by the time required for handling a prey item; "handling" refers to the time between prey detection and ingestion. If a discovered prey item has a profitability that is below the current intake rate, a bird would lower its long-term intake rate by accepting it. If waders are not threatened by starvation, they do best by eating only food items with profitabilities above the average, long-term intake rate. Depending on the size of the shorebird and its feeding style, profitability will vary with the taxon, size, body condition, quality and behaviour of the prey. In a comparative study of four scolopacid waders feeding on mudshrimps (*Corophium volutator*), Least and Semipalmated Sandpipers were predicted to select shrimps longer than 2·5 mm, Common Redshanks to select shrimps longer than 4·5 mm, and Bar-tailed Godwits to eat shrimps with a body length over 7 mm. As a matter of fact, all four predator species obliged. Obeying the profitability principle, the two small sandpipers ate the smallest mudshrimps and the godwits the largest. When different waders eat different size and age classes of the same prey species, the waders may indirectly compete for food. In European estuaries Red Knots may deplete small, up to one year old, bivalves to an extent that subsequently, when the remaining bivalves are older and larger and profitable for Eurasian Curlews and Eurasian Oystercatchers (*Haematopus ostralegus*), their densities are below the threshold where they can be economically harvested by the large waders.

Another issue is the relative digestibility of the prey. Invertebrates such as crabs and molluscs carry a good deal of indigestible calcareous matter and are unprofitable for this reason. Some tropical crabs escape wader predation by becoming so salty and unpalatable that they can walk in hordes on exposed sandflats without being captured and eaten by the Whimbrels and Terek Sandpipers roaming around in like fashion. Then there are other criteria which are not so easily measured as nutritional value. Prey carrying parasites that use scolopacids as intermediate hosts,

The Scolopacidae show a great and exciting variety of mating systems, including males mate with several females (polygyny), females laying eggs for several males (polyandry), and also social monogamy. A few species use a lekking system in which males display on an arena with the aim of being chosen by passing females. Once such lekking species is the Buff-breasted Sandpiper, which breeds from the Chukotskiy Peninsula east into northern Canada. In this species, the males do not fight among one another in order to gain ascendancy, but limit themselves to showing off their strikingly outlined white underwings to the females present on the lek-site.

[*Tryngites subruficollis*, Alaska, USA. Photo: Kevin T. Karlson]

are best avoided, even though the parasites may try hard to turn infected prey into effective extensions of their phenotype, by making them nicely available and highly profitable. Although this topic has hitherto scarcely been addressed by wader ecologists (see page 314), the fact that two genera of tapeworm are found only in shorebirds suggests the biological relevance of the interactions between waders and their parasites.

In stark contrast, scolopacid waders have featured prominently in classic studies on feeding dispersion and territoriality in relation to prey availability, competitor densities and other constraints, especially those by L. Zwarts, J. D. Goss-Custard, J. P. Myers and their respective research teams. For example, the problem of feeding territories of wintering Eurasian Curlews and Sanderlings was tackled in populations in which many individuals were colour-ringed. The system of linear beach territories maintained by Californian Sanderlings in winter proved particularly accessible for study. At very low food densities there are not enough buried crustaceans to make defence worthwhile. However, at high densities there are so many Sanderlings trying to feed, that defence would not be feasible because of high intruder densities. Along parts of the beach where food conditions are intermediate Sanderlings do maintain territories of which the size varies inversely with prey density: the higher the intrusion rate the smaller the length of beach that can be kept free of competitors. This suggests that feeding territories are not aimed to prevent absolute prey depletion by conspecifics, but rather to enhance temporarily food availability and feeding rate by reducing the disturbance of prey. A clear example of short-term benefits of feeding territories is provided by Dunlins that take up the defence of human foot prints against nearby flock members as soon as prints are made in soft mud. In such depressions polychaete worms have lost cover and can very easily be captured. Some Eurasian Curlews feeding on intertidal flats, especially long-billed females, may defend territories over the entire winter season and return to these sites from year to year. Such territories may serve the dual function of preventing long-term depletion and reducing interference. Interference effects may work through the short-term depression of prey availability as a consequence of the presence of many predators, or through direct aggressive and indirect evasive behaviour of co-occurring foragers.

The most important variable determining the abundance and dispersion of feeding waders is the availability of prey. As we have seen, availability is related to prey size, composition and behaviour, but availability can also be a direct or indirect function of substrate characteristics. For example, Dunlins find it easier to locate buried polychaetes and crustaceans in sediments that are soft and that are covered by a film of water. Most probing waders have difficulty in foraging in sediments that are either unsorted, with lots of small stones or shell fragments, or in sediments that are stuffed with the sandgrain tubes of tube-living polychaetes. Indirectly, sediment characteristics affect the amount of detrital organic material and thus the growth of the invertebrate food organisms, as well as affecting the depth of living of burrowing creatures in other ways. For example, the North Atlantic intertidal bivalve *Macoma balthica* lives deeper in sandy than in muddy sediments, and is therefore easiest to obtain on the muddy foreshore. In addition, there will be seasonal variation in prey availability owing to depth differences and growth. In a remarkable megastudy sustained over a full seven years, L. Zwarts and his team measured the availability parameters of a whole intertidal macrobenthic community on a site in the Wadden Sea, in the Netherlands, and managed to combine this with studies of the presence and the diet of waders. Apart from a wealth of insight about predator-prey relationships on tidal flats, they come to the conclusion that despite the abundance of waders on intertidal flats, such areas provide them with a poor and unpredictable dinner table, especially in winter.

Perhaps, a poorly laid table is exactly what one would expect if scolopacid waders and their prey have been evolutionarily exposed to each other for long periods of time. In all predator-prey relationships, for the prey their lives are at stake, but for the predators only their meals. Thus, prey species exposed to particular predation pressures should have evolved the traits to minimize the risk of dying because of those pressures. If scolopacid waders are a regular and important component of the communities in which they live, rather than a transient phenomenon that takes what is given at any one time, the continuing evolutionary arms race will ensure relative scarcity. Predatory roles can sometimes be dramatically reversed when bivalves damage or kill bivalve eaters, by closing their valves around part of a foot or around a bill. Mussels and cockles can hold their valves clasped tight for long periods, and are frequently reported to have wrecked Dunlins and Red Knots.

Another layer of complication can be added by the realization that food scarcity is not only related to food availability, but also to the predators' nutritional and energetic demands. A small sandpiper requires 3-4 times as much food at temperatures below 5°C than above 20°C. In the tropics the energy demands of scolopacid waders are thus much lower than in temperate climates, especially in winter. In sheltered habitats where there is no wind, energy requirements are reduced relative to exposed shorelines and mudflats, particularly when it is cold. Finally, during fuel storage before long distance flights the required intake also goes up by a factor of two to four. Higher energy demands imply that the lower thresholds of available prey densities that can be accepted go up too: in cold weather and during migration waders should become more choosy.

The size of organs in scolopacids is rather flexible (see Morphological Aspects), a characteristic that comes into play in the course of their annual cycles. When lower demands no longer necessitate large machinery to keep the food processed and the body going, the birds reduce the size of parts of that machinery, the organs. Smaller metabolic machinery has the added benefit of being cheaper to maintain, thereby further reducing the food requirement and the choosiness with regard to suitable habitat. The energy that is necessary to maintain a body can be measured as the basal metabolic rate. This is the rate of oxygen consumption of thoroughly resting waders at congenial air temperatures. Scolopacid waders have relatively low basal metabolic rates during their stay in the tropics, but the same species have high levels when wintering at temperate latitudes. Similarly, woodcocks living in sheltered forests have a lower basal metabolic rate than equal-sized waders living exposed on intertidal flats at the same latitude.

In most conditions, a diet of animal matter suffices. However, during the pre-breeding period, the normal diet of scolopacids may not yield enough calcium for egg-formation. S. F. MacLean found many lemming teeth and bones in the stomachs of pre-laying females and growing chicks of four tundra-breeding sandpiper species in northern Alaska, and no such skeletal remains in males, fully-grown chicks or non-laying females. As an alternative to eating calcium-rich bone fragments to enhance their laying performance, female sandpipers might also store labile calcium in their own skeletons before egg-laying. Evidence for this has recently been obtained for Red Knots.

Breeding

The observations by E. Selous on the breeding displays of Ruffs published in 1906 and 1907 report the first modern ethological studies of reproductive behaviour in birds. His observations on breeding scolopacid waders were soon followed up by two of the founding fathers of modern evolutionary biology and ethology. J. S. Huxley studied the display behaviour of Common Redshanks and Black-tailed Godwits, while N. Tinbergen published a long paper on breeding Red-necked Phalaropes in Greenland. In recent decades, scolopacid waders have been widely recognized as an interesting group showing an especially wide variation in reproductive strategies. This has led to detailed comparative studies of causal and functional aspects of the various and variable breeding patterns.

Many of the Scolopacidae have a reproductive strategy that most of us take for granted as being the basic, "normal" strategy: they form monogamous pairs. Monogamy is the rule for Jack Snipes, Common Snipes, Common Redshanks, Black-tailed Godwits, Long-billed and Eurasian Curlews and many other spe-

Woodcocks provide an exception to the rule that scolopacid waders live in open habitats. This roding Eurasian Woodcock patrols its territory in deciduous woodland with plenty of undergrowth and moist soils. The woodcocks show specific adaptations for life in a woodland setting: the eyes are located high in the skull and allow the bird a complete view of the sky, facilitating detection of approaching predators; the elliptically shaped wings provide the means for a "rocketing" take-off amidst a dense tangle of twigs and small branches, in case a predator should approach too close for comfort; and the basal metabolic rate is relatively low, constituting an energy-saving adjustment to a sheltered life in the woods.

[*Scolopax rusticola*. Photo: A. Christiansen/ FLPA]

cies. However, this common arrangement belies the great flexibility of the reproductive systems of scolopacid waders, even within species where most individuals do establish monogamous pair-bonds. For example, female Sanderlings can produce one, two or three clutches per summer season. In this species monogamy prevails, but females may also mate sequentially with different males, the first clutch being sired by one male, the second by another and so forth. Having laid two clutches, the female often departs from the breeding site shortly after the males have started incubation, and males are thus fully responsible for all parental care. Alternatively, females may lay twice and assume full care of the second clutch themselves. When a single individual of one sex reproductively claims more than one individual of the other sex, the system is called polygamous. Systems in which females pair up with more than one male, as in the Sanderling example, called called polyandrous. When males pair with more than one female, the system is called polygynous. At the extreme end are polygynous systems in which the only thing that one of the sexes contributes is sperm. This happens in promiscuous lek-breeding waders where males compete with one another for access to fertile females, but otherwise do not contribute reproductively.

In phalaropes male parental care is the rule, and it is the colourful females that defend the territory and display. Females will try to produce clutches for more than one male, and so they court, harry and pursue the males. They do so to the extent that male Wilson's Phalaropes have developed a special wing-fluttering display that signals to females that they are unavailable as mates. Such a polyandrous system with an exchange of "normal" sex roles is shared with Spotted Sandpipers and perhaps a few other scolopacid wader species, such as Upland Sandpipers and Spotted Redshanks. J. R. Jehl recently uncovered an explanation for the polyandry of Wilson's Phalaropes. It was published in 1923 in a respectable scientific magazine and tells an interesting tale about the reproductive attitudes of human society in some places around that time. The large numbers of female phalaropes seen in summer on the Great Salt Lake in Utah were considered to represent non-breeders, rather than the post-breeding birds in moult that they are now known to be. The atrophied, non-functional ovaries found in dissected females were taken as proof of a venereal disease that was thought to have its origin in the "strange excess of *libido* which has brought the females of the species to their musky perfection of size and power". With so few healthy females around on the breeding areas, the poor phalarope males were thus forced to accept at least one rival male partner if they were to breed at all.

The bewildering diversity of parental care and reproductive social systems within and among the species of Scolopacidae can be explained with respect to intricate webs of interactions between ecological conditions, fitness advantages and sexual

Ruffs are easily the most variable of waders and they are also perhaps the weirdest. Males are some 25% larger than females, which are known as Reeves. The reproductive process is all rather complicated and extremely spectacular, involving groups of males competing for potential matings on leks. With their colourful and endlessly variable ruffs, head-tufts and wattles for display, and with their wings and strong legs as armour and weapons, individual males defend small parts of a lek. Males come in two behavioural categories: the "residents" or "independent males" that defend an area on the lek; and the "satellites" that do not defend their own court but which are tolerated in the arena and can then "steal" matings. Satellite males are somewhat smaller than residents and usually show white or light-coloured ruffs and tufts. The group of extravagantly displaying males has often been said to bring to mind a medieval court full of strutting dandies.

[*Philomachus pugnax*, Workumer Waard, Netherlands. Photos: Günter Ziesler/ Bruce Coleman]

selection. For example, in conditions of much food, low costs of living and few predators, a single parent will be able to raise a brood, so that females can afford to leave their mates after clutch delivery, start another clutch with a second male, or breed on their own. In populations where some females are polyandrous, there will be competition between females for males, and this may open the way for the evolution of competitive traits such as intense coloration and increased size, as in female phalaropes. Relatively congenial ecological conditions would also allow for male emancipation from breeding activities, as occurs in lekking species like Ruffs and non-lekkers like Curlew Sandpipers and White-rumped Sandpipers.

Over the last 20 years, an ecological framework for the evolution of social organization in calidrine sandpipers, all of which breed in the Arctic, has been developed by F. A. Pitelka, P. S. Tomkovich and their respective associates. A distinction is made

The rival males adopt a series of stereotyped postures, such as the "Upright-posture", the "Forward-posture" and the "Tiptoe-posture", which have certain slight variants, and may be combined with actions such as "Bill-thrusting", "Tail-trembling", "Wing-lifting" and a "Strut-walk" display. Upon the arrival of females, or other males, the males will perform "Wing-fluttering", in which the wings are opened, raised and lifted backwards, as can be seen in some of these birds. Higher intensity forms of this greeting ceremony are "Flutter-jumps" in which the bird spreads its wings more fully and jumps into the air, and a "Hovering-display" whereby the bird may rise a few metres into the air, although at the cost of its white underwing being less visible; both of these variants are also visible here. Except on very small arenas, actual fighting is generally rare; it involves birds jumping at each other, often striking out with the claws towards the opponent's bare facial skin, and sometimes drawing blood. The females visit the leks for the purpose of mating. Once they have received the sperm, they take on the entire responsibility of caring for the eggs and chicks without help from any male. The intriguing behaviour of male Ruffs at the lek has invited much detailed research, and has now been shown to have some genetic basis.

[*Philomachus pugnax*, Workumer Waard, Netherlands. Photos: Günter Ziesler]

between "conservative species" that show monogamy, high site fidelity in males, the defence of overdispersed breeding territories, and minor population fluctuations from year to year, and "opportunistic species" that show polygamy and promiscuity, low site fidelity, a pattern of clumped dispersion, and large year-to-year fluctuations in abundance. The latter species concentrate in areas where environmental conditions happen to be favourable in a particular year. In this view, reproductive strategies of sandpipers primarily reflect variations in amount and dependability of food resources in the Arctic modified by intensity of nest predation.

The fact is that those sandpiper species in which one of the partners departs early from the breeding grounds, and also those that deviate from monogamy, migrate farther than biparental monogamous species, which suggests that the relative investments made by males and females do not depend merely on eco-

Not all shorebirds copulate in silence. Female Willets have been heard making rather soft grunted exclamations during copulation, and the male emits a sort of jaunty clicking, said to be reminiscent of a man snapping his fingers. The intimacy of the occasion can sometimes end abruptly, when the female throws off the male, forward over her shoulders, whereafter the irritated male may attempt to continue in a rougher manner.

[*Catoptrophorus semipalmatus inornatus*, Inyo County, California, USA. Photo: John Gerlach/DRK]

logical circumstances in the breeding areas. Sex role division may also depend on factors like the distance to and from the wintering areas, which may differ between the sexes, and the extent to which mates are engaged in sexual selection games. Long distance migration, as well as the development of extravagant secondary sexual characters and display, divert nutrients away from reproduction proper, and thus set additional constraints on the way parental roles must be shared or can be divided. In addition, evolutionary explanations for any specific reproductive system have to take historical constraints into consideration. For example, J. G. van Rhijn has argued that the ancestral state of birds is pure male parental care. This system can evolve into biparental care with identical roles for the two sexes, via uniparental care where females take over if males desert, or via double-clutching. The latter system, nowadays seen in Temminck's and Little Stints and Sanderlings, is perhaps the original pattern in scolopacid waders. Lek systems where females perform all the parental care may have evolved from double-clutching systems where there is intense competition between males.

Of the three ground-lekking scolopacid wader species, the Great Snipe, the Buff-breasted Sandpiper and the Ruff, the last species is the most extreme and has been studied in greatest detail. Male Ruffs not only come in innumerable different plumage colours, but also in two distinct behavioural types. "Independent" males defend lek mating courts against other independents, whereas "satellites" are non-territorial males that move between, are recruited to, and share the courts of independent males. Satellites are slightly smaller in size and have pale coloured or white tufts and ruffs, whereas independents are more pigmented. By carrying out cross-breeding experiments between the two forms in captivity, D. B. Lank, C. M. Smith and colleagues showed that environmental factors can not alter a chick's development into a satellite or an independent male. Instead, the two plumage-linked reproductive behavioural strategies of Ruffs have a simple genetic basis. That independent males clearly display their sex, whereas satellites seem to mimic female behaviour, has led to the suggestion that the alternative strategies may have derived from a double-clutching system where females select males with good care qualities (later becoming the satellites) for the first clutch, and males with other good genetic properties (independent males) for the second clutch. In contrast to Ruffs, Buff-breasted Sandpipers are monomorphic and males do not engage in the courtship battles so typical for Ruffs. When females arrive near a lek, all resident males start flashing their white underwings against the tundra's brown background. The rest of the courtship of Buff-breasted Sandpipers involves much fluttering and the stretching and turning of open wings.

The fact that many sandpipers arrive unpaired on the breeding grounds and begin nesting within a few days after arrival may indicate that there is selection for rapid pair formation, possibly in view of the short northern breeding season. Apart from the three ground-lekking species, in the many scolopacid waders that breed in open habitats where there is a definite lack of elevated perches, the competing sex tries to attract the choosing mate to the territory through persistent flight singing, which is followed by ground displays associated with nest-site selection. Temminck's Stints and several other species often use perches, provided by dwarf willow and alder, for singing, whereas Dunlins use mossy hummocks. In addition to attracting females, aerial courtship flights and perch-singing also help to establish the boundaries of territories. Aerial courtship varies from the rather discrete butterfly flights low over the female's head in Baird's Sandpiper to the wild pursuit flights of Curlew Sandpipers; during the only two weeks of the year that males of the latter show up on the breeding grounds, they relentlessly, even in small groups, pursue single females until copulation. Display flights are lacking in turnstones.

It is difficult to think of a greater contrast with these systems than that provided by the Subantarctic (*Coenocorypha aucklandica*) and Chatham Snipes (*Coenocorypha pusilla*), species that live on oceanic islands off New Zealand. The islands are free of predators and in this stable environment the snipe populations are limited by intense competition for food. Instead of making costly aerobatic display-flights, the male displays his quality by bringing food to the female as part of the courtship ritual. Both sexes take part in incubation and the care for chicks; *Coenocorypha* chicks are fed over a period of at least 40 days and take even longer to fledge.

Coition usually takes place on the ground, though Eurasian Curlews have been observed to attempt aerial mating. Waders may copulate several times a day over a period of several days in some

Red-necked Phalaropes have a polyandrous mating system, in which the colourful female produces clutches for more than one of the dull-coloured males, each male taking on the responsibility for all of the parental duties. Females are not only more colourful than the males, but also defend a territory, perform displays and pursue potential partners in ways that normally tend to be associated with the role of the masculine sex.

[*Phalaropus lobatus*, Varanger, Norway. Photo: Jan van de Kam]

species, and only once or twice in others, though little information has been collected on this aspect. In polyandrous species, such as the Spotted Sandpiper, copulation rates are high, presumably because males compete to fertilize the female's eggs. In view of the possibility of extra-pair copulations, even males of monogamous species can not be completely sure that all hatched chicks are theirs. As a means to ensure paternity, males must try to inseminate their female partners around the time of ovulation, a few days before the eggs are laid, and prevent other males having access to their fertile partners. Again, in Spotted Sandpipers this is a particularly relevant problem since not only does a female try to monopolize more than one male, but the males are also subsequently responsible for all parental tasks. L. W. Oring and associates found that copulation rates of Spotted Sandpipers peak on the day before the eggs start to be laid, and that males engaged with females that are often absent from the territory mate most frequently. That males show little evidence of mate-guarding during egg-laying may relate to the discovery, using DNA fingerprinting, that males pairing early in the season cuckold their females' later partners by means of their stored sperm.

Most shorebird nests are nothing more than a vague depression or scrape in the open ground, scantily lined with soft pieces of vegetation, and barely deep enough to hold four eggs. A large species like the Marbled Godwit merely stamps the grass flat and sits down. In contrast, Baird's Sandpipers have been found to make nice nest cups in thick cushions of *Dryas* plants, whereas Nordmann's Greenshanks build large nests from twigs and bearded lichens in larch trees. Scolopacids may thus use a wide variety of nest-sites, even in the far north where the rather uniform habitats seem to offer limited choice. Several species such as the Little Stint and the Curlew Sandpiper like wet marshy ground, while others nest on nearby dry uplands, including bare stony tundra. Sanderlings, Red Knots and Ruddy Turnstones prefer the latter, although in Finland and Sweden Ruddy Turnstones nest almost exclusively in colonies of gulls and terns. Surfbirds inhabit rock slides, Wandering Tattlers like gravel bars in mountain river beds above the tree-line, Spotted Sandpipers nest among vegetation in the vicinity of fresh water, and American Woodcocks nest in forests on soft ground not far from the base of a tree or shrub. Species that nest in grassland are at pains to bend grasses over the nest so that they become invisible from above. Wood Sandpipers have a tendency to nest on raised tussocks in dense vegetation and may occasionally even nest in an old thrush nest in a tree. Solitary and Green Sandpipers and Grey-tailed Tattlers (*Heteroscelus brevipes*) as a rule make use of nests left by thrushes or other species in spruce or other dense trees. These exceptional species regularly breed at heights of more than 10 m, and only occasionally on the ground among tree roots.

Scolopacid eggs are pear-shaped, so that the pointed ends of three or four of them neatly fit together in the centre of a nest scrape. Pyriform eggs also have the advantage of rolling in circles and never far away. The ground colour of shorebird eggs may vary from buff and pale green to red or purple. In most species eggs are blotched earthy brown at the blunt end and scratchily marked elsewhere. These random streaks and squiggles break up their outline. Unlike in thrushes, the eggs of tree-nesting Solitary and Green Sandpipers have cryptic markings too. The coloration and pattern of sandpiper eggs is very variable even within species, but is rather constant for individual females.

Scolopacid waders share with other shorebirds the habit of not laying more than four eggs per clutch. Fewer are laid by the dowitchers, and the snipes and woodcocks of temperate and tropical latitudes. The smallest clutch size is reached by the *Coenocorypha* snipes that lay two relatively large eggs that take a long time to incubate and hatch. The size of the clutch of scolopacids is fixed, and is not adjusted in response to external conditions. Nutritional constraints during egg formation have traditionally been invoked to explain why scolopacids only lay two, three or four eggs, and this may indeed partially account for the two-egg clutches of *Coenocorypha* snipes. It has also been suggested that brood patch size limits the number of eggs and chicks that can be successfully brooded, to a maximum of four. Small clutches might be adaptive when the rates of nest predation are high, since larger clutches are exposed to the risk of predation for longer periods, and small clutches are replaced more easily when lost.

Full incubation starts only when the clutch of 2-4 eggs has been completed. During the first week of incubation eggs can still survive periods of serious cooling. In monogamous biparental care systems, both partners share incubation duties usually fairly equally. The duration of uninterrupted incuba-

As with this Short-billed Dowitcher, all scolopacid waders lay clutches of four eggs, never more. The formation of eggs requires a great deal of calcium, and this may be a limiting nutritional component in birds engaged in the business of egg-laying. Some female sandpipers breeding in the Arctic appear to overcome this problem by ingesting lemming teeth and bones found loose on the tundra, but they may also store calcium in advance of egg-formation, perhaps accumulating it within their own skeletons.

[*Limnodromus griseus hendersoni*, Churchill, Manitoba, Canada. Photo: Ralph A. Reinhold/ Animals Animals]

tion bouts is variable between species and breeding areas. Some of the high Arctic nesters may remain on the nest for periods of 15-18 hours per session. Single incubators like female Curlew Sandpipers and male phalaropes regularly leave the nest to feed. Also incubating alone, female White-rumped Sandpipers increase the time spent on the nest early and late in the day, and make most feeding trips in the middle of the day when air temperatures are highest.

Many of the Arctic breeding scolopacids are not afraid of humans. For example, Western Sandpipers and Little Stints may crawl under a hat placed on their nests, while female White-rumped Sandpipers may attack an approaching hand. Some well camouflaged species sit extremely tight when approached by potential predators, whereas others leave early, either discretely or calling loudly. Nice contrasts are provided by three species breeding in high Arctic Canada. Ruddy Turnstones tend to leave the nest when an approaching human or fox is still very far away. Disturbed birds will approach the intruder and give intense alarm calls. The abandonment of the nest by Baird's Sandpipers is very discrete, and these birds may not be seen leaving at all. Red Knots commonly remain tight on the nest until they are almost stepped upon. Even repeated nest visits make them no more wary; they have complete trust in their excellent camouflage. Red Knots share with Great Knots, Surfbirds, White-rumped Sandpipers, Long-billed Dowitchers and Willets the technique of sitting close to the final second, then to "explode" in the face of the intruder. The Alaskan breeding range of the Surfbird overlaps extensively with that of Dall mountain sheep. The first nest ever found in 1926 was within a metre of one of their trails. The pair of Surfbirds at this nest kept exploding at the sheep at very regular intervals. Large species, such as Long-billed and Bristle-thighed Curlews and Marbled Godwits, sit very tight as well but do not explode upon disturbance; instead, they hurriedly fly away, calling loudly.

Certain tundra-nesters, when disturbed by potential nest robbers such as Arctic foxes (*Alopex lagopus*), Snowy Owls (*Nyctea scandiaca*) and humans, react with a true distraction display called the "Rodent Run". Purple Sandpipers are the acknowledged masters of this behaviour. They jump into view 1-2 m from the nest and zig-zag away, feathers fluffed like fur and squeaking like a mammal; the black line that splits the white rump of many *Calidris* species even resembles the dorsal stripe of a fleeing lemming. Some species such as Sanderlings and Red Knots do not usually run like rodents but reveal themselves fully with loud squeaks when they are some distance away from the nest. They spread the tail, and feign injury by drooping their wings and flapping them on the ground. They also show "False Brooding".

Skuas, crows and hawks, dangerous intruders of the neighbourhood of nests or chicks, are pursued in the air by some of the larger species, in what is called predator-mobbing. Among the *Calidris* sandpipers this is shown only by Red Knots, but also by godwits, curlews, large tringines, and, of course, the turnstones. Ruddy Turnstones are suspected of boring their bills into the anal openings of these predatory birds. This would explain why victims scream so loudly and disappear so swiftly after aerial encounters with turnstones.

After about three weeks of incubation, somewhat shorter in the small species and a few days longer in the large species, the eggs pip and all four chicks hatch within about a day. To ensure that the strikingly white insides of the eggshell do not attract the unwanted attention of predators, the empty shell is carried away by one of the parents as soon as the wet chick has left it. Wader chicks are highly precocial and are able to walk and pick up food items within a few hours of hatching; indeed, a Spotted Sandpiper chick was seen teetering 31 minutes after hatching! The chicks usually lose some weight during the first day of life when they catabolize the little yolk that remains in their belly cavity at hatching. Their precociality means that scolopacid

chicks grow 3-4 times slower than altricial passerine birds, since fast-growing tissue can not do much work or generate heat. In spite of this, small chicks are still thermolabile. They are not able to keep up their core temperature of about 40°C for very long at low air temperatures. After periods foraging in cold conditions, the body temperature of small chicks drops below 30°C, so that the chicks must return to the parent before they become lethargic. Under the father or mother the chicks are heated up with their necks pressed against the brood patch. Thermolability means that in colder weather conditions chicks must be brooded more often, have less time to feed, and thus grow slower. Chicks of small calidrines may take almost two weeks to become thermally independent, whereas those of the large species such as godwits and curlews reach this point within a week. Species differ considerably in the susceptibility of their chicks to cold. Young of high Arctic breeding species still grow at fast rates in weather conditions during which temperate wader chicks would surely die. Depending on adult body size, after two weeks of growth in small species, to five weeks in large species, the young bird is ready to fly, even though its flight-feathers take a few more days to complete growth fully.

The care-taking parent guards the chicks and gives them alarm calls warning them to hide and stay immobile when predators are in the vicinity. The parent also broods the chicks when their body temperatures have dropped too low. In scolopacids nesting in open habitats such as tundra and grassland, the families move around over large areas, perhaps as an adaptation to avoid "stationary" predators such as Rough-legged Buzzards (*Buteo lagopus*) or Arctic foxes that may re-search areas where they previously had success. Only in woodcocks and snipes are chicks fed by their parents. Snipe broods are usually split up, the parents separately taking care of half of the brood each. The recurring suggestion that the American Woodcock and its relatives routinely carry their chicks in flight is believed to be a myth by some specialists; wildlife biologists who observe and ring hundreds of broods apparently never see it. If it does occur in any of the woodcocks or snipes, it is probably accidental and quite unusual.

As soon as chicks are old and mature enough no longer to require brooding, the broods of different parents and even of different species may come together in crèches. This has been described for several tundra-breeding long distance migrating scolopacid species such as the Least Sandpiper, Bar-tailed and Hudsonian Godwits, Whimbrel, Bristle-thighed Curlew and perhaps Ruddy Turnstone and Red Knot. In the Bristle-thighed Curlew in Alaska, chicks quite often come together with other locally breeding wader species, especially Bar-tailed Godwits and Whimbrels. Regularly, one or both of the parents leave their chicks, which then remain attended by another curlew, usually a male. The formation of such wader crèches is probably no "accidental" response to highly localized food, but seems to serve the function of predator defence by means of more effective detection and shared mobbing. The formation of brood amalgamations also allows some adults, enforced by severe nutritional depletion, to desert their young early.

At fledging or immediately afterwards, young scolopacids are left alone by the last of their attendants. Most adults have departed on southward migration before the young have stored sufficient fuel to embark on the same trip. Brood amalgamation thus also helps the young to establish flocks with which to migrate to the distant non-breeding areas, thus minimizing energy expenditure and enhancing orientation. For Spotted Sandpipers there is evidence that siblings remain associated for at least part of their first year. In spite of the fact that young migrate by themselves, the southward flights can still be very rapid. On the *pampas* of Argentina, Pectoral Sandpipers still carrying yellow natal down on the head were seen by the end of August, no more than a month after they could have fledged in northern Canada. The chicks do not become imprinted on their attendants as happens in the equally precocial chicks of geese, where families stay together over the whole winter. K. Lorenz reports that chicks of the Eurasian Curlew can not be brought to respond to their keeper in any way other than attempted escape, even when they are hatched artificially and have never seen any other living creature.

In most scolopacids, less than half of the fledglings survive the first year. In some species, Common Sandpipers and Little Stints for example, the survivors return northwards to breed as one-year-olds. In many other species, juveniles remain on the southern wintering areas or make incomplete northward migrations, to return "home" only when they are two or three years old. In most species where this has been examined, juveniles

Spot the Sanderling! With its perfectly mottled plumage, this incubating bird merges most effectively into the Greenland tundra, and indeed it relies fully on camouflage to remain undiscovered by predators. Highly gregarious outside the breeding season, Sanderlings lead a lonely life on the vast open spaces of the Arctic tundra while they are breeding. In fact, even in their winter flocks they may have no "friends", since these flocks appear to be composed of randomly associated individuals.

[*Calidris alba*, Greenland. Photo: Hubert Klein/Bios]

Scolopacids commence incubation only once the clutch has been completed, so that the nidifugous chicks all hatch in a brief period and are all ready to leave the nest at about the same time. The duration of incubation is approximately three weeks, a little more or less depending on the species. In the Stilt Sandpiper the period has been found to be 19·5-21 days, the male sitting during the day and the female at night. This species shows a high degree of fidelity, both to partner and to breeding site, with about 15% of the birds reusing the nest scrape from the previous year.

[*Micropalama himantopus*. Photo: Tom Vezo]

show rather little natal philopatry or hatch-site fidelity, although Rock Sandpipers and some populations of Dunlins show it quite strongly. A return, year after year, to the same breeding site may be beneficial in view of the enhanced familiarity with local environmental factors such as food, cover and predators, enhanced familiarity with local conspecifics and enhanced competitive ability as a consequence of local dominance. Since chicks have not had the chance to build up much of this sort of experience, it makes sense that they are not as faithful to the natal area as adults are to the previous breeding territory. This will be especially the case for males of what we have earlier described as conservative, monogamous species, which usually show high breeding site fidelity. In contrast, species that are not strongly site faithful are characterized by uniparental care and little territorial behaviour. As is true for most birds, females are much less site faithful than males. Since males and females are unlikely to return to a previous territory, they can not form long-term pair-bonds, which are indeed never reported in scolopacid waders.

In 1979, C. S. Roselaar published a short paper in Dutch in which he pointed out that the numbers of Curlew Sandpipers observed in autumn in the Netherlands peaked approximately every three years. He proposed a functional link with the famous three-year Arctic lemming cycles. A couple of years later the idea was corroborated by R. W. Summers and L. G. Underhill, who demonstrated correlations between rough indices of lemming abundance in Arctic Siberia and juvenile proportions of wintering populations of Brent Geese (*Branta bernicla*) in western Europe, and Curlew Sandpipers, Sanderlings and Red Knots in southern Africa. They suggested that densities of predators such as skuas, gulls, Snowy Owls and Arctic foxes build up during lemming peak years. During the following summer, after the collapse of the lemming populations, these predators would be forced to switch to more unprofitable prey: the eggs and chicks of waders and geese. This hypothesis has since received empirical underpinning from studies on the Siberian breeding grounds, where indeed few eggs and chicks survive the onslaught of hungry predators in seasons following lemming peak years. Variable recruitment at the population level may even be a feature of temperate breeding wader populations. In the Netherlands, chick survival of grassland-breeding scolopacids is lower in years with small vole densities, a phenomenon that is also attributed to the vole-eating predators switching to eggs and chicks.

Scolopacid waders are comparable in that almost all species have a clutch of four eggs, that they start breeding when 1-2 years old, and that they live quite long. Aspects of their population dynamics have been studied at many locations during different phases of their annual cycle, including a 27 year long study of the breeding biology of Common Greenshanks in Scotland, but science can boast about rather few comprehensive analyses of scolopacid demography. The team of L. W. Oring has studied the breeding and population biology of several scolopacids, and spent 17 summer seasons following a population of polyandrous Spotted Sandpipers on Little Pelican Island in Leech Lake, Minnesota. In this species, males as well as females live up to nine years, but females have more mates, eggs, chicks, fledged young, and young returning in subsequent years than do males. Females produce an average of 5·2 fledglings over an average of 3·0 reproductive seasons; for males the values are 3·3 young over 2·8 seasons. Reproductive lifespan and the proportion of chicks that fledge determine their lifetime reproductive success. Compared to other scolopacids, the Spotted Sandpiper can be considered a pioneering species that quickly and frequently colonizes new sites in response to reproductive failure at a previous breeding site, breeds first at an early age, lives a relatively short time, lays many eggs per female and has low nesting success. The Common Sandpiper of Eurasia shares most of these characteristics. In the only study on lifetime reproductive success of scolopacids in the Western Palearctic, female Common Sandpipers in England were shown to rear on average about 3·5 fledglings per lifetime. This is just enough to balance mortality in this population. As in their spotted congener, the longer a female lives, the more fledglings she produces. Over half of the fledglings were produced by just 14% of the females.

Compared to temperate breeding songbirds and other birds of similar size and with similarly high rates of energy expenditure, scolopacid sandpipers reach rather advanced ages, most species easily showing longevity of 10 years. This characteristic is shared with other charadriiform birds and is interpreted by A. A. Goede to be a consequence of the high levels of selenium-rich enzymes found in the bodies of species belonging to this group. Such enzymes can "catch" free radicals that otherwise

damage DNA, the carrier of genetic information, and thus slow down the process of ageing. For some years the longevity record for the Scolopacidae was of a 17-year-old male Least Sandpiper, ringed as a two-year old on migration in 1970, that was recaptured on its nest on Sable Island, Nova Scotia, in 1975 and 1976 and captured again on the same nesting site in 1985. This record has since been beaten a few times, most recently by a Red Knot that was ringed as a first-year bird in Langebaan Lagoon in South Africa, and was shot in the Bay of Cadiz, Spain, in May 1995, at the age of 22. It was on its way back to Siberia, probably for the 21st time. This bird not only convincingly demonstrates the fact that free-living scolopacid waders can reach considerable ages, but also impresses one with the distances flown by these birds over a lifetime. If the Red Knot migrated back and forth to Langebaan Lagoon during its whole life, it covered over 700,000 km. This little creature thereby covered the distance to the moon, and made it back again!

Movements

Four of the six subfamilies of Scolopacidae, and 58 of their 59 extant species, breed at moderate to high latitudes in the Northern Hemisphere. Almost all these species show extensive southward movements in autumn to escape the stress and vagaries of northern winters. The Tuamotu Sandpiper, restricted to a handful of tropical Pacific islands, stands out as the grand exception. In the woodcock and snipe subfamilies, inhabitants of tropical regions and isolated islands are also resident, but the temperate breeding species migrate. The southernmost breeding populations of two snipes in South America, the Fuegian Snipe (*Gallinago stricklandii*) and the South American Snipe (*Gallinago paraguaiae*) in southern Patagonia and Tierra del Fuego, show south-north rather than north-south directed post-breeding migrations. Although little is known about the details of their movements, the South American Snipe apparently migrates a few thousand kilometres northward into northern Argentina and Uruguay. Even in the otherwise highly migratory calidrine sandpipers, some restricted populations may opt for a sedentary lifestyle. This is demonstrated by Rock Sandpipers breeding in coastal regions of the North Pacific, where strictly coastal birds in the southern part of the range do not migrate. More northerly and inland breeding Rock Sandpipers do travel up to a few thousand kilometres south along the Pacific shores of North America, leap-frogging over their resident conspecifics.

For the typical north-south migrating scolopacids, life is definitely one of great hurry. To prove this point with a little narrative, let us start in the tropics, or even further away from the Arctic, where birds spend the northern winter season. After having arrived between August and November, the waders go through a complete moult of flight- and body contour feathers. Those that winter within 10,000 km of their breeding areas usually then have time to do "nothing": no moult, no nutrient storage, just survival. But soon, from early February onwards, waders must start preparations for breeding. They do so by growing a new breeding plumage, and by storing the fat and protein needed for the first of a series of long northward flights. Some birds cover the distance in a few very long flights, others do it in a longer series of much shorter flights, visiting many refuelling sites *en route*. Depending on wintering latitude, northward migration may take up most of March, April and May. Especially for the high Arctic breeders, the short summer season dictates that they arrive as early as possible, as soon as the first tundra vegetation is uncovered by the melting snow. The "early" timing implies that the northernmost staging areas, areas that can be used after breeding, are still covered with snow and ice. The waders have thus to embark for the Arctic from refuelling areas in the temperate zone, which are often at a distance of 3000 km, and sometimes over

Even though the plumage of this American Woodcock mirrors the different shades of brown found in the leaves on the surrounding ground, nesting remains a risky business in a wood full of ground-dwelling predators. The visual world of a woodcock is almost entirely monocular, but its field of vision is huge and the incubating bird has no blind spots from which potential enemies might suddenly creep up on it unseen. Woodcocks have been claimed to be capable of carrying their chicks between their feet in flight, but extensive observation by scientists has yielded no corroboration; if it occurs at all, it is likely to be very rare and accidental.

[*Scolopax minor*, USA. Photo: R. Austing/FLPA]

Breeding in the high Arctic is energetically costly. During mid-summer snowfalls, arthropod prey availability is reduced and the surrounding world becomes even colder than normal, as experienced by this Red Knot incubating its eggs in late June. At such high latitudes shorebirds expend energy at maximum rates for about 15% of the days. The birds can save 10% of their daily energy expenditure by choosing a relatively sheltered nest site.

[*Calidris canutus canutus*, Sterlegova Cape, Taymyr Peninsula, Siberia. Photo: Jan van de Kam]

5000 km. Once they have arrived in the taiga or the tundra, they need to find a suitable partner, a process that may involve the establishment of a good territory and intense behavioural escapades, and select a nest-site. Within one or two weeks of arrival, the first eggs are usually laid and "romance" is over. In some of the species one of the partners takes the rest of the breeding season for granted and migrates southwards straight away. Reproductively successful birds spend three weeks incubating and then a further three weeks caring for chicks, but then also leave southwards as quickly as they can. By that time in late July most of the northern arthropod peaks are over, snow may start to fall in the northernmost parts of the range, and food availability is already on the decline in temperate staging areas. Although more of the northerly sites are suitable for refuelling than in spring, overall southward migration is just as stressful, and many birds succumb during the trip. Those that make it to tropical wintering areas, often arrive exhausted; occasionally they can be picked up by hand there at this time of the year. Then, after a year of intense use in flight, the worn wing feathers urgently need renewal, and the birds also change their colourful breeding dress into the cryptic plumage of winter. An annual cycle is complete.

This was the story of a typical long distance migrating scolopacid, and at this point it will not surprise any reader that there are many intriguing variations to this theme, some of which will be discussed below. That we now know so much about the details of the migration of many species in all parts of the world is to a considerable extent due to the creativity, infectious enthusiasm and pushing-power of a single person, C. D. T. Minton. An industrial manager by profession, he made his first attempts to catch large numbers of waders in the 1960's by firing nets over roosting flocks at high tides in Britain. He and his friends not only developed the cannon net, and a special vocabulary with which to make it operational, they also established groups of enthusiastic amateurs in different parts of Britain that go out at weekends and during holidays to catch, ring, and measure the size, mass and moult of waders. Among these groups, the Wash Wader Ringing Group always has, and continues to handle the largest numbers of waders, many thousands per year. The activities in Britain were soon followed up by British-based ringing expeditions overseas, initially to Iceland, Mauritania, Morocco, and countries in western Europe where the seeds of enthusiasm, and sets of catching equipment, were left.

This surge in wader migration studies also began to receive academic involvement, and led in 1970 to the establishment of the international Wader Study Group. Initially based in Britain, but now worldwide, this highly active, politically low-profiled, research network of amateurs and professionals, has done much to further the research on scolopacids and other wader families, by arranging meetings and by co-ordinating fruitful international collaborative volunteer research programmes. For Minton the work was not over by the time he left Britain in the late 1970's for a career in Australia. Together with his Australian colleagues, he started another surge in wader migration studies, now along the west Pacific rim. Many thousands of scolopacids are captured each year in Australasia, even in rather remote places. Worldwide, the web of wader workers leaves its mark on their favourite birds: in many wader populations, a notable proportion of the individuals now carry rings, and these continue to inform us about their worldwide movements.

Especially in the early years of large-scale ringing, great strides were made in the delineation of the movements of different breeding populations. In many cases, birds of a single species from different segments of a circumpolar breeding range were found to winter in different parts of the world, with populations usually, but not always, moving to areas roughly south of their breeding grounds. The discovery that there is reasonable congruence between the movements of populations of different species breeding in the same areas or staging at the same refuelling sites, led to the recognition of different wader "flyways", a concept borrowed from North American waterfowl biologists. About eight different north-south flyways are now recognized around the world. These are (following sunrise): the East Asian/Australasian; the Siberian/Indian; the East African/West Asian; the Mediterranean; the East Atlantic; the West Atlantic; the Interior American; and the East Pacific. Obviously, the flyways provide only approximate descriptions of seasonal wader movements in different parts of the world. There are five flyways that converge in northern Eurasia and three that do so in northernmost America; different species make the migratory divides in different ways. Some species do not obey the flyway definitions given here. For example, Pectoral Sandpipers and

In order to give predators as few and as limited clues as possible, this Common Greenshank prepares to remove an empty eggshell from the vicinity of the nest immediately after the chick has hatched. The eggs of scolopacid waders are relatively large since the chicks emerging from them are precocial; they can walk and feed independently less than an hour after emerging from their eggs.

[*Tringa nebularia*, Scotland. Photo: Dennis Green/ Windrush]

Long-billed Dowitchers from the Taymyr Peninsula in central Siberia migrate to South America! Several species also show the tendency to use one flyway during southward, and another during northward migration. Such species carry out "loop migrations". For example, of the Curlew Sandpipers breeding in Arctic Siberia, a certain proportion travels via western Europe and northwest Africa to wintering areas in West and southern Africa. In spring, however, most of these birds take a more easterly route, the great majority then following the Mediterranean flyway northwards. Another loop migrant, the Eskimo Curlew, first migrates eastward from breeding areas in the Canadian Arctic, then overflies the western Atlantic Ocean in southern directions to end up on the South American *pampas*. Eskimo Curlews migrate northward via a more coastal route along the Andes, then over the Central American land-bridge and along the northern shores of the Gulf of Mexico, and finally following the Interior American flyway northwards into the Arctic.

Species with atypical ecological requirements are also hard to fit against the crude and linear flyways. For example, Red Phalaropes avoid continental routes, and migrate from the circumpolar Arctic breeding areas to the tropical oceans over the open sea, not following the chains of wetlands that comprise the main wader flyways. Red-necked Phalaropes do show extensive overland migrations, however, the most spectacular of which is the south-eastward migration from Arctic Europe and west Siberia, via lakes in Kazakhstan, to the Indian Ocean. Prairie-breeding Wilson's Phalaropes migrate west and south along the Rocky Mountains, travelling from mountain lake to mountain lake, before a short Pacific sea crossing and the arrival at wintering lakes high in the Andes. Using alpine tundra rather than mountain lakes for feeding, a rather similar route is followed by Baird's and Pectoral Sandpipers migrating from the Nearctic to southernmost South America. A peculiar migration is also shown by the Sharp-tailed Sandpiper, the adults of which migrate transcontinentally in a straight line from the east Siberian breeding grounds to the Australian wintering grounds, but the young of which migrate southwards down the Pacific coast.

Although it might be expected that species breeding furthest south also winter furthest south, and that, within the same species, the southernmost breeding populations winter furthest south too, this type of "chain migration" appears to be rather rare among scolopacid waders. In comparisons between species, it is clear that the reverse is more usual, with northernmost breeders often wintering furthest south. For example, temperate breeding Willets and Common Redshanks winter much further north than Arctic breeding Hudsonian and Bar-tailed Godwits. Such "leap-frog migration" patterns also hold widely for comparisons within scolopacid genera and subfamilies. Some of the clearest avian examples of intraspecific leap-frog migration are also provided by scolopacids. For example, the northerly breeding populations of Common Snipes, Dunlins, Bar-tailed Godwits and Rock Sandpipers overfly the more southerly populations, and thus combine a more extreme breeding climate with a longer migration and a more contrasting, warmer, wintering climate. The migration system of Purple Sandpipers, some of which remain north of the Arctic Circle in mid-winter, is a composite of chain and leap-frog patterns.

Of course, these patterns, and especially leap-frogging, invite explanation. T. Alerstam and G. Högstedt start their reasoning by assuming that intraspecific competition for resources is an important factor for wintering shorebirds, and that birds distribute themselves so that on an annual basis the mean suitability of sites in different parts of the winter range is similar for all birds. Leap-frog migration would then be explained by the strong selection on temperate breeding birds to remain close to their breeding sites, so that they can respond quickly to the onset of favourable conditions, the timing of which varies markedly from year to year. Arctic breeding waders would obtain no extra advantages from wintering close to their breeding sites, since outside the polar climatic zone spring progress in the Arctic can not be detected anyhow. Alternative hypotheses are based on the general argument that, for many different reasons, shorter migration distances are favourable, and invoke the existence of differences in size and dominance between northern and southern winterers. Dominant or large southerly breeders would displace sub-dominant or small birds attempting to winter in the north. It is now widely understood that there is a host of rather confusing factors that influence the evolutionary shaping of migration patterns. The time of unidimensional explanatory hypotheses is behind us.

Recent studies have attempted to measure the energetic costs and benefits of long distance migration in scolopacids. In a comparison between Siberian breeding Red Knots that winter in tropi-

cal West Africa and Nearctic breeding Red Knots that winter in north temperate Europe, the African winterers were shown to expend only half as much energy over the non-breeding season as the European winterers, even when the extra energy costs of flight incurred by the Africans were included. This large difference is due to the enormous effect of climatic conditions on energy expenditure of relatively small birds living in open and exposed intertidal habitats. Though the Red Knots wintering in Africa expend little energy in winters with high air temperatures, much sunshine and calm winds, nevertheless, given the scarcity of their mollusc food at these sites, they would not be able to expend much more. A real contrast with these tropical winterers is provided by the Canadian breeding population of Red Knots that flies all the way to the frigid southern point of South America. These birds' high rates of energy expenditure are probably compensated for by the rich feeding grounds that they encounter on the underexploited tidal flats of Tierra del Fuego. Northerly wintering not only leads to high costs of sustaining a body temperature of 41°C, but also entails a substantial risk of starvation when mudflats freeze over or are covered with ice. Common Redshanks appear particularly prone to die in severe weather. For example, during a single spell of freezing weather in February 1992, almost 50% of the 4000 Common Redshanks wintering on the Wash in eastern England died.

Good timing of long distance migrations, as carried out by most scolopacids, includes well timed starts of moult and fuelling activities, and puts high demands on the birds' abilities to organize an annual cycle properly. In spring, good scheduling is particularly critical, since the profitable time window for arriving on the breeding grounds, especially at Arctic latitudes, is short, both for ecological reasons and because of intrasexual competition. In northern resident birds, changes in day length are known to trigger seasonal activities. Ruddy Turnstones, Red Knots and Dunlins maintain appropriate seasonal cycles of body mass and moult when kept outdoors under conditions of constant food availability. However, the fact that so many scolopacids spend the non-breeding season in the tropics or even further south, where photoperiodic changes are either small or show a reversed cycle, suggests that they have an internal chronometer quite independent of external stimuli. Scolopacids have not been well studied in this respect, but the single study on Red Knots kept under constant climatic and photoperiodic conditions, confirms the possibility of an "endogenous circannual clock".

The preparations for the breeding season include a moult of part of the contour feathers into a fresh and sometimes colourful breeding plumage, and the storage of fuel to keep the birds in the air until the next suitable stopover site. Recent studies on scolopacid waders have clearly shown that long distance migrants not only store fat, but increase the size of the flight muscles as well. At intermediate stopover sites the picture is even more complicated, as waders may have catabolized part of the metabolic machinery that they need for rapid refuelling. In Bar-tailed Godwits and Red Knots arriving on a stopover site, the birds first grow a large digestive apparatus, of which the protein is turned into breast muscle in the last few days before take-off on the next flight. In the meantime they may have doubled their body mass. In waders that are ready to fly, fat can make up 50% of total body mass. Subcutaneous fat envelopes the body in a thick white layer. Until late last century, Eskimo Curlews provided abundant examples of such light-coloured fat migrants. Before take-off on their transoceanic flights from north-east America, their thin skins were stretched so taut with fat that when they were shot and fell from the sky, the fat would sometimes burst out of the skin when they struck the ground. For this reason, Eskimo Curlews were called "dough-birds" in New England. Before departure on their transoceanic flights to the Guianas in northern South America, Semipalmated Sandpipers in the Bay of Fundy, Canada, can be so fat that they have difficulty in getting airborne and remaining so. When such sandpipers are harassed by raptors, they can fall on the beach and burst out of their skins, as if they were small dough-birds.

Of course, the actual timing of migratory flights is not only a function of appropriate physiological and behavioural changes. The external ecological conditions must also be good enough to enable the storage of fuel and the moult into breeding plumage. A nice example of food availability constraining the timing of departure from the wintering grounds is provided by the Whimbrels on the Banc d'Arguin, Mauritania. Whimbrels feed

Growing shorebirds, like these Whimbrel hatchlings, face an energetic dilemma. Being brooded by one of the parents saves them important energy, but their energy gains amount to zero since they are not fed by their parents. During feeding bouts to catch surface-living insects, however, small wader chicks lose body heat faster than they can generate it, and thus they quickly cool off. This problem is most marked in the smallest species, which may therefore avoid the coldest breeding areas. Each of these small chicks still has an egg tooth at the bill tip.

[*Numenius phaeopus phaeopus*, Fokstummyra, Norway. Photo: Allan G. Potts/ Bruce Coleman]

on crabs, especially fiddler crabs (*Uca tangeri*). In winter fiddler crabs are in short supply, since they keep to the safety of their deep burrows most of time. In spring, however, the males come to the surface to display and attract mates. The timing of these reproductive activities is entrained on the lunar rhythm, so that a new moon early in the period from 10th March to 10th April leads to an early start of enhanced fiddler crab availability, and thus to an early start of maximal nutrient storage. In years when the new moon is early, the Whimbrels pass Europe at earlier dates than in years when it is late. Thus, more than 4000 km further north and several weeks later, the timing of migration of this species attests the extent to which moonlight influences the reproductive activities of tropical fiddler crabs.

During long distance migration, scolopacids fly in flocks. Such flocks usually contain 10-60 conspecific individuals, with the larger species occurring in larger flocks. A small percentage of flocks may contain more than one species, although in such cases the co-occurring species are of roughly the same size. During peak migration and at high tides, the moments when the greatest numbers of conspecifics are available, departing flocks are largest. Starting flocks usually assemble from clusters into V-formations or echelons, and ascend to flight heights of several hundred to several thousand metres with climb rates of approximately half a metre per second. In coastal areas, wader departures bear no uniform relationship with the timing and the height of the tides, but at all study sites most flocks leave just before sunset. With such a departure timing, birds can maximize the use of multiple orientational cues such as skylight polarization patterns and the position of both the setting sun and the stars, and also fly under the calmer wind conditions of the night. For many species the night is also a better period to fly because foraging is less profitable than during the day.

The flock, with its cumulative sense of direction, prevents individuals from straying off into wrong directions, while formation-flying may be important in reducing flight costs. The ability of Ruddy Turnstones and Bristle-thighed Curlews to navigate reliably to the same lonely islands in the Pacific year after year, bears witness to the immense navigational capacities that the birds must possess, but that have never been studied. It provides an area of research where the technologies of the late twentieth century could do wonders: for instance, terrific insights could be gained from the use of micro-satellite-transmitters attached to Bristle-thighed Curlews, following them through their entire transoceanic migrations!

Transmitter techniques may also help to clarify the energetics of long distance flights, as has been demonstrated in recent studies, by G. C. Iverson and associates, of Western Sandpipers during their northward migration up the Pacific coast of North America. Although body mass proved a poor predictor of subsequent flight range, accurate measurements of individual travel speeds and staging times were obtained. Hitherto, studies on flight costs in migrating scolopacids were limited to longitudinal studies of the average individual in populations showing synchronized migrations. Estimates of average values of mass loss and fat depletion during specific flights, divided by the roughly estimated lengths of these flights, give just an approximation of the costs of travel. Using such data for the northward migration of Bar-tailed Godwits from West Africa to western Europe, on their way to Arctic Siberia, T. Piersma and J. Jukema were able to suggest that without the help of tailwinds *en route*, these godwits would not be able to cover the 4500 km separating the Banc d'Arguin from the Wadden Sea in a single flight. In order to encounter these tailwinds, godwits have to fly at altitudes of several thousand metres along the north-west African coast, and somewhat lower when overflying southern Europe. Such altitudes are commonly reached by the species that overfly the 5000-8000 m high Himalayan mountain chain, and should provide no major difficulties in spite of greatly reduced oxygen pressure and air temperatures of 20-30°C below zero. Red Knots travel the same route as Bar-tailed Godwits, and have been shown to overfly French stopover sites during their migration to the Wadden Sea only in years when high altitude winds are favourable.

Flying high has its risks, of course, an important one being the possibility of being blown off course. High altitude winds are often much stronger than the flight speeds of 60-70 km per hour attained by long distance migrating scolopacids. Especially when clouds obscure the view of the landscape below, it must be

Thermoregulatory capacities not only depend on the age and size of an individual bird, but also differ between species. Purple Sandpipers are the only sandpipers that overwinter along Arctic seashores where days are short and temperatures low. As they winter relatively close to the tundra regions where they breed, and where they in their turn hatched, their migration flights are short, and their departure from the breeding grounds occurs later than in any other calidrine sandpiper.

[*Calidris maritima*, Spitsbergen, Svalbard. Photo: Hubert Klein/Bios]

When Bar-tailed Godwits arrive on the Wadden Sea in May, flying in from their West African wintering grounds, they already wear their rufous breeding plumage, as in this flock of males. Nevertheless, during the stopover some birds start to moult again, replacing even more breast feathers with bright rusty red ones. Individuals that do so carry more fat, have better blood profiles and carry fewer intestinal parasites than non-moulting birds. With only these birds able to overcome the nutritional stress of migration and afford to become so brightly coloured, breeding plumages may thus reliably signal "migratory quality" and be used as a cue in mate choice decisions.

[*Limosa lapponica lapponica*, Wadden Sea, Germany. Photo: Jan van de Kam]

hard to keep to the optimal track. With regard to the strong winds at great heights, it is easy to imagine that some Red Knots might reach the point of exhaustion above Switzerland, where there is no suitable habitat for them. Inland and coastal waders may also be blown offshore, a mechanism that may explain an observation of a flock of nearly 1000 Willets resting on the Atlantic Ocean east of Newfoundland in May 1907. These Willets had overshot their breeding destination by about 1000 km. While many species can rest on a water surface if necessary, they can not survive long if the sea is rough. P. Matthiessen has suggested that whales and turtles may have provided resting points when they were still abundant throughout the tropical seas, and Red Phalaropes have been seen to use both of these types of animal in this manner, but the reported sensitivity of the whales' skin may make them quite unsuitable as dependable floats.

Avoidance of inhospitable areas, dependence on particular suitable staging sites, and the use of favourable wind streams all provide factors that may explain why some species do not fly the shortest routes between breeding and wintering areas, but sometimes deviate substantially. For example, Red Knots and Bar-tailed Godwits travel via West Africa and western Europe to Siberia instead of taking a straight route over the Middle East, a substantial detour of almost 3000 km, one way. According to some accounts the Buff-breasted Sandpipers breeding in northern Canada fly a real zig-zag course to Argentina. First they go east from the breeding grounds towards Hudson Bay and somewhat beyond, then they fly south-west following the Appalachians to Central America, and then south-east again until they reach the Argentinian *pampas*.

Every single wader must establish its own lifetime track. How do young birds select a wintering area, and how do they subsequently select a breeding site? Experimental fieldwork with Sanderlings in California demonstrates that young birds captured shortly after their arrival on wintering grounds can be "transplanted" to other wintering sites. If juveniles are transported to other sites before January, none of them returns to its capture site. A year later, about 50% of the transplanted Sanderlings are seen again along the beaches where they were released. Juvenile Dunlins, transported between Italian wintering sites in December, fly back to the catching sites just as frequently as site faithful adults. This means that they have developed a certain attachment to the wintering site by the time they are four months old. Scolopacids that have a certain degree of faithfulness to their breeding sites, may use part of the first full summer in the north to reconnoitre the potential breeding range. A study on individually marked Spotted Sandpipers showed the presence of transient birds on a high density breeding island. Such birds are mostly young, and several facts suggest that transient birds are searching for good future breeding sites. Strong intrasexual competition makes this information more important for females than for males in this polyandrous species, but it is likely that the reverse will hold for the majority of waders with monogamous or polygynous mating systems.

As already mentioned, flocks of migrating waders may be blown off course at times, but observations of single shorebirds at unusual localities are much commoner. Records of such vagrancy suggest that wader species common on the coast and making long transoceanic migrations, such as Semipalmated Sandpipers, cross the Atlantic Ocean far less often than species with a more inland distribution, for example Buff-breasted and Upland Sandpipers. Another observation is that species that breed in the western Nearctic, such as the Long-billed Dowitcher, wander more frequently to Europe than similar species breeding further east, such as the Short-billed Dowitcher. In Britain, the Pectoral Sandpiper is observed about eight times more often than Baird's Sandpiper, a species that breeds much closer in northeastern Canada and actually overlaps with several scolopacid species that winter in Britain, notably Ruddy Turnstones and Red Knots. It has been hypothesized that waders from western North America which habitually first fly east before striking south are more apt to carry on eastwards to Europe than species which set out on a southerly course straight away.

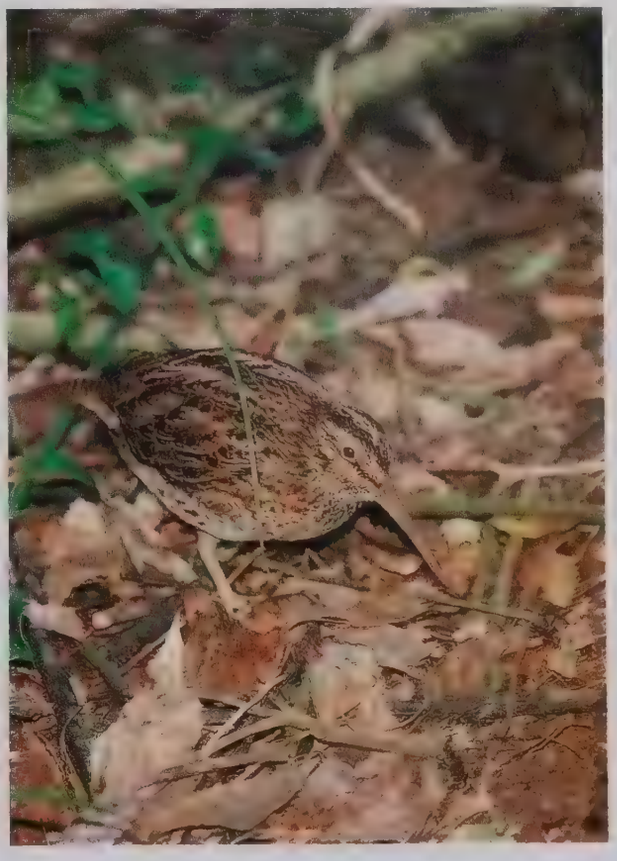
Relationship with Man

Few birds are so closely associated with folklore as the Common Snipe. In the Middle Ages, snipes were often associated with the supernatural. In parts of France, for some reason, female Common Snipes were believed to represent the devil's wife. Most omens, however, were related to the first appearance of the birds in spring. The time and place at which a farmer in northern

Germany hears his first Common Snipe gives him a prognosis of certain events of the year. In parts of Newfoundland fishermen have long associated Common Snipes with the arrival of lobsters inshore: "when the snipe bawls, the lobster crawls". In New England, the arrival of Common Snipes was associated with good river catches of a commercial fish, the alewife. In Delaware the arrival of Common Snipes in spring coincided with the appearance of an inshore commercial fish, the shad.

In their vernacular naming, the Nunamiat Eskimos of Alaska compared the bleating of the Common Snipe to the blowing sound made by the walrus. They also believed that killing a Common Snipe would bring bad weather, and alternatively called the bird "weather maker". In many parts of Europe the presence of snipes is also associated with storms and rain. In parts of northern Germany the bleating of Common Snipe at twilight was believed to be made by the god Donar's team of goats, as they drew his chariot across the heavens. The Faeroese say that its bleating predicts rain, or snow if heard before 25th March. Forecasting rain by the intense bleating of snipe is not very difficult. According to L. M. Tuck, in Newfoundland snipes are inclined to display intensely during the approach of high pressure areas. The erratic bleating at low levels during the day thus nearly always precedes rain. The departure of Eurasian Curlews from a given place is supposed to occur just prior to a storm, and in the old days in England the curlew's cry boded good to no man. In northern England, Eurasian Curlews and Whimbrels were called "Gabriel's hounds"; the name Whimbrel comes from "whimpernel" which in the Durham Household Book of 1530 refers to a habit attributed to it of hound-like whisperings. Both species were known as harbingers of death.

As part of initiation ceremonies, members of an Aborigine tribe in north-central Arnhem Land in Australia carry out "sandpiper dances". The dancers dress up as sandpipers and godwits, and look very realistic, with excellent jizz! In this part of the world the return of the migratory waders coincides with the first rains of the wet season. This is the first supply of fresh water after the long hot and dusty dry season during which water-holes either dry up or the water becomes undrinkable. Shorebirds are thus associated with good health. In other parts of the world, specific shorebirds may be associated with *machismo* and sexual appetite. The lekking behaviour of Ruffs so impressed the indigenous people of Chukchi Peninsula in The Russian Far East, that they celebrate it with an imitative dance.



As symbols of low, wet countryside more than as economic icons, in 1977 the Central Bank of the Netherlands issued bank notes of 100 guilders that feature a Common Snipe on one side, and a Great Snipe on the other. Unfortunately, the depiction of the latter species was rather an inappropriate choice, as Great Snipes are very rare in the Netherlands. Going for a very common wader instead, in 1996 the same bank issued new notes, of 1000 guilders, depicting a Northern Lapwing (*Vanellus vanellus*) and its egg.

Over the ages, however, man's relationship to scolopacid waders has usually been one of more severe economic exploitation. In the Middle Ages, Ruffs, and perhaps Red Knots too, were captured alive in late summer in the countries bordering the North Sea in Europe. The birds were kept in caged flocks and fed wasted grain to make them fat before they were consumed later in winter. The Red Knot may have gained both its common name and its scientific name, *canutus*, from King Canute's love of knot meat, although alternative derivations come from the tendency of Red Knots to stand "Canute-like" on the edge of the sea and from their characteristic "cnut" contact calls. The Rock Sandpiper of the north Pacific has the unfortunate habit of gathering on top of boulders. The Aleuts made good use of this behaviour by knocking them off these rocks with well aimed sticks, often in large numbers. Further north, in Arctic Alaska, Red-necked Phalaropes are so tame that they are hunted commonly and with great success by very young Eskimo children.

But the real slaughter of scolopacid waders came with the arrival of European immigrants in North America. The habit of many waders of bunching together in the air when disturbed, was very convenient for the market gunners in North America in the nineteenth century. Marbled Godwits came in huge flocks to coastal estuaries, and together with Long-billed Dowitchers they were harvested by the wagon load in the basin of the Columbia River. If early success by the hunters filled the wagons too quickly, they were emptied on the ground and the slaughter began anew. The abundance of the now nearly extinct Eskimo Curlew in North America has been compared to the great flights of the definitely extinct Passenger Pigeon (*Ectopistes migratorius*). From earliest colonial times onwards these small curlews were hunted in spring and autumn together with American Golden Plovers (*Pluvialis dominica*). Only in the last part of the nineteenth century, when the Passenger Pigeon had been hunted to oblivion and market hunters turned their attention towards shorebirds and waterfowl, did Eskimo Curlew populations begin their steep decline. By the turn of the century they had become a rare commodity. In 1954 a novel was published on the plight of the Eskimo Curlew. This book, *Last of the Curlews*, was written by F. Bodsworth and stunningly illustrated by T. Shortt. It was translated into Dutch, Spanish, Portuguese, Italian, French, German, Japanese and six other languages, and sold over 3 million copies! Hanna-Barbara Productions made the story into a one hour animation movie that was shown on television and in schools, and that won the 1973 Emmy award for children's broadcasting.

Not only were waders trapped and shot in enormous numbers, large numbers of Red Knots and other species were also taken by "fire-lighting", a nocturnal practice on Long Island and elsewhere in north-eastern USA. Resting flocks were blinded by bright beams so that they stayed put while the market hunters captured them by hand and wrung their necks. Barrel loads of the birds were sent to the Boston markets for sale. Scolopacids larger than Red Knots suffered much more heavily from hunting than smaller species, but even Least Sandpipers were gunned when the large species were in short supply. According to one account, 97 of these diminutive sandpipers were killed in one shot.

Snipes and woodcocks, of course, have long been a popular worldwide hunting quarry. The word "sniper" was doubtlessly used first to describe a man skilled in shooting these erratic zigzag fliers. One such gentleman was James J. Pringle from Louisiana who, from 1867 to 1887, kept careful records and indicated a personal bag of 69,087 snipes, plus several thousand other waders "killed accidentally". Since many hunters consider snipes the most diffi-

Due to the absence of regulating predators on remote oceanic islands, populations of the Chatham Snipe are obviously not limited by predation, but rather by the abundance of food. This has made the competition for food so intense that male snipes show their quality by feeding their females during courtship. Low food abundance induces a slow growth rate of chicks. Predatory mammals introduced to the Chatham Islands pose a serious threat to the breeding population of this threatened species. However, on the bright side, this snipe was successfully reintroduced to predator-free Mangere Island in 1970.

[*Coenocorypha pusilla*, Chatham Islands. Photo: Geoff Moon/FLPA]

cult of all gamebirds to bring down, these figures bear stern witness to both Pringle's prowess and snipe prosperity.

Although wader eggs may have been collected for local consumption since time immemorable, egg collecting only became something of a gentleman's sport in Europe late last century. In 1875, Henry Seebohm, a successful Sheffield steel manufacturer and an amateur ornithologist of great repute, set out for the Pechora Valley in northern Russia in search of the nests and eggs of waders that he only knew from their British wintering grounds. So successful was his first trip that he made a second one in 1877 to the Yenisey River, further east in Siberia. His journeys were great tales of bird and egg collecting, even though some dearly wanted scolopacid waders still escaped him and the others that followed his lead. An ultimate "pipe-dream wader" was the Red Knot. Red Knot eggs were found first on the New Siberian Islands in 1886, and in Taymyr eggs were first collected in 1901. North America had to wait until 1909 when the first clutch was found in northernmost Ellesmere Island, Canada, by a member of the team of Admiral Peary as they journeyed southward from "discovering" the North Pole. In oological circles this discovery was scarcely less momentous than the possibility that Peary had reached the pole, since the nest of the Red Knot had been searched for assiduously by westerners for half a century. Many hunters of Red Knot eggs, even when they had reached the extremely remote breeding grounds, mistakenly interpreted the presence of Red Knots near tundra pools as indicating that the nests must lie in nearby grass, instead of the dry barren tundra and rocky shales where the perfectly camouflaged nests are usually found.

Nests of other scolopacid waders proved difficult to find too. The first nests of the Wandering Tattler and the Surfbird were found in the mountains of Alaska in 1912 and 1926 respectively. Grey-tailed Tattler nests escaped discovery in eastern Siberia until 1960, but the most recent of all is Nordmann's Greenshank, for which the first nests were found in 1976 on Sakhalin. The first nest of the Bristle-thighed Curlew was located only in 1948 on upland tundra inland near the Yukon River, western Alaska, nearly two centuries after the species was made known to science by the crew of Captain James Cook. The Solitary Sandpiper confused nest seekers for nearly a century, until in 1903 a settler in what is now Alberta discovered the sandpiper flying to the nest of an American Robin (*Turdus migratorius*), five metres up in a tree. The first nest of a Great Knot was found in 1914, and the second only in 1976. The first nests of the Critically Endangered Slender-billed Curlew were found early this century on large bogs in south-west Siberia but the current breeding grounds still remain to be found, possibly somewhere in the steppes of Kazakhstan and Siberia.

Upland Sandpipers nested widely on the plains of North America cleared by the colonists, and together with the great migrating clouds of plovers, curlews and other shorebirds, they provided the farmers excellent service by eating grasshoppers, cutworms, wireworms and their likes. Yet their role as insect-destructors was so little appreciated that in the nineteenth century they were poisoned in the belief that they ate grain. On the other hand, scolopacids breeding in temperate grasslands have built up a reputation as conservation symbols in some parts of the world. For example, Black-tailed Godwits concentrate most of their breeding in the grasslands and meadowlands of the Netherlands, which thus harbours the great majority of the European population in spite of its small land surface. The Netherlands recognizes its responsibility for this species by setting aside specially managed land, and by subsidizing farmers for godwit-friendly management practices. In spite of these efforts, the greatest part of suitable grassland habitat is now too intensely managed to accomodate the large numbers of Black-tailed Godwits and other species of breeding waders of the twentieth century.

Status and Conservation

Although the status of no fewer than 21, or almost a quarter, of all extant scolopacids gives reasons for concern, only two species are known to have become extinct over the past few centuries. Both are members of the tringine genus *Prosobonia*, and until 1991 they were lumped together as a single species. The White-winged Sandpiper (*Prosobonia leucoptera*) and Ellis's Sandpiper (*Prosobonia ellisi*) lived in the Society Archipelago, on the adjacent islands of Tahiti and Moorea respectively. Based on a few skins and several drawings, the two sandpipers were different with respect to several plumage characteristics and in the shape of the bill. If they

According to the reckoning of BirdLife International, there is a 50% chance that no Slender-billed Curlews will survive the next five years. Less than 100 individuals persist on the Mediterranean wintering grounds of this Critically Endangered species. The decline of the Slender-billed Curlew is probably due to uncontrolled hunting, a factor that has also caused the near-extinction of the Eskimo Curlew (Numenius borealis) *in the Americas. Extensive habitat modifications severely damaging the species' breeding grounds have probably aggravated the plight of the Slender-billed Curlew.*

[*Numenius tenuirostris*, Merja Zerga, Morocco. Photo: Hans Gebuis/ Aquila]

The aberrant and little known Tuamotu Sandpiper, here seen perched in a mangrove tree, lives on a series of scattered oceanic islands in the South Pacific. It appears to be nowhere numerous and may be close to extinction. Two close relatives from Tahiti and Moorea disappeared after the opening up of this zone by European settlers in the eighteenth century. The causes for their demises were most probably the introduction of exotic mammals, especially cats and rats, which would likely have left no nest unfound, let alone untouched.

[*Prosobonia cancellata*, Tuamotu Islands. Photo: R. Seitre/Bios]

indeed lived as residents along mountain streams, it is quite likely that the two populations were geographically isolated in spite of their proximity. The sandpipers of Tahiti and Moorea passed away unnoticed in the late eighteenth century, perhaps as a consequence of the introduction of goats, pigs and rats on the islands. A close relative, the Tuamotu Sandpiper is still distributed widely but thinly over a 3700 km area of ocean within the Tuamotu Archipelago, east of Tahiti in French Polynesia. It is considered Endangered, being judged to have a 20% chance of going extinct in the next 20 years. Several hundred individuals live scattered over two groups of islands, all of which are isolated and rarely visited, and all of which have no rats.

A similar status has been fixed for the migratory Nordmann's Greenshank, breeding at the edge of peatmoss-larch bog forests near coastal salt-marshes around the Sea of Okhotsk in the Russian Far East, and wintering in coastal sites in south Asia. With a world population of less than 1000 birds, Nordmann's Greenshank is threatened by habitat loss in breeding and non-breeding areas and by hunting. Its decline may have been advanced by its popularity as a noisy decoy bird with hunters in the Shanghai region, who used it to attract other wader species to their clap-nets. Two other migratory species, both of them curlews, are in even graver danger and are considered Critically Endangered, with a 50% chance of going extinct within five years. The Eskimo Curlew was hunted close to extinction in the last century (see Relationship with Man), and was not seen for several decades until two birds were encountered in Texas in 1945. Eskimo Curlews were reported in 24 of the next 40 years, but the numbers observed were never greater than 23 individuals. Still, the Eskimo Curlew may linger on to this very day as suggested by the sporadic sightings. The reasons behind the slump of the Slender-billed Curlew certainly include heavy hunting pressure on its Mediterranean wintering grounds, but this process may have been aggravated by serious habitat loss both on the breeding grounds, now thought to be the heavily developed steppe-land of the Kazakhstan region, and in the winter range. Although the species is observed every winter in very small numbers, it is now likely to number fewer than 100 individuals.

The category Vulnerable has a purported 10% chance of going extinct in the next 100 years and includes the peculiar long distance migrating Spoon-billed Sandpiper, as well as the Bristle-thighed Curlew, which breeds in Alaska and winters on islands spread out over the Pacific, and four species of essentially sedentary snipes and woodcocks. The populations of the sandpiper and the curlew both number several to many thousand individuals. The Moluccan Woodcock (*Scolopax rochussenii*) is restricted to the small islands of Obi and Bacan in the Moluccas, Indonesia. Only known from eight specimens, the most recent of which was collected in 1980, the species may still occur on Obi, where its description appears to coincide with the reports of a local guide. The Amami Woodcock (*Scolopax mira*), restricted to broadleaf forest on several small islands in the Ryukyu chain, off southern Japan, is probably less rare and may number several thousand birds. It is nevertheless seriously threatened by deforestation, and also predation by newly released mongooses. A thousand pairs of Chatham Snipe are confined to two small predator-free islands in the Chatham group, New Zealand. The Wood Snipe (*Gallinago nemoricola*) is a bird of alpine meadows with scattered scrubs and streams. With an unknown population size, it is confined to the Himalayan region, escaping the harsh winters by a short southward migration to the lowlands of southern Asia. Another snipe of high slopes close to the tree-line, the Imperial Snipe (*Gallinago imperialis*), was thought to be extinct for over 100 years until it was discovered in 1967 in the Andean highlands of Peru, about 2000 km south of the locality from which it was originally known.

Several species confined to the Asian and Australasian regions which were considered quite rare for a long time have been found in considerable numbers during recent extensive surveys. Asian Dowitchers are not as rare as previously supposed, and 13,000 were counted in south-east Sumatra in November 1988. Great Knots were also thought to be rather rare, the world population numbering fewer than 20,000 individuals, until the Australians began to count their remote shores. Along Eighty Mile Beach in north-west Australia, aerial and ground surveys have registered up to 160,000 Great Knots, out of a total population of 270,000 birds. This has turned them into the second most abundant wader of Australia. Also, recent work by Russian scientists in the 1990's has shown them to be more common on alpine tundra in the Russian Far East than previously supposed. Similarly, the Little Curlew was considered a rare species with a restricted and fragmented breeding distribution, and it was included

in the Red Data Book of the USSR. Since the early 1980's new studies have indicated a more extensive breeding range, while counts in the Australian wintering grounds have shown a minimum wintering population of 180,000 birds. That the waders breeding in the immense territory of the former Soviet Union are still rather poorly known comes as no surprise if one realizes that the average density of ornithologists is one knowledgeable person per 22,000 km² of land area, with many of them concentrated in the Moscow area.

In the Americas similar discoveries have been made as a result of several counting efforts, including continent-wide surveys. The most epic is the circumnavigation of the South American continent in small aeroplanes by R. I. G. Morrison, R. K. Ross and collaborators. In January and February 1982-1986 they covered some 28,000 km of the South American coastline, including nearly all parts of the coast thought to contain significant habitat for shorebirds. More than 2,900,000 shorebirds were counted, and among the discoveries was that of the wintering grounds of Hudsonian Godwits in Tierra del Fuego and southern Chile. As recently as the 1940's this species was thought to be on the verge of extinction, since rather small numbers were seen during passage on the east coast of North America. During the aerial surveys, over 45,000 godwits were seen.

The recent increases in knowledge about scolopacid species are part of a general recent upsurge in the enthusiasm for shorebirds, especially the migratory species, for other than economic reasons. This has not only led to several research projects in different parts of the world, but has simultaneously stimulated several conservation initiatives. In the early 1960's the International Waterfowl Research Bureau (IWRB) was established as the first conservation organization devoted to waterbird and wetland conservation. Its foundation and early growth was certainly to an extent inspired by migratory shorebirds. Working alongside IWRB since 1982, the Working Group for International Wader and Waterfowl Research (WIWO) from the Netherlands aims to stimulate and facilitate the research expeditions and related activities of volunteers, focused on waders and wetlands especially in Europe, Africa and the Middle East. In 1983 the East Asia/Pacific shorebird study programme Interwader began to carry out conservation-relevant studies of migratory wader and waterbird populations in South-east Asia and nearby regions. Interwader quickly grew larger, and was soon transformed into a more widely and politically orientated conservation organization, the Asian Wetland Bureau, based in Kuala Lumpur, Malaysia. In the meantime Interwader had made an impressive series of wader and wetland surveys, and, in 1989, produced an unrivalled and very stimulating guide to baseline wader studies, the *Shorebird Studies Manual*. On the other side of the Pacific, shorebird workers in the Americas established the Western Hemisphere Shorebird Reserve Network (WHSRN) in 1985. By networking activities between sites and through designations of sites of national, international or hemispheric importance, WHSRN aimed to achieve the protection of entire flyways. Following a rather similar ontogeny as the other groups, WHSRN showed steep growth and soon developed into an organization with a wider working remit, covering not only shorebirds but whole wetland ecosystems and called Wetlands for the Americas. Not surprisingly, IWRB had broadened its scope too, and was meanwhile rechristened the International Waterfowl and Wetlands Research Bureau. From 1996, the three organizations will join forces as Wetlands International, with the three founding bureaux taking care of, respectively, the African-Eurasian, Australasian and American flyway systems.

The multiplication of politically conscious non-governmental waterbird and wetland organizations brought with it the development, jointly with national governments, of a host of international conventions and agreements aimed at protection of the wetlands of the world and the waders and waterbirds that depend on them and link them. The best known, and most widely signed, is the Ramsar Convention of 1975, but several others have followed. The extent to which these conventions have helped to safeguard scolopacid populations and their habitats is hard to evaluate at present, but their existence has certainly brought the birds into focus as an important aspect of the world's heritage, as sensitive indicators of the ecological health of wetland ecosystems, and as interesting phenomena in their own right.

The increased efforts in determining the abundance of scolopacids makes it possible to evaluate their fates and fortunes over several different time scales. In North America some shorebird species were much commoner two centuries ago than they are now, the Eskimo Curlew being a clear example. Whimbrels are now on the increase and may gradually be occupying the territory that the smaller curlew has left. Grassland-breeders such as the Upland Sandpiper may have profited initially from the coming of the white man to North America, since the area of open country was increased enormously by the clearing of primeval forests. On the Eurasian scolopacid breeding grounds similar changes are taking place. During this century, Marsh Sandpipers have expanded northwards and eastwards into Siberia, partly in response to forest clearance. In contrast, the Great Snipe has greatly declined in numbers. Around the turn of the century Russian hunters quite often used to bag several hundred per autumn, but by the 1950's and 1960's the maximum bag for a specialized hunter was only 30 Great Snipes per autumn season. The Great Snipe is now rare in European Russia, and further east its range seems to have fragmented, possibly due to drainage and deforestation. Ruff populations declined in European Russia but expanded in the east, possibly as a consequence of better feeding conditions during migration and in winter, since birds began to use the spilled grain and rice in south-eastern Russia and adjacent countries.

In North America and Europe Long-billed and Eurasian Curlews, respectively, are adapting to breed in modern farmland, thereby slightly expanding their ranges. Marbled Godwits, rare through the early part of the century, may have increased in recent decades as a consequence of similar adjustments. In the lowlands of western Europe, several species of scolopacid have benefited from the drainage of marshland and the application of fertilizers. In the Netherlands, populations of the meadow-breeding bird community, including Black-tailed Godwits, Ruffs, Common Redshanks and Common Snipes peaked during the first half of this century. Continued drainage has now led to a decrease in the availability of arthropod food for chicks. Early mowing with fast machinery has also reduced to almost nil the chance of small chicks surviving. Over the last 20 years, the Dutch population of Black-tailed Godwits has declined by a third. Other, even more sensitive species such as the Common Redshank, Common Snipe and Ruff, have decreased by 50-90%; in an international context these declines are less of a tragedy since these species are not confined to the Netherlands.

Given the minor role that humans still play in the polar regions, it is reasonable to suppose that scolopacids breeding on the tundra have not been affected as much by habitat modification. That hunting pressure has recently been the key factor responsible for early declines is suggested by the fact that when viewed over a century, most coastal scolopacids in North America have shown positive population trends. Data collected in the collaborative International and Maritimes Shorebird Surveys in north-eastern North America, however, suggest that the general upward swing in shorebird numbers has now reversed. Significant declines are reported for Least and Semipalmated Sandpipers, Sanderlings, Red Knots, Short-billed Dowitchers and Whimbrels, most of the decreases occurring during the latter part of the 1970's. In Europe, wintering Red Knots showed a steep decline during the same period too, but they have partially recovered since. Other wader species showed variable fortunes, but few show sustained increases. The wintering areas in Mauritania and Guinea-Bissau are numerically very important but have been covered by complete surveys only once or twice around 1980. Partial surveys of the Banc d'Arguin made in the early 1990's suggest that many species have dramatically decreased in number, some by more than half over 10 years. These are very drastic numerical changes in an area that could previously boast of holding a third of all coastal waders wintering along the East Atlantic flyway.

Such dramatic population declines should perhaps not surprise us. Long distance migrating waders in particular have life history characteristics that make them rather susceptible to changes in their

As vulnerable as a wader chick is the status of this highly specialized species, the Spoon-billed Sandpiper. The total population is currently estimated at 2000-2800 pairs, but the main wintering sites remain largely unknown. Its extraordinary spoon-like bill may help in the capture of surface-living arthropods when the species is on its Arctic tundra breeding grounds, and also during prey-detection when foraging in soft mud on the coastal non-breeding areas. This hatchling already shows an incipient version of the characteristic broad, rounded bill.

[*Eurynorhynchus pygmeus*, Kolyuchinskaya Bay, Chukotskiy Peninsula, Siberia. Photo: Pavel S. Tomkovich]

environments. First of all, their habit of migrating long distances along chains of critical sites brings them together at particular times. At such sites and times they are all at risk at once, a characteristic that violates the basic assumption of conservation biology that being common means being safe. Long distance migration is nutritionally and behaviourally highly demanding and is constrained in time by the seasons, adding to the fragility of the system. A maximum clutch of four eggs is indicative of relatively low reproductive rates and hence a limited capacity to recover from population declines. Finally, for many scolopacid species there is evidence of strong sexual selection pressures. Sustained sexual selection may compromise adaptations with respect to other components of fitness. Thus, sexually dimorphic species may allocate less energy to adaptations that reflect selection pressures arising from interspecific competition, environmental change, and co-evolutionary responses to parasites and prey. Consequently, strongly sexually selected populations may be especially vulnerable to extinction, a factor that could be aggravated in scolopacid populations by the reduced levels of genetic heterogeneity resulting from past population bottlenecks.

These ecological and biological characteristics are played out in a world where scolopacids compete with humans for critical habitats, especially in tropical regions and at temperate staging areas close to large human populations. Worldwide, the application of pesticides in agriculture may interfere with migratory competence. On the oceans an increase in particle pollution may affect fuel deposition in phalaropes: birds do not get fat from eating plastics! The pressure of sport hunting has perhaps slightly decreased over the last 100 years, but can not be discounted as an unimportant factor, especially in view of possible synergisms with other ecological pressures. Apart from adding a mortality factor, hunting clearly lowers the quality of a habitat for waders. Hunting is therefore basically similar to other forms of habitat degradation and habitat loss. The effects that rapid climate change, with its influence on sea-level and weather systems, may have on breeding, staging and wintering habitats and profitable flight routes are far beyond present comprehension. Growing numbers of scientists are involved in the development of theoretical models to investigate and simulate the consequences of habitat changes on migratory populations of waterbirds. Until now, the biological features of scolopacid waders have proved too complicated to make such exercises a success with respect to prediction, and in their possible role as sentinels for a caring human society. The wonderfully diverse Scolopacidae provide a great vehicle for ecological and biological understanding on vast spatial and temporal scales. They enrich our lives, and the webs of migration that they spin around the world tell us about global connections, global causality and global responsibility.

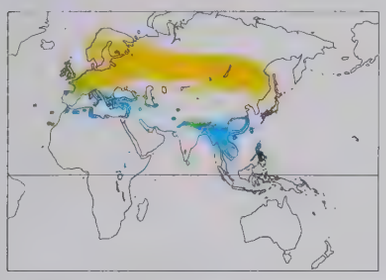
Subfamily SCOLOPACINAE



Genus *SCOLOPAX* Linnaeus, 1758

1. Eurasian Woodcock

Scolopax rusticola

French: Bécasse des bois **German**: Waldschnepfe **Spanish**: Chocha Perdiz
Other common names: (European) Woodcock

Taxonomy. *Scolopax Rusticola* Linnaeus, 1758, Sweden.
Forms superspecies with *S. mira*, with which often considered conspecific. Traditionally considered rare winter visitor to Philippines, where recorded on Luzon; however, recent work indicates presence of probably new, as yet undescribed, species on Mindanao (see page 448), so occurrence of present species in Philippines probably requires reviewing. Monotypic.
Distribution. Azores, Madeira, Canary Is and British Is through N & C Europe and C Asia to Sakhalin and Japan; also Caucasus, NW China and N India. Winters from W & S Europe and N Africa to SE Asia.

Descriptive notes. 33-35 cm; 144-420 g; wingspan 56-60 cm. Bill long and straight, but relatively shorter than congeners; thick transverse bars on crown, typical for all woodcock species; mainly rufous brown and reddish above providing good camouflage; broad wings, in flight recalling owl. Plumage somewhat variable; individuals with bill half normal length have been recorded in W Europe, especially since 1970, possibly related to pesticide contamination. Differs from very similar, possibly conspecific, *S. mira* in having area of whitish feathering around eye, rather than bare skin; rounder head; dark subterminal band on tail; narrower wings and shorter tarsi. Sexes alike. No seasonal variation. Juvenile very similar to adult, but forehead more spotted.
Habitat. During breeding season occurs in moist forests, where favours mosaic habitats, and extensive woodland covered by undergrowth of scrub, e.g. of brambles, holly, whin or gorse and bracken; avoids warm and dry areas. Often feeds along streams or springs, or in damp and swampy patches. Non-breeding habitat similar to breeding habitat during daytime, but less restricted, e.g. also occupies young conifer plantations; avoids habitat with coppice less than 7, or more than 20, years old, or that which lacks coppice; often gathers for roosting and feeding in earthworm-rich permanent grasslands at night.
Food and Feeding. Mainly animals, with some plant matter. Animals include earthworms, insects and their larvae, particularly beetles, but also earwigs; millipedes, spiders, crustaceans, slugs, leeches and ribbonworms. Plant material comprises seeds, fruits, oats, maize grain and roots and blades of various grasses. Earthworms often dominate diet, but relatively less common on harder soil. Composition of diet and use of habitat may differ between sexes. Feeds by probing in puddles or damp ground, or by pecking at ground surface, or under leaf litter and twigs; may use foot-trembling. Mostly feeds at night, especially outside breeding season, when earthworms taken on pasture land may predominate.
Breeding. Lays from early Mar to mid-Apr, late nests to mid-Jul. Polygynous mating system; male performs self-advertising display flight (roding flight) around dusk and dawn. Nest is a shallow depression in ground concealed by shrubs. Clutch 4 eggs (2-6), laid at interval of 24-48 hours; normally single brood, sometimes two; incubation 22 days (21-24), by female only; chick pale pinkish buff with large, ferruginous brown and chestnut brown blotches and bands above; fledging 15-20 days; female alone cares for young, and occasionally claimed to carry young chicks between feet and belly during flight (see page 475). On average 2·3 hatchlings per nest. Males start roding in 1st year. Annual adult survival 0·39-0·63. Apparently, 9-year cycle exists in numbers of W European wintering birds, peaks coinciding with high proportion of juveniles in population; this might be result of an 8-year cyclical abundance of a major predator or of this predator's main prey.
Movements. Mostly migratory. Fenno-Scandian and some W Russian birds winter in W & S Europe and N Africa; breeding birds of British Is and France mainly resident. Asian breeders winter in Iraq, Iran, Azerbaijan, Afghanistan and India through Indochina to SE China, and occasionally S to Brunei; few records in Luzon (N Philippines) perhaps require reconfirmation. Timing of autumn departure related to onset of frosts (Oct-Nov); return to breeding grounds, Mar to mid-May, also closely related to temperature. Females migrate first, at least in some areas. Both young and parents often return to previous nesting areas. Migrates nocturnally.
Status and Conservation. Not globally threatened. African and European post-breeding population estimated at 15,000,000-37,000,000 birds (1982); 310,000 pairs estimated breeding in Fenno-Scandia (1986); population of Asia unknown. Small increases in NW Europe from 1930 to 1970, probably due to climatic changes and population shift from E to W; however, in Azores and on Madeira populations decreased. From 1970's onwards, substantial decline in large wintering population in France, probably due to excessive hunting on migration and wintering grounds. Up to 3,700,000 individuals hunted annually in Europe, with 1,500,000 in Italy, 1,300,000 in France, 400,000 in W USSR and 200,000 in Britain. No clear trend in European breeding population; numbers wintering in Morocco seem stable since 1950's; numbers declining in several regions of Russia, with 3-6 fold decreases locally during last 10-15 years; formerly occurred in summer in Azerbaijan, presumably breeding, and might still breed there. Increased fragmentation of woodlands might explain decline in some areas in Britain and C & N Europe. Disappearance of permanent grasslands is a threat to wintering birds; in France, this involves 160,000 ha per year. Appearance in recent years of short-billed individuals, which sometimes also show malformations, may be caused by some pesticides having teratogenic effect.

(1983), Yeatman-Berthelot (1991).

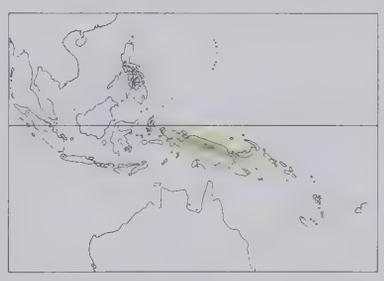
2. Amami Woodcock

Scolopax mira

French: Bécasse d'Amami **German**: Amamischnepfe **Spanish**: Chocha de Amami

Taxonomy. *Scolopax rusticola mira* Hartert, 1916, Amami-O-shima.
Forms superspecies with *S. rusticola*, of which often considered a subspecies. Monotypic.
Distribution. Amami-O-shima, Tokuno-shima, Okinawa and Tokashiki Is (C Ryukyu Is).



Descriptive notes. 34-36 cm. Plumage variable, can be rather dark, but equally can be paler than *S. rusticola*. Differs from very similar *S. rusticola* by broader wings, longer tarsi, flatter forehead and crown, deeper base of bill and pinkish bare skin around eye (not present in all individuals); generally less rufous brown, more olive brown and more uniform in general coloration, with far fewer contrasting dark and grey areas on wings and mantle; first crown bar slightly narrower than second; lacks dark subterminal band in tail. Sex and seasonal differences and juvenile undescribed.
Habitat. Occupies broadleaf evergreen hill forests; possibly also adjacent fields, including sugar cane plantations, although this might refer to *S. rusticola*.
Food and Feeding. Nothing known of diet. Probes in soft earth and short vegetation on forest floor, along road edges and mud of roadside banks.
Breeding. Laying mid-Mar to early May. No aerial display recorded; single males observed displaying on the ground in vicinity of single females, with quivering, hanging wings and gently bobbing head, uttering strong "gu" calls and softer "ku" calls. 2-4 eggs. No further information available.
Movements. Sedentary.
Status and Conservation. VULNERABLE. No precise information available, but population does not exceed 10,000 individuals. Locally common on Amami, but less numerous on the other islands. In some parts of range, threatened by habitat loss through deforestation; may be hunted locally. Another cause for concern is predation by mongooses, which have been introduced to Amami and Okinawa in order to control poisonous snakes. This seems to have caused population decline already in part of Amami. Census work on species complicated by presence of very similar, easily confusable, *S. rusticola* as winter vistor to the islands.
Bibliography. Austin & Kuroda (1953), Beaman (1994), Brazil (1991), Brazil & Ikenaga (1987), Collar *et al.* (1994), Hachisuka (1952), Perennou *et al.* (1994), Sonobe (1982).

3. Rufous Woodcock

Scolopax saturata

French: Bécasse de Java **German**: Malaienschnepfe **Spanish**: Chocha Oscura
Other common names: Javanese/East Indian/Dusky Woodcock; Horsfield's Woodcock (*saturata*); Rosenberg's Woodcock (*rosenbergii*)

Taxonomy. *Scolopax saturata* Horsfield, 1821, Mount Perahu, Java.
Races sometimes treated as two separate species. Two subspecies recognized.
Subspecies and Distribution.
S. s. saturata Horsfield, 1821 - mountains of N & SC Sumatra and W Java.
S. s. rosenbergii Schlegel, 1871 - mountains of New Guinea.

Descriptive notes. 29-31 cm; 220 g (1 female *rosenbergii*). Smallish, rather dark woodcock with long bill; breast and most of belly brownish, chin buff; pale area on upper belly separates from all congeners. Sex and seasonal differences and juvenile undescribed. Race *rosenbergii* normally has more contrasted plumage; has whiter chin and cheeks, usually white spot above lores, much more white on belly and more conspicuous brown barring of underparts.
Habitat. Remnants of montane primary rain forest with moderate or dense understorey, at 1500-3000 m. Not found in secondary forest; often in little patches of forest in alpine grasslands.
Food and Feeding. Two stomach analyses yielded caterpillars and moth pupae. Feeds nocturnally.
Breeding. Breeds during wet season, Feb-Apr, in Java; chicks in mid-May in Sumatra; in E New Guinea roding observed during Aug-Sept. Performs roding display at dawn and dusk, particulary around clearings. Nest consists of a bed of moss in between ferns, slightly raised above forest floor. Probably lays 2 eggs.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. No precise information available. Not uncommon in New Guinea, but inconspicuous so infrequently recorded. Surveys required, especially in Sumatra, in order to establish limits of distribution.

(1985b, 1992), Beehler (1978), Beehler *et al.* (1986), Coates (1985), Diamond (1972b), Gregory (1995a), Hellebrekers & Hoogerwerf (1967), MacKinnon (1988), MacKinnon & Phillipps (1993), Majnep & Bulmer (1977), van Marle & Voous (1988), Mayr & Rand (1937), Meyer de Schauensee & Ripley (1940), Perennou *et al.* (1994), Rand (1942), Rand & Gilliard (1967), Ripley (1964)

4. Sulawesi Woodcock

Scolopax celebensis

French: Bécasse des Célèbes **German**: Celebesschnepfe **Spanish**: Chocha de Célebes
Other common names: Celebes/Indonesian Woodcock

Taxonomy. *Scolopax celebensis* Riley, 1921, Rano Rano, Sulawesi.
Forms superspecies with *S. rochussenii*, with which sometimes considered conspecific. Race *heinrichi* proposed for N Sulawesi, based on somewhat smaller bill of only three specimens. Form recently discovered breeding on Mindanao (SE Philippines) might be attributable to present species, but probably constitutes new, as yet undescribed, species (see page 448). Monotypic.
Distribution. NE & C Sulawesi.

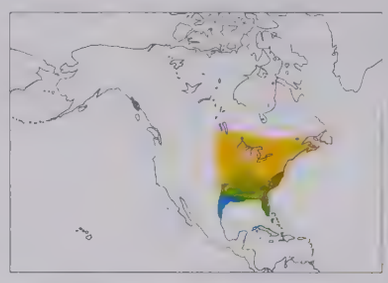
Descriptive notes. 30-35 cm. Large woodcock with shortish, rounded wings; upperparts blackish with red-brown markings; underparts almost unbarred ochre-buff. Pattern somewhat similar to that of *S. rusticola* and *S. mira*, but darker above, with much brighter, almost unbarred underparts; bill and tarsi longer and much darker. Sex and seasonal differences and juvenile undescribed.
Habitat. Dense, mature montane forest at 1100-2500 m; hides in thick undergrowth, running when disturbed; requires some wet, open patches with little undergrowth for foraging.
Food and Feeding. Feeds in wet spots; has been seen in puddles of water in hollows made by wild pigs.
Breeding. No information available.
Movements. Apparently sedentery.
Status and Conservation. Not globally threatened. Currently considered near-threatened. Very poorly known; no precise information available; inconspicuous so infrequently recorded.
Bibliography. Andrew, P. (1992), Collar & Andrew (1988), Collar *et al.* (1994), Perennou *et al.* (1994), Scott (1989), Stresemann (1932, 1941), White & Bruce (1986), Whitten *et al.* (1987).

5. Moluccan Woodcock

Scolopax rochussenii

French: Bécasse des Moluques **German**: Obischnepfe **Spanish**: Chocha Moluqueña
Other common names: Obi/Maluku/Indonesian Woodcock

Taxonomy. *Scolopax Rochussenii* Schlegel, 1866, Obi.
Forms superspecies with *S. celebensis*, with which sometimes considered conspecific. Monotypic.
Distribution. Obi and Bacan (N Moluccas). Also claimed to occur on Ternate and Halmahera, but probably erroneously, due perhaps to inaccurate museum labels and misidentification.



Descriptive notes. 32-40 cm. Largest woodcock, c. 25% bulkier than *S. rusticola*; fairly long, heavy, dark bill; large, contrasting ochre-buff spots on black upperparts; bright ochre-buff underparts with only faint traces of barring. Larger and much brighter than *S. celebensis*; spots on upperparts larger and yellower. Sex and seasonal differences and juvenile undescribed.
Habitat. Apparently a bird of dense, moist montane forest; maximum altitude of Obi is c. 1550 m.
Food and Feeding. No information available.
Breeding. No information available.
Movements. Probably sedentary.
Status and Conservation. VULNERABLE. Last definite record was a specimen collected in 1980; in total, only 8 specimens have been collected, probably all from Obi and Bacan. No birds located during surveys of Obi and Bacan in 1991 and 1992; however, a local guide on Obi was familiar with birds apparently of present species, which he occasionally encountered in forests on ridge tops above c. 500 m during dry periods; birds apparently fairly tame, flushing at very close range and flying only short distances. The areas of hill forest on Obi and Bacan are small, but have official protection.
Bibliography. Andrew, P. (1992), Collar & Andrew (1988), Collar *et al.* (1994), Hartert (1903), Lambert (1994), Perennou *et al.* (1994), White & Bruce (1986).

6. American Woodcock

Scolopax minor

French: Bécasse d'Amérique **German**: Kanadaschnepfe **Spanish**: Chocha Americana

Taxonomy. *Scolopax minor* Gmelin, 1789, New York.
In past sometimes placed in genus *Philohela*. Monotypic.
Distribution. S Manitoba through Ontario and Quebec to New Brunswick and SW Newfoundland, and S through Great Plains and E USA to EC Texas, Gulf states and Florida. Winters in SE USA, on Atlantic and Gulf coastal plains from S Texas to S Florida.
Descriptive notes. 25-31 cm; male 116-219 g, female 151-279 g. Smallest woodcock, with unbarred orange-buff underparts and underwing-coverts; silverly grey "V" along edges of mantle, and another (less obvious in flight) on scapulars; outer three primaries greatly reduced in size, producing broad, square-ended wings in flight. Female slightly larger than male. No seasonal variation. Juvenile very similar; on middle four secondaries, clear pale tips and dark brown subterminal zone.
Habitat. Mixed or deciduous moist woodlands with scattered openings (40% of surface area seems to be minimum). Preferably in young forest and abandoned farmland mixed with forest; often areas with herbaceous ground cover; mainly crepuscular and nocturnal, especially in winter. During non-breeding season occurs in similar habitat, with preference for shrubland, particularly bottomland hardwoods and pine hardwoods; also found in pine uplands and even gardens.

Food and Feeding. Earthworms form 68-86% of diet; when available, also Diptera, beetles, Hymenoptera, Lepidoptera, snails, millipedes, centipedes and spiders; plant material rarely eaten. Variety of diet may increase in early spring due to frost, and in summer if soil moisture low, as earthworms may be unavailable in such conditions. Constant rocking motion during feeding; probes deeply into moist soil or picks from surface; forages in damp fields and marshes in non-breeding season.
Breeding. Lays from Jan (S USA) to late Apr (N USA and Canada). Male performs display flight above bare, open ground, often in forest clearing. Males apparently promiscuous, and take no share in parental care. Nest has rather rudimentary structure and often close to tree, bush or bushy field edge. 4 eggs, sometimes 3; when renesting, unsuccessful females lay 3 eggs (2-4); incubation c. 21 days (20-22); chick pale grey and pale brown, with darker brown markings; young can fly at 14-15 days, nearly fully-grown after 4 weeks; females claimed to carry young chicks between feet and belly during flight (see page 475). Hatching success (considering all nests) 50-89%. Maximum recorded longevity 8 years.
Movements. N breeders migratory, leaving area from Sept to mid-Nov; start and progress of migration considerably influenced by weather; cold fronts appear to prompt heavy flights S; earliest autumn movements precede decrease in food availability. Birds return Jan to mid-Apr. Migrants probably follow coastline in E and broad river valleys in Midwest. Birds from NE USA and most of Canada E of Ontario move into S Atlantic states, from Virginia southward; birds from W of Appalachian Mts and also from Quebec and Ontario probably follow Mississippi R and major tributaries into Gulf states; Gulf states receive migrants from NW, NC & NE of range. S breeders probably mostly sedentary, but some early hatched young might join northward migrations. Vagrant W to Montana and Colorado.
Status and Conservation. Not globally threatened. No population estimate available. At present, c. 2,000,000 birds shot annually by c. 700,000 hunters. In period 1963-1973, no clear trend in population; numbers have declined recently, particularly in E of range. Decline probably due to natural succession and man-induced loss of forest; however, no evidence that overall range has shrunk. Uneven-aged stands, favoured by forest management, do not provide suitable large areas of shrubland and young forest required by species for successful breeding, and this will result in further decline in numbers. Nevertheless, extensive use of N coniferous forests that are being opened up by large-scale timber harvesting suggests that species may be extending distribution northward. Introduced to California, apparently unsuccessfully.
Bibliography. Anon. Subfamily GALLINAGININAE

Genus *COENOCORYPHA* G. R. Gray, 1855

7. Chatham Snipe

Coenocorypha pusilla

French: Bécassine des Chatham **German**: Chathamschnepfe **Spanish**: Chochita de las Chatham
Other common names: Chatham Subantarctic Snipe

Taxonomy. *Gallinago pusilla* Buller, 1869, small rocky islet off Chatham Island.
Forms superspecies with *C. aucklandica*, of which sometimes considered a race. Monotypic.
Distribution. Chatham Is, occurring only on islands of Rangatira (South-east), Mangere, Little Mangere and Star Keys.
Descriptive notes. 19-20 cm; 61-110 g, wingspan 28-30 cm. Small, compact, short-legged snipe; creamy white lower breast and belly. Smaller than very similar *C. aucklandica*; paler below even than palest races of latter, with less barring and blotching on underparts; bill smaller and shorter. Female paler and less brightly patterned above. Juvenile has less well defined upperpart markings, greyish legs and base of bill.
Habitat. Mainly in areas with substantial bush cover and remnant forest, especially among *Carex* sedges; less often among damp grasses and mosses in more open habitats.
Food and Feeding. Diet includes earthworms, amphipods, beetles and insect larvae and pupae. Feeds by probing in leaf-mould or moist grassland soils; probes to full length of bill. Most prey swallowed without bill being withdrawn from soil.
Breeding. Laying Sept-Mar. Monogamous. Male probably performs nocturnal drumming display flight and shows courtship feeding. Solitary and territorial; in relatively high densities, up to 5·6 pairs/ha. Nest placed in between sedges or grasses under canopy, preferably *Carex*; nest filled with leaves, or unlined scrape. 2 eggs, sometimes 3; incubation period more than 19 days; sexes share incubation, and

brood divided between parents; chick similar to those of *Gallinago*, but only dimly patterned, with inconspicuous white powder-puff tips; chick develops relatively slowly, and fed entirely by parents for first 2-3 weeks; able to fly after 21 days; independent at c. 41 days. Pair-bond often re-formed after chicks independent. On average, c. 1·7 hatchlings per nest, c. 1·9 per successful nest.

Movements. Sedentary, although inter-island movements within Chatham Is have occurred. All ringing recoveries within 200 m of ringing site.

Status and Conservation. VULNERABLE

Total population estimated at 900-1050 pairs, with Rangatira I holding 700-800 pairs, Mangere I holding 200-250 pairs, and Little Mangere I and Star Keys less than 50 pairs. Population stable but in danger of rapid extinction if island refuges colonized by rats, cats, pigs or Wekas (*Gallirallus australis*), which are all present on nearby islands. Formerly occurred throughout Chatham group, but became confined to Rangatira I when the other populations were exterminated by introduced predators (feral cats on Pitt, Mangere and Little Mangere). Successfully reintroduced to Mangere I in 1970, after feral cats had died out. Scarce on Rangatira I before removal of livestock in 1961, probably as result of loss of ground cover through overgrazing and burning.

Bibliography. Chambers (1989), Collar & Andrew (1988), Collar *et al.* (1994), Falla *et al.* (1981), King (1978/79), Lowe (1915), Marchant & Higgins (1996), Miskelly (1987, 1990a, 1990c), Robertson (1985), Soper (1976), Tuck (1972).

8. **Subantarctic Snipe**

Coenocorypha aucklandica

French: Bécassine d'Auckland **German**: Aucklandschnepfe **Spanish**: Chochita de las Auckland
Other common names: New Zealand/Auckland Snipe

Taxonomy. *Gallinago aucklandica* G. R. Gray, 1845, Auckland Islands.

Forms superspecies with *C. pusilla*, with which sometimes considered conspecific, especially in past. Race *barrierensis* of Little Barrier I known from single specimen taken in 1870; presumably extinct. Four extant subspecies recognized.

Subspecies and Distribution.

C. a. iredalei Rothschild, 1921 - Little Moggy I, Big South Cape I and other small islands off Stewart I.

C. a. huegeli (Tristram, 1893) - Snares Is (North-east, Broughton and Alert Stack).

C. a. aucklandica (G. R. Gray, 1845) - Auckland Is (Disappointment, Ewing, Adams, Figure of Eight, Rose, Enderby, Ocean and Dundas).

C. a. meinertzhagenae Rothschild, 1927 - Antipodes Is (Antipodes, Bollans, Archway and Inner Windward).

Descriptive notes. 21-24 cm; 82-131 g; wingspan 30-35 cm. Small, compact snipe with very short legs and long, slightly drooping bill. Nominate is largest and palest race, with almost unbarred, pale buff belly, so rather similar to *C. pusilla*, but separated by longer, slightly decurved bill. Female slightly larger than male. Juvenile very similar to adult, but black markings and streaking on upper breast and throat are less distinct. Racial variation considerable: *meinertzhagenae* tends to be darkest, with yellowest underparts; *huegeli* has totally barred underparts; *iredalei* is the most rufous form, with barred flanks and belly and spotted throat. Juvenile *huegeli* greyer above than juvenile nominate, with bill base greyer.

Habitat. Cool temperate and subantarctic islands, occurring in tussock grassland on cliff tops, and in moist open woodlands with mosaic of dense undergrowth, including grass tussocks, mat-forming herbs, sedges and shield ferns; also herb fields and scrubland.

Food and Feeding. Mainly soil-dwelling invertebrates, such as earthworms, amphipods, adult beetles, and larvae and pupae of flies and beetles. Probes soil and bases of tussocks, to full length of bill, evidently feeling for insect movements; rarely pecks prey from surface. Most prey swallowed while probing; only large items are removed from soil and manipulated before swallowing. Diurnally and nocturnally active, feeding in more open areas at night.

Breeding. Based mostly on information from *huegeli*. Lays mid-Aug (*meinertzhagenae*) to Apr. Monogamous (95%), sometimes polygynous. Male performs nocturnal drumming flight and courtship feeding. Solitary in territory; nests at relatively high densities, up to 4 pairs/ha. Nest often under shield ferns; nest is natural depression or bowl in plant detritus. 2 eggs, with laying interval of 3 days; single-brooded, though pairs renest after failure; incubation for pairs 22 days by both parents, but with polygyny 37-39 days for mated female; brood divided between parents; chick similar to those of *Gallinago*, but only dimly patterned, with inconspicuous white powder-puff tips; chick develops relatively slowly, and fed entirely by parents for first 2-3 weeks; able to fly after 30 days; fully independent only after 65 days. Pair-bond often re-formed after chicks independent. Each pair produces c. 0·6 fledglings/year. Adult annual survival 83%; longevity probably exceeds 20 years; oldest ringed bird more than 14 years old.

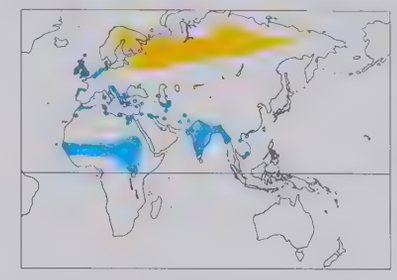
Movements. Presumably sedentary, even within island groups. Occasional sightings on Enderby, Rose, Ocean and Dundas Is may represent dispersal from Ewing I, 1·7-5 km away, although these islands may all have undiscovered resident populations.

Status and Conservation. Not globally threatened. Currently considered near-threatened. Total population estimated at 34,000 birds, with Auckland Is probably holding more than two thirds of total, mostly on Adams I, Disappointment I and Ewing I; race *aucklandica* numbers c. 25,000 birds, *meinertzhagenae* c. 8000 birds and *heuegeli* c. 1100 birds; no recent information on race *iredalei*. Current populations stable, but in danger of rapid extinction if islands colonized by new predators. One or two subspecies were recently exterminated by feral cats and black rats (*Rattus rattus*): race *barrierensis* only known from single specimen from Little Barrier I, taken in 1870; introduced Wekas (*Gallirallus australis scotti*) probably eliminated population of race *iredalei* on Jacky Lee I. Race *iredalei* formerly bred on at least 9 islands off Stewart I, and may still survive on Big South Cape I, Little Moggy I and some other islands, although definite information lacking. Population of *huegeli*, confined to Snares Is, is so small that risk of extermination if rats introduced is a major concern. Race *meinertzhagenae* is surviving on Antipodes I in presence of introduced house mice (*Mus musculus*).

Bibliography. Anderson (1968), Bell (1975), Chambers (1989), Collar & Andrew (1988), Falla *et al.* (1981), Galbreath & Miskelly (1988), King (1978/79), Marchant & Higgins (1996), Miskelly (1987, 1988, 1989, 1990a, 1990b, 1990c), Robertson (1985), Sibson (1982), Soper (1976), Tuck (1972), Warham & Bell (1979).

Genus *LYMNOCRYPTES* Boie, 1826

9. **Jack Snipe**



Lymnocryptes minimus

French: Bécassine sourde **German**: Zwergschnepfe **Spanish**: Agachadiza Chica
Other common names: Half-snipe

Taxonomy. *Scolopax minima* Brünnich, 1764, Christiansø Islands, off Bornholm, Denmark.

Monotypic.

Distribution. Subarctic, boreal and sub-boreal zones from NE Scandinavia to E Siberia; isolated populations in S Sweden, N Poland, N Belarus and Baltic states. Winters from British Is S through W Europe and Mediterranean to N Afrotropics, and E through Asia Minor, N Middle East, Azerbaijan, Iran, Afghanistan and India to S China and Vietnam.

Descriptive notes. 17-19 cm; 28-106 g; wingspan 38-42 cm. Smallest snipe; large head, relatively short bill; narrow wings with white trailing edge. Differs from all other snipes by wedge-shaped tail, which lacks white; also lacks central stripe on crown and has purple and green gloss on black upperparts. Sexes alike. Juvenile very similar to adult, but has white undertail-coverts with smaller and paler brown stripes.

Habitat. Breeds in open marshes, floodplains and bogs, in forest tundra and northern taiga. In winter, found in various brackish and freshwater habitats, often a mosaic of moist and waterlogged mudflats with tussocks of vegetation; prefers soft silty mud. During cold spells often along margins of rivers, streams and inland spring-fed meadows.

Food and Feeding. Diet includes adult and larval insects, annelids, small freshwater and terrestrial gastropods and sometimes seeds. Moves body rhythmically up and down when probing in mud; also pecks prey items from surface. Chiefly nocturnal or crepuscular. Usually feeds singly, sometimes in groups of up to c. 5 birds.

Breeding. Nests May to early Sept. Probably monogamous; male performs switchback display flight, typically at dawn and dusk, but sometimes throughout day. Nest often on floating bogs, but sometimes on drier ground among bushes; lined with pieces of grass or leaves. 4 eggs, sometimes 3; possibly double-brooded; incubation at least 21-24 days; chick mahogany red, slightly paler below, with black and white bands on face and black areas with small white down tips on crown, nape, wing-pads and upperparts; brood care apparently only by female. No further information available.

Movements. Migratory. Both adults and young remain in, or close to, breeding area during moult, Aug-Sept. SW movements over broad front across Europe from mid-Sept to mid-Nov, with arrival in non-breeding areas from Oct onwards, in tropics mainly from Nov. Migrates across C Russia Sept-Oct; reaches Egypt in Oct-Nov and India in Oct; sometimes winters in Iceland. High degree of site fidelity to staging areas. Birds wintering in Asia and E Africa originate from Siberia; uncommon migrant in Azerbaijan, but small numbers overwinter. Departs from wintering grounds Mar to mid-Apr; returns to breeding grounds mid-Apr to mid-May, up to end May in Siberia.

Status and Conservation. Not globally threatened. European breeding population may number several 100,000's of birds; estimated 28,000 pairs in Finland and Sweden (1986); up to 10,000 birds may winter in Sudan; sizes of Russian breeding and Asian wintering populations not known, but species apparently fairly common in parts of S Asia. Due to substantial loss and degradation of wetlands, breeding population believed to have declined during 19th and 20th centuries; although breeding population may now have stabilized, wintering population in Denmark and Britain declined between 1970 and 1990; now up to 100,000 winter in Britain and Ireland. Major threats are wetland drainage for agricultural intensification, afforestation and peat extraction. Hunting is another reason for concern: during autumn migration, 5% of European population is believed to be shot. Apparently rather rare in Russia, particularly E of Urals.

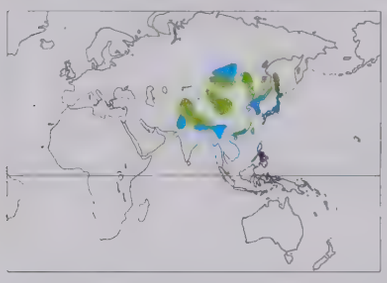
Genus *GALLINAGO* Brisson, 1760

10. **Solitary Snipe**



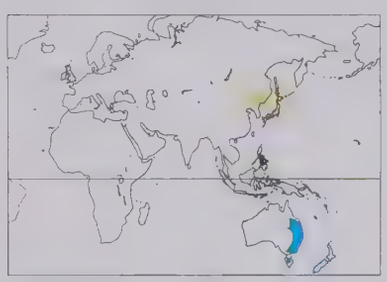
Gallinago solitaria

French: Bécassine solitaire **German**: Einsiedlerbekassine **Spanish**: Agachadiza Solitaria
Other common names: Tibet/Hermit Snipe

Taxonomy. *Gallinago solitaria* Hodgson, 1831, Nepal.

Genus formerly named *Capella*, as this name erroneously considered to pre-date *Gallinago* (see page 446). Validity of races uncertain. Two subspecies normally recognized.

Subspecies and Distribution.
G. s. solitaria Hodgson, 1831 - high mountains of C Asia, from SC Siberia through Altai, Tien Shan and Pamirs to Himalayas and probably S Tibet; winters S to E Pakistan and N India, and E to Myanmar.
G. s. japonica (Bonaparte, 1856) - mountains of Sakhalin and NE China (Heilongjiang), and probably also from Stanovoy Mts through Dzhugdzhur and Kolymskiy Mts to Kamchatka, and S to Sikhote Alin; winters from Amurland and Sakhalin to Kamchatka, and in Korea, Japan and E China.



Descriptive notes. 29-31 cm; 126-227 g; wingspan 51-56 cm. Largest of Palearctic snipes, except for *G. nemoricola*; large and heavy, with rather long bill; typically with distinctive gingery brown breast and vermiculated upperparts, although plumage somewhat variable; head greyish white; crown stripe thin, sometimes broken; white fringes to mantle and scapulars; long wings, tertials and tail; prominent chestnut on tail. Female slightly larger than male. No seasonal variation. Juvenile very similar to adult. Race *japonica* may have more red and less white on upperparts.
Habitat. Almost exclusively found at high altitudes, 1500-5000 m, well above tree-line; river valleys, grassy swamps and mountain bogs, often near running water. Outside breeding season, occurs at lower altitudes in similar habitat, at unfrozen water bodies in foothills and adjoining plains, along mountain streams, in paddyfields and marshes, and even on coast.
Food and Feeding. Diet includes small snails, worms, beetles, insect larvae, flies. Feeds by probing in wet grass and mud. Whole body bobs up and down while feeding. Feeds solitarily.
Breeding. Breeds late Jun to Aug. Nest is a well concealed depression in shrubs, sparsely surrounded or lined with dead rushes, grass or moss. 4 eggs. No further information available.
Movements. Partial migrant; generally flies only short distances. Some birds essentially sedentary, being driven to lower altitudes by cold spells. Others migratory, wintering S to foothills of Himalayas, in N India and Pakistan, and also sometimes in NE Iran; E birds winter S to Korea, Japan and E China.
Status and Conservation. Not globally threatened. Included in Russian Red Data Book, in category "insufficiently studied species". Numbers generally appear to be low, and species only locally common in SC Siberia. Less than 10,000 birds winter in Japan; rather scarce in S & E Asia; in 1992, total of 74 birds counted in Assam (NE India), and 82 birds counted in China. Occupation of bleak, high altitude habitats in extensive, but rather poorly studied, zones suggests species may be relatively secure at present.
Bibliography. Ali & Ripley (1980), Brazil (1991), Dementiev & Gladkov (1951b), Étchécopar & Hüe (1978), Flint *et al.* (1984), Hollom *et al.* (1988), Hüe & Etchécopar (1970), Inskipp & Inskipp (1991), Irisov (1976), Knystautas (1993), Kozlova (1961a), Lobkov (1989), Meyer de Schauensee (1984), Perennou *et al.* (1994), Ripley (1982), Roberts, T.J. 11. Latham's Snipe
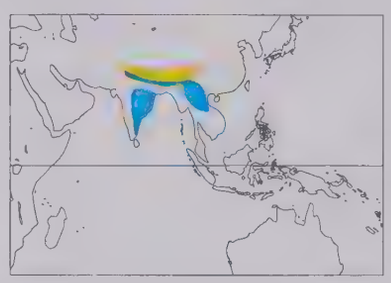
Gallinago hardwickii

French: Bécassine du Japon **German**: Japanbekassine **Spanish**: Agachadiza Japonesa
Other common names: Japanese/Australian Snipe

Taxonomy. *Scolopax Hardwickii* J. E. Gray, 1831, Tasmania.
Genus formerly named *Capella*, as this name erroneously considered to pre-date *Gallinago* (see page 446). Monotypic.
Distribution. E Primorskiy, S Sakhalin and S Kuril Is S to Hokkaido and N & C Honshu, and possibly Kyushu (S Japan). Winters in E Australia and Tasmania; perhaps also small numbers in New Guinea.

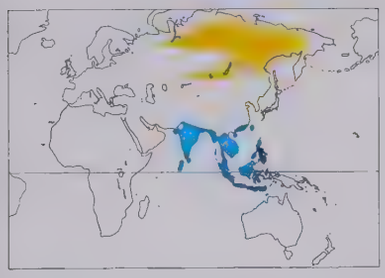


Descriptive notes. 23-33 cm; 95-277 g; wingspan 48-54 cm. Extremely similar to *G. megala* and *G. stenura*, but larger, with proportionately long tail and wings forming smoothly attenuated rear end at rest; in flight, toes do not project beyond tip of tail; differs in primary-tail and primary-tertials projections; only 18 tail feathers, as opposed to 20-22 in *G. megala*, and 26 in *G. stenura*; outer tail feathers fairly broad; structure and colour of tail feathers not visible in field. Differs from *G. gallinago* and *G. paraguaiae* by supercilium broader than eyestripe and crown stripe at base of bill; pale panel across median upperwing-coverts, evident in flight, with white trailing edge virtually absent. Sexes similar. No seasonal variation. Juvenile has pale buff, not brown-buff, fringed wing-coverts; primaries with clearer white fringes.
Habitat. Breeding habitat consists of farmland, such as meadows, pastures, fallow fields, and areas of firing and reafforestation, from coast up to 1400 m; also natural grassland, hillock bogs, river valleys with low herbaceous cover. Outside breeding season, found in variety of permanent or ephemeral freshwater wetlands, generally with dense cover, including meadows, bogs, swamps, edges of creeks and rivers, flooded areas and rice paddies. On migration, rarely on beaches and other saline or brackish habitats.
Food and Feeding. Mainly earthworms, also beetles, cranefly larvae and pupae, spiders and freshly fallen seeds; occasionally molluscs, centipedes and isopods. Diet varies with locality and month. Feeds by probing bill into soft soil. Occurs singly or in small loose groups; mainly crepuscular.
Breeding. Laying May to early Jun. Courtship flights performed alone or in groups of 4-7 birds. Nests in scattered, single pairs. Nest is shallow depression filled with stems and leaves, placed against tussock or under bush, in dry site near bog; rarely on hillock close to water. 4 eggs (2-5); single brood; apparently only female incubates.
Movements. Strongly migratory. Migration route is still a mystery; presumably flies from Japan to E Australia in few days, non-stop or stopping only at few staging sites, e.g. New Guinea and N Australia. Leaves breeding grounds late Jul to early Aug, concentrating in wet lowlands, then departing Sept to early Oct; arrival in Australia from late Jul to Oct. Erratic movements in non-breeding quarters, probably in response to rainfall and food availability. S Australia vacated in late Feb, and birds move gradually to N Australia; Japan reached early Apr to May, Primorskiy late Apr to mid-May, Sakhalin from late Apr. Fair numbers visit New Guinea, but few, if any, overwinter; species rarely spends N winter in NW Australia; vagrant in New Zealand. Most first-year birds put on fat in winter quarters, and migrate N. Species said to move at night; weather might influence timing and use of stopover sites.
Status and Conservation. Not globally threatened. Currently considered near-threatened. Total population c. 36,000 birds; estimated 27,400 birds breed on Hokkaido (1985), over 500 pairs on Sakhalin (1989); non-breeding population in Victoria, South Australia and Tasmania estimated at 15,000 birds, but hard to assess; small numbers may winter in New Guinea. During 1950's and 1960's, species expanded range from Japan to Sakhalin and Primorskiy, perhaps filling new niches in anthropogenic landscape; range in Primorskiy has recently expanded further. Adversely affected by drainage, modification of wetlands or creation of less suitable artificial wetlands, e.g. farm dams and hydro-electric impoundments; also sensitive to disturbance by humans and grazing cattle, although sometimes inhabits wetlands prone to disturbance, e.g. near factories, along roads, airfields, railways and school grounds. Industrialization in Japan gives cause for concern. Declined in Tasmania, coastal and N New South Wales and Victoria in early 1900's, 1930's, 1960's and 1970's; decline also noted in Japan during present century. Formerly shot in most Australian states, with up to 10,000 birds killed annually; in Japan c. 2,000 were killed each year; no hunting in Japan since 1974; after termination of hunting in Victoria (1984) and Tasmania (1983), slight, but not significant, increase recorded; moratorium on snipe shooting now in force throughout Australia.
Bibliography. Austin & Kuroda (1953), Baker *et al.* (1986), Beehler *et al.* (1986), Blakers *et al.* (1984), Brazil (1991), Bywater & McKean (1987), Coates (1985), Elsukov & Labzyuk (1981), Endo & Hirano (1986), Étchécopar & Hüe (1978), Frith *et al.* (1977), Fujimaki (1994), Fujimaki & Skira (1984), Garnett (1993), Hoogerwerf (1964), Iida (1991), Knystautas (1993), Lane, B.A. & Davies (1987), Lane, B.A. & Forest (1984), Lane, S.G. (1978), Leach & Hines (1992), Lida (1991), Marchant & Higgins (1996), Miskelly *et al.* (1985), Murobushi (1986), Naarding (1986), Nakamura & Shigemori (1990), Nechaev (1994), Nitta & Fujimaki (1985), Ohata (1988), Pook (1992), Scott (1989), Sutton (1981), Tuck (1972), Wolfe (1954).

12. Wood Snipe
Gallinago nemoricola

French: Bécassine des bois **German**: Nepalbekassine **Spanish**: Agachadiza del Himalaya
Other common names: Himalayan Snipe

Taxonomy. *Gallinago nemoricola* Hodgson, 1836, Nepal.
Genus formerly named *Capella*, as this name erroneously considered to pre-date *Gallinago* (see page 446). Monotypic.
Distribution. Himalayas, from NW India (Himachal Pradesh) through S & E Tibet, Nepal, Bhutan and NE India (Arunachal Pradesh and extreme NE Assam) to N Myanmar and probably SC China (W Sichuan); possibly also Pakistan. Winters in India, Bangladesh, Myanmar, N Laos, N Vietnam and rarely N Thailand.



Descriptive notes. 28-32 cm; 142-198 g. Large, dark, woodcock-like snipe with broad, rounded wings and barred underparts, extending to belly; plumage somewhat variable; narrow pale crown stripe and blackish upperparts with dull buff-grey fringes; bill broad at base. Juvenile very similar to adult but has narrower fringes to feathers of mantle and scapulars, giving scaly appearance.
Habitat. Woodlands and dense tall herbage, especially at relatively high altitude around tree-line, at 1200-4000 m. In China, breeds in alpine meadows with scattered bushes and a few streams, and in dwarf scrub in barren, boulder-strewn areas, at 3000-5000 m. After breeding, occurs at lower altitudes, usually in densely vegetated marshes or swamps, and along streams, under waist-high grass and scrubs.
Food and Feeding. Poorly known. Worms, small aquatic insects and their larvae and seeds. Usually feeds singly.
Breeding. Virtually unknown. Lays Jun. Male performs aerial drumming display.
Movements. Probably partly sedentary, although many birds move down to lower altitudes after breeding season. Some are migratory and winter to S in hill ranges of India; only rather occasionally recorded in Indochina; vagrant to Singapore and Sri Lanka.
Status and Conservation. VULNERABLE. One of least known of all snipes; believed to be very rare, with total population probably not more than 10,000 birds. Population declining locally in Nepal; since breeding habitat seems to be secure, this decline is thought to be caused by loss of wintering habitat. Might occur in Pakistan, but only single dubious record from 1887.
Bibliography. Ali & Ripley (1980), Buckton & Morris (1993), Clive (1928), Collar & Andrew (1988), Collar *et al.* (1994), Deignan (1945), Étchécopar & Hüe (1978), Hackney (1940), Inskipp & Inskipp (1991), King *et al.* (1975), Lekagul & Round (1991), Meyer de Schauensee (1984), Perennou *et al.* (1994), Phillips (1978), Phythian-Adams (1934), Ripley (1982), Roberts, T.J. (1991), Smythies (1986), Suter (1950), Sutton (1981), Tuck (1972).

13. Pintail Snipe
Gallinago stenura

French: Bécassine à queue pointue **German**: Spießbekassine **Spanish**: Agachadiza Colirrara
Other common names: Pin-tailed/Asiatic Snipe

Taxonomy. *Scolopax stenura* Bonaparte, 1830, Sunda Islands.
Genus formerly named *Capella*, as this name erroneously considered to pre-date *Gallinago* (see page 446). Monotypic.
Distribution. NC & E Russia, from Ural Mts through Siberia and Transbaikalia to Sea of Okhotsk. Winters from Indian Subcontinent and Maldives through Indochina to SE China and Taiwan, and S to Philippines and W Indonesia; also found irregularly in small numbers in Saudi Arabia, E Africa and Aldabra Is.
Descriptive notes. 25-27 cm; 84-170 g; wingspan 44-47 cm. Medium-sized snipe, very similar to *G. hardwickii* and *G. megala* but primaries normally only just longer than tertials, and tail projects only slightly beyond primaries; wing-coverts have brown-buff spots at tip; has short tail, with distinctive pin-shaped outer tail feathers, not usually visible in the field; in flight, toes project beyong tail tip notably more than in *G. megala*. Differs from *G. gallinago* and *G. paraguaiae* by supercilium broader than eyestripe and crown stripe at base of bill; pale panel across median upperwing-coverts, evident in flight, with white trailing edge virtually absent. Female very similar to male, but bill averages slightly longer. No seasonal variation. Juvenile very similar to adult, but with pale buff fringes on wing-coverts and narrower fringes on upperparts.
Habitat. During and outside breeding season occurs in slightly drier areas than those favoured by *G. gallinago*. Breeds in Arctic and boreal wetlands, damp meadows and shrub tundra with patches

of dwarf birch (*Betula nana*); up to 2500 m, along tree-line. Reports of species in grassy swamps and sphagnum bogs possibly erroneous, referring to *G. gallinago*. After breeding, found in wide variety of wetland habitats, e.g. flooded paddyfields, wet grassland, seepage swamps and marshland. Often feeds on muddy shorelines and stream banks.

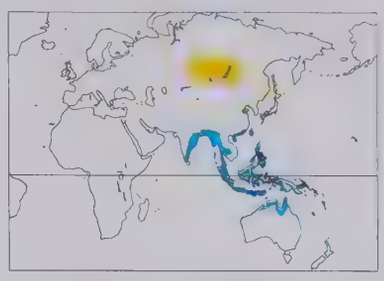
Food and Feeding. Diet includes molluscs, insects and their larvae, earthworms, occasionally crustaceans, seeds and other plant matter. Feeds by probing in soft ground, or pecking from surface. Crepuscular, nocturnal and, when undisturbed, diurnal.

Breeding. Lays late May to mid-Jun. Presumably monogamous. Dazzling communal aerial display (called "tok"), in which flock of up to 15 males suddenly plunges sideways, or each male glides and falls downwards, turning from side to side, whilst uttering frequent cries and producing sounds with modified tail feathers. Densities highly variable, locally up to 0·34 birds/ha, especially in forest clear-cuts. Nest is shallow depression lined with vegetation, usually well concealed by dense cover. 4 eggs, sometimes 3, laid at intervals of 24 hours; single brood; incubation 20 days; role of sexes in incubation and brood care unclear; chick yellowish brown or dark brown with white or pale buff-tipped down; independent after 2 months.

Movements. Migratory. Moves overland in broad front; crosses Pakistan and Iran, C Asia, Mongolia, Tibet, N China, NE Bo Hai (Gulf of Chihli), Hong Kong and Taiwan; birds in W breeding range cross Himalayas to India; common on passage in Borneo (spring and autumn); uncommonly recorded in Korea. Arrives in winter quarters late Aug to Oct, and remains till Mar to early May. Many birds winter in S & NE Indian Subcontinent. Probably also some movement over Middle East and across Indian Ocean towards E Africa (Kenya), where species occurs in small numbers at least in some years; recently reported from Benin and Gabon. Migrates in small flocks of 5-10 birds.

Status and Conservation. Not globally threatened. Number in wintering grounds in Indian Subcontinent in order of 25,000-1,000,000 birds, and similar numbers in E & SE Asia. On Russian breeding grounds fairly rare, though actual population size hard to assess. At favourable breeding sites density generally high. Anthropogenic forest changes, especially creation of forest clear-cuts, lead to increase in numbers and range; breeding range expanding slightly westwards. Commonest snipe in zone from India through Indochina to Sumatra. Subject to some hunting pressure.

Bibliography. Ali & Ripley (1980), Baccetti (1987), Backhurst (1969), Berman & Kuz'min (1965), Brazil (1991), Bundy (1983), Byrkjedal (1990), Cramp & Simmons (1983), Deignan (1945), Dementiev & Gladkov (1951b), Dickinson *et al.* (1991), Étchécopar & Hüe (1978), Flint *et al.* (1984), Hirschfeld (1992), Hüe & Étchécopar (1970), Jaensch (1990), Knystautas (1993), Kozlova (1961a), Lekagul & Round (1991), MacKinnon & Phillipps (1993), Madge (1977), Madoc (1976), Malkov *et al.* (1983), van Marle & Voous (1988), Medway & Wells (1976), Meissner & Skakuj (1988), Morozov (1993b), Olsson (1987), Pearson (1984b), Perennou *et al.* (1994), Phillips (1978), Prys-Jones & Wilson (1986), Ripley (1982), Roberts, T.J. (1991), Rogacheva (1992), Scott (1989), Shcherbakov (1979), Shirihai (1988), Short *et al.* (1990), Smythies (1981, 1986), Sutton (1981), Taylor, P.B. (1984b, 1988), Tuck (1972), Urban *et al.* (1986), White & Bruce (1986), Williams, M.D. (1986).



14. Swinhoe's Snipe
Gallinago megala

French: Bécassine de Swinhoe **German**: Waldbekassine **Spanish**: Agachadiza del Baikal
Other common names: Chinese/Forest/Marsh Snipe

Taxonomy. *Gallinago megala* Swinhoe, 1861, between Takoo and Beijing, north China.

Genus formerly named *Capella*, as this name erroneously considered to pre-date *Gallinago* (see page 446). Monotypic.

Distribution. CS Siberia and N Mongolia; Amurland and Ussuriland. Winters from S & E India to E & S China and Taiwan, and S through Malay Peninsula, Philippines and Indonesia to New Guinea and N Australia.

Descriptive notes. 27-29 cm; 82-164 g; wingspan 38-44 cm. Medium-sized snipe, very similar to *G. stenura* and *G. hardwickii*; primaries project beyond tertials slightly more than in *G. stenura*; tail projects beyond primaries slightly more than in *G. stenura*, but less than in *G. hardwickii*; paired buffish white spots on tips of upperwing-coverts more clearly marked than in the other two species; in flight, toes project only slightly beyond tail tip. Differs from *G. gallinago* and *G. paraguaiae* by supercilium broader than eyestripe and crown stripe at base of bill; pale panel across median upperwing-coverts, evident in flight, with white trailing edge virtually absent. Female very similar to male, but bill averages slightly longer. No seasonal variation. Juvenile very like adult, but wing-coverts and tertials narrowly fringed whitish buff; tertials have buff barring.

Habitat. In, or at margins of, deciduous or mixed open woodland, river valleys, and grassy localities near marshes and streams; usually favours drier and more enclosed sites than *G. gallinago*; sometimes on alpine meadows at tree-line. During non-breeding period, found at edges of wetlands, including marshy areas, paddyfields, sewage farms and freshwater streams. Often feeds among hummocks or on mudflats around seepage areas.

Food and Feeding. Diet includes earthworms, glow-worms, adult and larval insects, such as beetles and ants, terrestrial gastropods and seeds. Crepuscular and nocturnal; mainly solitary.

Breeding. Laying May-Jul. Monogamous. Flight display usually solitary, but can apparently be performed by flock, flying in large circles above forest. Scattered solitary pairs at highly variable densities, 2-63 pairs/km^2; highest concentrations in industrial clear-cuts in boreal mountain forests. Nest placed among bushes, in meadows, often on slight elevations; simple scrape, sparsely lined with grass. Usually 4 eggs (2-5); single brood; males do not participate in incubation; chick overall tawny chestnut with white-tipped down on back and sides of head; male probably shares in care of chicks; fledging 18-20 days.

Movements. Strongly migratory. Post-breeding movement through Russia chiefly towards SE, then apparently via E Mongolia, China (late Jul to Aug), Taiwan and Philippines, occasionally through Japan, rarely Korea; present in Australia mainly Nov-Feb, late birds up to mid-Apr. Birds moving N from Philippines may follow coast of China from early Mar, until they move inland near Bo Hai (Gulf of Chihli).

Status and Conservation. Not globally threatened. Status uncertain due to confusion with other extremely similar species and secretive behaviour; total population probably numbers 25,000-100,000 birds. In 1992, total of 146 birds counted wintering in China; uncommon but regular visitor to India and Pakistan; in some seasons very abundant in rice fields in Philippines. At beginning of 20th century, considered extremely abundant in forest-steppe and sub-taiga areas of C Siberia; nowadays, species is locally distributed in this area, and has become rare in forest-steppe zones; still rather numerous in sub-taiga zone.

Bibliography. Abdulali (1970), Ali & Ripley (1980), Beehler *et al.* (1986), Blakers *et al.* (1984), Brazil (1991), Coates (1985), Dementiev & Gladkov (1951b), Dickinson *et al.* (1991), Étchécopar & Hüe (1978), Ey (1984), Flint *et al.* (1984), Hoogerwerf (1964), Knystautas (1993), Königstedt (1986), Kozlova (1961a), MacKinnon & Phillipps (1993), Madge (1989a, 1989b), Madoc (1976), Marchant & Higgins (1996), Medway & Wells (1976), Meissner & Skakuj (1988), Meyer de Schauensee (1984), Naumov (1962), Perennou *et al.* (1994), Poslavsky & Sokolov (1980), Prys-Jones & Wilson (1986), Rabor (1977), Ripley (1982), Rogacheva (1992), Scott (1989), Smythies (1981, 1986), Sutton (1981), Tuck (1972), Wallace (1989), White & Bruce (1986).

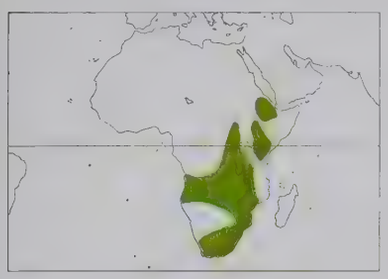


PLATE 41

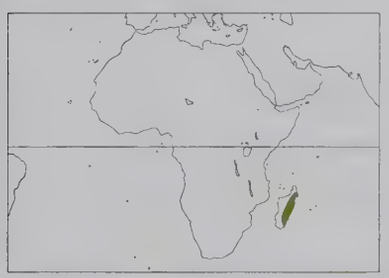
inches 5
cm 13

15. African Snipe
Gallinago nigripennis

French: Bécassine africaine **German**: Afrikanische Bekassine **Spanish**: Agachadiza Africana
Other common names: Ethiopian Snipe

Taxonomy. *Gallinago nigripennis* Bonaparte, 1839, Cape of Good Hope.
Genus formerly named *Capella*, as this name erroneously considered to pre-date *Gallinago* (see page 446). May form superspecies with *G. gallinago* and *G. paraguaiae*, and all three sometimes treated as conspecific. Species sometimes considered monotypic. Three subspecies recognized.
Subspecies and Distribution.
G. n. aequatorialis Rüppell, 1845 - Ethiopia through Uganda, E Zaire, Kenya and Tanzania to Malawi, E Zimbabwe and N Mozambique.
G. n. angolensis Bocage, 1868 - Angola and Namibia through Botswana to Zambia and W Zimbabwe.
G. n. nigripennis Bonaparte, 1839 - S Mozambique and South Africa.

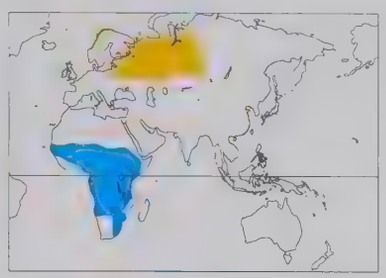


Descriptive notes. 25-29 cm; 93-164 g. Resembles *G. gallinago* and other close relatives, but larger, and has darker upperparts contrasting with white belly; bill often longer; white trailing edge to wing; more white on outer tail feathers, noticeable in flight. Female very similar to male, but bill averages slightly longer. No seasonal variation. Juvenile has mantle, scapulars and wing-coverts more narrowly fringed. Races rather similar: *aequatorialis* somewhat blacker above; *angolensis* averages longer-billed.
Habitat. Breeds in highland bogs, swampy lake edges and ditches, seasonally flooded grassland and wet moorland; in Ethiopia and E Africa occurs at altitudes above 1500 m, occasionally up to 4000 m; during breeding season typically at 1800-2700 m. After breeding, found at lower altitudes, even down to coastal lowlands. Feeds in muddy areas with scattered low vegetation.
Food and Feeding. Mainly larvae of beetles, dragonflies, and flies, annelids, small crustaceans and molluscs, sometimes seeds. Chiefly crepuscular or nocturnal feeder, usually in small numbers and somewhat scattered groups.
Breeding. In tropics, laying irregular, Mar-Nov, during or just after rains; in S Africa, mainly Apr and Jun-Oct. Monogamous. Solitary, or several pairs clustered. Nest is pad of grass leaves, hidden in tussock, surrounded by flooded or moist ground. 2-3 eggs; chick has rich tawny down. No further information available.
Movements. No regular migration, but may move erratically several hundred kilometres from nesting grounds, often associated with drying of temporary floods. In E Africa, descends somewhat from higher areas after breeding.
Status and Conservation. Not globally threatened. Limits of breeding range very poorly known. Locally common (e.g. in South Africa) to abundant, but, like most snipes, true status hard to judge; no population estimates available.
Bibliography. Benson & Benson (1975), Britton, P.L. (1980), Brown & Britton (1980), Clancey (1967), Dowsett & Dowsett-Lemaire (1980, 1993), Dowsett & Forbes-Watson (1993), Ginn *et al.* (1989), Hockey & Douie (1995), Lippens & Wille (1976), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), van Perlo (1995), Pinto (1983), Pirow (1981), Short *et al.* (1990), Sinclair & Davidson (1995), Sinclair *et al.* (1993), Snow (1978), Sutton (1981), Taylor, P.B. (1980a), Tuck (1972), Urban *et al.* (1986).

16. Madagascar Snipe
Gallinago macrodactyla

French: Bécassine malgache **German**: Madagaskarbekassine **Spanish**: Agachadiza Malgache
Other common names: Malagasy/Madagascan Snipe

Taxonomy. *Gallinago macrodactyla* Bonaparte, 1839, Madagascar.
Genus formerly named *Capella*, as this name erroneously considered to pre-date *Gallinago* (see page 446). Has been treated as conspecific with *G. gallinago* and *G. nobilis*, and might form part of *G. gallinago* superspecies. Monotypic.
Distribution. Madagascar, mainly in C & E.



Descriptive notes. 29-32 cm; 216 g (1 female). Large, heavy, long-billed snipe. Structurally similar to *G. nigripennis*, but with less contrast between upperparts and underparts; outer rectrices greyer brown; similar to *G. gallinago* and other close relatives, but long bill and legs dark; only narrow greyish trailing edge to secondaries, darker underwings and wing-coverts with warm olive-buff fringes. Adult has cold olive-brown spots on tips of wing coverts. Female very similar to male, but bill averages slightly longer. No seasonal variation. Juvenile has narrower and paler warm olive-buff fringes to scapulars and mantle feathers.
Habitat. Grassy and sedge-covered marshes and swamps, margins of water courses, and rice paddies, from sea-level up to elevations of 2700 m; prefers presence of dense vegetation and muddy areas.
Food and Feeding. Invertebrates, seeds and other plant matter recorded. Probes deeply into mud; normally feeds in muddy areas or shallow water. Outside breeding season, frequently forages in small groups of 4-8 birds.
Breeding. Very poorly known. Laying probably Jul-Jan. Nest is depression on dry hummock, scantily lined with grass. 3 eggs (2-4). No further information available.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. No population estimate available; apparently uncommon within restricted breeding range, but, as with other snipes, secretive habits probably mean species under-recorded. Threatened by habitat transformation, particularly with spread of paddyfields; hunting pressure may also be significant.
Bibliography. Albignac (1970), Benson (1981), Benson *et al.* (1976-1977), Dee (1986), Delacour (1932), Dowsett & Forbes-Watson (1993), Langrand (1990), Milon *et al.* (1973), Rand (1936), Salvan (1970, 1972b), van Someren (1947), Sutton (1981), Tuck (1972).

17. Great Snipe
Gallinago media

French: Bécassine double **German**: Doppelschnepfe **Spanish**: Agachadiza Real
Other common names: Double Snipe

Taxonomy. *Scolopax Media* Latham, 1787, England.
Genus formerly named *Capella*, as this name erroneously considered to pre-date *Gallinago* (see page 446). Monotypic.
Distribution. Scandinavia E through Baltic states, Poland and W Russia to R Yenisey. Winters in sub-Saharan Africa.

Descriptive notes. 27-29 cm; 140-260 g; wingspan 47-50 cm. Medium-sized, bulky snipe; differs from similar species by bold white tips on wing-coverts, bold dark barring on white underparts, and unbarred white corners to tail; distal half of bill has slight droop. Female very similar to male, but averages slightly larger. Non-breeding adult has duller and darker upperparts. Juvenile like breeding adult, but duskier and less well marked; brown bands on white tail corners; white on wing-coverts obscure; belly often more fully and regularly barred.
Habitat. Selects habitats rich with sub-surface invertebrates and medium scrub cover for breeding, usually in wide river valleys; floodplain meadows, tussock meadows, peatland, tundra with scattered bushes, and sometimes drier woodlands adjacent to marshes or bogs. After breeding, occurs in marshland, in short grass or sedges on lake edges or flooded fields, tracks in wooded areas; usually drier habitat than that preferred by *G. gallinago*.
Food and Feeding. Mainly earthworms, but also gastropods and larvae and adults of terrestrial insects, such as beetles and tipulids; also seeds, mainly of marsh plants. Probes in soil for earthworms, but also pecks from surface and feeds in very shallow water. Feeds singly or in small numbers. Crepuscular and nocturnal feeder.
Breeding. Lays mid-May to early Jul. Polygamous. The only *Gallinago* with no aerial nuptial display in which distinctive sounds made by tail feathers; instead, has complex lekking system, with males gathering after sunset on traditional display grounds (leks); performs elaborate display on top of small mound in which white outer tail feathers are distinctly advertised; female alone builds nest, incubates, and cares for young. Solitary breeder. Nest is shallow depression in ground, filled with some moss or grass; in thick vegetation, usually completely concealed, but sometimes more open. 4 eggs (3-5); incubation 22-24 days; chick cinnamon-buff or densely mottled ferruginous brown above with brown median zone bordered black with dense buffish white down tips, distinctly marked head with brown and black bands and cinnamon- or ochraceous-buff underparts grading to nearly white on central belly; fledging 21-28 days; young independent immediately after fledging.
Movements. Migratory. Departure from breeding grounds from early Aug onwards, and wintering on flooded grasslands in African regions just after rainy season. Migrates across Turkey and down R Nile to Ethiopian plateau, arriving Aug-Sept; only rare passage visitor in Egypt, late Aug to late Oct and early Mar to mid-Apr. In Ethiopia, large numbers stay until grasslands dry up in Oct, whereafter they move S & SW, following the rains; recorded in Kenya, SW Tanzania, Malawi, Zambia, Zaire, Zimbabwe, Namibia and South Africa from mid-Oct; 5000-10,000 birds have been counted in Mali, in Nov. High numbers probably migrate to wetlands along Gulf of Guinea where they stay Aug-Dec; as wetlands dry up, these birds migrate to other, undetermined areas in Africa; moult data suggest that these birds constitute separate population. Northward migration occurs in broad front over Africa Mar-Apr, and probably orientated more to W, crossing Mediterranean, but northward migration passes largely unnoticed; males arrive in Ukraine before females; arrives on R Yenisey in early Jun. Irregularly, some birds winter in NW Europe and S Scandinavia.
Status and Conservation. Not globally threatened. Currently considered near-threatened. Has declined enormously over entire breeding range this century; extinct as breeder in Germany and Denmark, primarily due to loss and deterioration of floodplain meadows and marshlands. In Russia, however, decrease started at end of 19th century, before beginning of land reclamation. Breeding in meadows is probably a secondary development; damp tussocky bogs are preferred. Also, excessive hunting and climatic change have been suggested as relevant factors; still hunted in E Europe. In USSR, was seen in large flocks until 1940's. World population estimated at 170,000-290,000 "pairs": Scandinavian breeding population has stabilized at 6000-17,000 "pairs"; breeding population in Poland 400-500 "pairs", Estonia 50-100, Lithuania 30-50, Belarus 12,000-20,000, Ukraine 400-500 and Russia 150,000-250,000 "pairs". Numbers still decreasing and breeding range contracting and fragmenting in some parts at western and southern limits. In Scandinavia, decreased grazing intensity in low alpine areas causes further decline. Ethiopian wintering population seems stable or even increasing since 1913, but this may be due to degradation of formerly used wintering areas; local densities in Ethiopian Highlands may reach 1300 birds/km² in Aug-Oct.

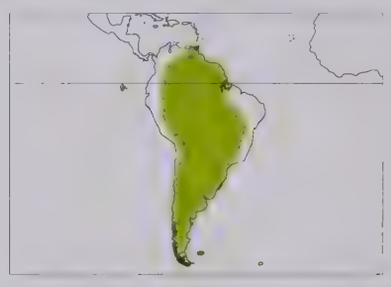
18. Common Snipe

Gallinago gallinago

French: Bécassine des marais **German**: Bekassine **Spanish**: Agachadiza Común
Other common names: Fantail/Wilson Snipe

Taxonomy. *Scolopax Gallinago* Linnaeus, 1758, Sweden.
Genus formerly named *Capella*, as this name erroneously considered to pre-date *Gallinago* (see page 446). Forms superspecies with *G. paraguaiae* and perhaps *G. nigripennis*, which are sometimes included as subspecies of present species, but differences in size, outer tail feathers and quality of aerial "winnowing" suggest separate species status; *G. macrodactyla* may also belong to superspecies. Race *delicata* may constitute separate species; has 16 tail feathers, as opposed to usually 14 (sometimes 12, 16 or 18) in nominate; both forms breed nearby in Aleutians. Three subspecies currently recognized.
Subspecies and Distribution.
G. g. faeroeensis (C. L. Brehm, 1831) - Iceland, Faeroes, Orkney and Shetland; winters in British Is.
G. g. gallinago (Linnaeus, 1758) - British Is, Scandinavia and W Europe through NC Eurasia to Kamchatka and W Aleutians, with isolated population from NE Afghanistan to N India; winters from W Europe, Mediterranean and equatorial Africa through Middle East, Arabia and Indian Subcontinent to E China, S Korea, S Japan, Philippines and W Indonesia.
G. g. delicata (Ord, 1825) - E Aleutians and Alaska E through Canada to Newfoundland, and S to C California, New Mexico, C Iowa and New Jersey; winters from NW & C USA through Central America and Greater Antilles to N South America.



Descriptive notes. 25-27 cm; 72-181 g; wingspan 44-47 cm. Small to medium-sized snipe, with rather long bill and white belly; plumage variable, and melanistic morph occurs (e.g. in Ireland); flight faster and more erratic than other snipes of similar size. Differs from very similar *G. paraguaiae* normally by neck, breast and flanks more heavily marked, and, in flight, wings more pointed; from *G. stenura*, *G. hardwickii* and *G. megala* by prominent white trailing edge to wing, and supercilium narrower than eyestripe at base of bill. Sexes alike. No seasonal variation. Juvenile very similar to adult, but wing-coverts more neatly fringed pale buff. Race *faeroeensis* darker and more rufous above, with narrower, less contrasting, back stripes; *delicata* darker than *faeroeensis*, generally less rufous than nominate with heavier barring on flanks, and usually has darker underwing.
Habitat. Open fresh or brackish marshland with rich or tussocky vegetation, grassy or marshy edges of lakes and rivers, wet hay fields, swampy meadows and marshy tundra, in forest tundra and extreme northern taiga zones; in general, found in areas providing combination of grassy cover and moist soils, rich in organic matter. Outside breeding season, generally occupies similar habitats, with more use of man-made habitats, e.g. sewage farms and rice fields; also upper reaches of estuaries, sometimes on coastal meadows.
Food and Feeding. Diet includes larval insects (10-80%), adult insects, earthworms, small crustaceans, small gastropods and spiders; plant fibres and seeds consumed in smaller quantities. Feeds by vertical, rhythmic probing in substrate, often without removing bill from soil. Feeds typically in small groups; essentially crepuscular.
Breeding. Laying Apr-Jun. Monogamous, but both sexes show high degree of promiscuity. Territorial; densities up to 10-38 (even 110) pairs/km². Nest usually on dry spot, covered by grasses, rushes, sedges or sphagnum. 4 eggs (2-5), with laying interval 1 day; lays replacement clutches; incubation 17-20 days, by female alone; chick mahogany red, more hazel brown or tawny on sides of head and underparts, with black and white bands on head; both parents care for young, but male entices oldest 1 or 2 from nest to tend; young initially fed bill-to-bill; fledging 19-20 days. Success 2·2 hatchlings per nest, 3·5 per successful nest. High proportion of eggs may be predated or trampled by cattle. Mean annual mortality 52%.
Movements. Mostly migratory, wintering S to N tropics; some populations sedentary or partially migratory, e.g. British Is, W & C USA. Moves quickly from breeding grounds to moulting areas, and after few weeks quickly migrates to wintering grounds. High degree of site fidelity at staging sites. Birds wintering in Afrotropics presumably from Russia, crossing Sahara on broad front. European and Atlantic birds move to S & W Europe; species seems to have shifted main moulting grounds from continental (particularly Netherlands) to Britain since late 1950's. Nearctic population mainly migratory, and birds from Canadian Maritime Provinces perform transoceanic passage to Neotropics. Autumn passage from late Jul to Nov, with arrival in N Africa mainly late Sept to early Oct, S of Sahara mainly Oct to early Nov, South America from Jul; most birds leave South America and Africa in Mar; crosses Europe Mar to early May, males typically arriving on breeding grounds 10-14 days earlier than females.
Status and Conservation. Not globally threatened. Total North American population probably numbers in low millions; in Europe 530,000 pairs (1986) and 100,000's of pairs in W Russia; in W Siberia at least 1,000,000 breeding birds; possibly more than 1,000,000 birds winter in SW & SC Asia, and 100,000's in E & SE Asia. Total of 300,000 pairs (*faroeensis*) breed in Iceland, 30,000 pairs in Britain, 100,000 pairs in Fenno-Scandia, c. 20,000 pairs in Germany, 20,000-30,000 in Estonia (1994) and 13,000-15,000 pairs in Poland. Common to very abundant on African wintering grounds (c. 1,500,000 in Sudan). Decline noted in breeding populations of Europe, W Siberia and C & E Canada, probably chiefly due to habitat changes, especially drainage; in Schleswig-Holstein, N Germany, decline from 13,000 pairs in 1970 to 1500 in 1992; 99-100% decline after improvement of marginal grasslands in N England. Low water levels shorten period of food availability in pastures, due to lower penetrability of soil, and thereby strongly influence length of breeding season; careful manipulation of water levels may allow improvement of breeding success. Estimated 1,500,000 birds hunted annually in Europe (notably France) and 500,000 in North America.

19. South American Snipe

Gallinago paraguaiae

French: Bécassine de Magellan **German**: Magellanbekassine **Spanish**: Agachadiza Suramericana
Other common names: Magellan/Paraguayan Snipe; Puna/Andean Snipe (*andina*); Chilean Puna Snipe ("*innotata*")

Taxonomy. *Scolopax Paraguaiæ* Vieillot, 1816, Paraguay.
Genus formerly named *Capella*, as this name erroneously considered to pre-date *Gallinago* (see page 446). Forms superspecies with *G. gallinago* and perhaps *G. nigripennis*, and all three occasionally considered conspecific. Race *andina* has often been regarded as full species, and *magellanica* too may be close to separate species status. Possible race *innotata*, from R Loa, N Chile, proposed on basis of densely barred underwing-coverts; on occasion, this form has even been considered separate species. Three subspecies recognized.
Subspecies and Distribution.
G. p. paraguaiae (Vieillot, 1816) - E Colombia through Venezuela to the Guianas, and S through E Peru and W, C & S Brazil to N Argentina and Uruguay; Trinidad and possibly Tobago.
G. p. andina (Taczanowski, 1875) - S Peru, W Bolivia, N Chile and NW Argentina.
G. p. magellanica (King, 1828) - C Chile and C Argentina S to Tierra del Fuego; Falkland Is.

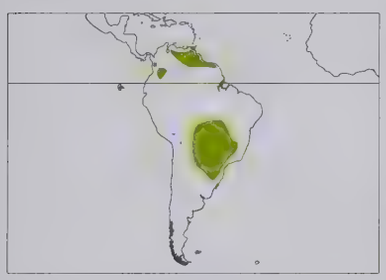
Descriptive notes. 22-29 cm; 1 nominate bird 136 g, *andina* 65-105 g. Small snipe, very similar to *G. gallinago* and *G. nigripennis*, but normally differs in having paler face and fainter markings on neck, breast and flanks; outer tail feathers narrower and whiter, underwing normally slightly paler. Separated from *G. stenura*, *G. hardwickii* and *G. megala* by prominent white trailing edge to wing, and supercilium narrower than eyestripe at base of bill. Female very similar to male, but slightly larger. No seasonal variation. Juvenile very similar to adult, but wing-coverts more neatly fringed pale buff. Race *magellanica* more buff tinted and generally warmer coloration with fainter markings on breast and flanks; longer wings. Race *andina* smallest, with shortest bill and dull yellow legs, (greenish grey in other races); more contrasting plumage, especially blackish mantle, primaries and primary coverts.
Habitat. Habitats quite different between races. Widespread *paraguaiae* typically occurs in wet grassy savannas. High altitude *andina* found along boggy rivers high in *puna* zone of Andes, up to 4500 m; occupies boggy ground with cushion-plants, but also areas of rushes, reeds and grassland. Race *magellanica* occurs in peat bogs and grass-covered *pampas* and steppes; also sometimes open, swampy woods; in S Patagonia, often in areas with tussock grass.
Food and Feeding. Said to feed mainly on invertebrates, e.g. insect larvae and earthworms. Feeds by probing in mud, in style similar to that used by *G. gallinago*.
Breeding. Race *paraguaiae* probably nests from late Nov onwards, and eggs found in May in Uruguay considered atypical; *andina* mainly Oct-Dec in C Peru, Sept in N Chile; eggs of *magellanica* found Aug and Nov. One nest in tussock of tall grass. Race *magellanica* typically lays 2 eggs and *paraguaiae* 4, but very few data available.
Movements. Nominate *paraguaiae* essentially sedentary, in some areas performing short seasonal movements to permanent marshland during austral winter. Race *andina* moves to lower altitudes, e.g. reaching Argentinian *pampas*. Race *magellanica* more migratory, especially on Tierra del Fuego, birds moving N to N Argentina and Uruguay in Apr-Jul; in past mostly summer visitor to Falkland Is, but no recent evidence of migration and some birds certainly overwinter.
Status and Conservation. Not globally threatened. No population estimates available, but numbers thought to be relatively stable and range huge. Race *andina* widespread and apparently common in *puna*, though least so in more arid S parts of range. Race *magellanica* common in all low valleys of S Andes, and in lake district around Valdivia, SC Chile; on migration, not uncommon on upland plateaux of Patagonian steppe.
Bibliography. Arango (1986), Barlow (1967), Belton (1984), Blake (1977), Clark (1986), Contreras, J.F. (1980), Contreras, J.R. *et al.* (1990), Dubs (1992), Fjeldså & Krabbe (1990), Forrester (1993), Haverschmidt (1968, 1976), Haverschmidt & Mees (1995), Hellmayr & Conover (1948), Hilty & Brown (1986), Howell & Webb (1995b), Humphrey *et al.* (1970), Johnson (1965b), Klimaitis & Moschione (1987), Meyer de Schauensee & Phelps (1978), Navas & Bo (1993), Parker *et al.* (1982), de la Peña (1981, 1992), Remsen & Traylor (1989), Scott & Carbonell (1986), Sick (1985c, 1993), Snyder (1966), Sutton (1981), Tostain *et al.* (1992), Tuck (1972), Wetmore (1926).

20. Noble Snipe

Gallinago nobilis

French: Bécassine noble **German**: Nobelbekassine **Spanish**: Agachadiza Noble
Other common names: Paramo Snipe

Taxonomy. *Gallinago nobilis* P. L. Sclater, 1856, Bogotá, Colombia.
Genus formerly named *Capella*, as this name erroneously considered to pre-date *Gallinago* (see page 446). Monotypic.
Distribution. N Andes, from NW Venezuela through C Colombia to Ecuador.
Descriptive notes. 30-33 cm; 188-197 g. Medium-sized, bulky snipe with disproportionately long, two-toned bill; underwing relatively dark; wings rather broad and rounded; tail virtually without white; toes project beyong tail tip. Larger and usually darker than *G. paraguaiae*, with broader wings which lack white trailing edge. Differs from *G. jamesoni* by white belly and larger white throat patch. Rather similar to *G. macrodactyla*, but breast warmer buff, and bill base pale. Female similar but bill longer. No seasonal variation. Juvenile very similar to adult, but has narrow buff edges on wing-coverts.

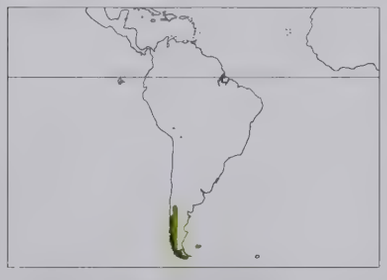


Habitat. Montane grassy wetlands, swamps and bogs, wet savannas, rushy pasture and reed-marsh adjoining eutrophic lakes; mainly at 2500-3900 m, but sometimes up to 4000 m and down to 2000 m; above and just below tree-line, typically in *páramo* zone.
Food and Feeding. No information available.
Breeding. Season Mar-Sept. Circling aerial display; may perform lek behaviour. Nest is depression on dry hummock of grasses and mosses; composed of grasses and fragments of other plants. Probably only 2 eggs; chick rich chestnut with black pattern and rows of white spots. No further information available.
Movements. Presumably sedentary.
Status and Conservation. Not globally threatened. No population estimates available; locally fairly common in Colombia. Very poorly known; research required.
Bibliography. Arango (1986), Blake (1977), Butler (1979), Fjeldså & Krabbe (1990), Hellmayr & Conover (1948), Hilty & Brown (1986), Meyer de Schauensee (1966), Meyer de Schauensee & Phelps (1978), Ortiz & Carrión (1991), Scott & Carbonell (1986), Sutton (1981), Tuck (1972), Varty *et al.* (1986).

21. Giant Snipe
Gallinago undulata

French: Bécassine géante **German**: Riesenbekassine **Spanish**: Agachadiza Gigante
Other common names: Guianan Giant Snipe

Taxonomy. *Scolopax undulata* Boddaert, 1783, Cayenne.
Genus formerly named *Capella*, as this name erroneously considered to pre-date *Gallinago* (see page 446). Some authors suggest that race *gigantea* may merit treatment as separate species. Two subspecies recognized.
Subspecies and Distribution.
G. u. undulata (Boddaert, 1783) - W & E Colombia; Venezuela to extreme N Brazil and probably E to the Guianas.
G. u. gigantea (Temminck, 1826) - E Bolivia, Paraguay and SE Brazil; probably also Uruguay and NE Argentina.

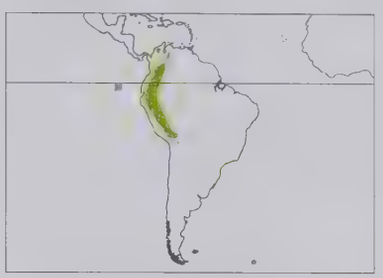


Descriptive notes. 40-47 cm; *undulata* 270-362 g, *gigantea* 420-500 g. Largest snipe, with flat-headed profile, and bill very long with broad base; bold blackish and cinnamon markings contrast with whitish ground colour; unlike any other snipe, has barred flight-feathers; in flight, shows broad, rounded wings and no white in tail. Race *gigantea* larger, and usually has more boldly marked plumage and broader cinnamon edging on upperparts.
Habitat. In swamps with tall vegetation, marshy pastures and flooded grasslands, from tropical zone up to 2200 m; sometimes in dense herbage of dry savannas, but possibly only for roosting.
Food and Feeding. Virtually nothing known; diet said to include frogs. Probably rather solitary, but possibly more gregarious during non-breeding season. May feed only at night.
Breeding. Very poorly known. Calls during display flight very different from those of *G. gallinago*: 2-5 sonorous cries with a human timbre, and loud buzz lasting c. 4 seconds. Nests found in Sept in Brazil, and from Nov to early Jan. Often nests on small hillock among swamps. 2-4 eggs; chick black, finely spotted white.
Movements. Virtually nothing known; arrives at some sites seasonally, apparently after rain.
Status and Conservation. Not globally threatened. No population estimates available, but Brazil may be main centre of population. Species nowhere common, but nocturnal habits, together with extreme wariness towards approaching humans, may exaggerate impression of scarcity. Local and uncommon in Colombia; rare in French Guiana, where reported to suffer severe hunting pressure. First definite record for Bolivia recently established by means of tape-recording of nocturnal display calls; surveys may show range to be more extensive in other areas. Population of race *gigantea* seems to be declining; apparently easier to shoot than some other sympatric snipes.
Bibliography. Abramson (1977), Arango (1986), Belton (1984), Blake (1977), Dubs (1992), Forrester (1993), Haverschmidt (1968, 1974b), Haverschmidt & Mees (1995), Hellmayr & Conover (1948), Hilty & Brown (1986), Mayer (1995), Meyer de Schauensee (1966), Meyer de Schauensee & Phelps (1978), Pearman (1995a), Pinto (1964), Scott & Carbonell (1986), Sick (1985c, 1993), Snyder (1966), Sutton (1981), Teixeira *et al.* (1983), Tostain *et al.* (1992), Tuck (1972).

22. Fuegian Snipe
Gallinago stricklandii

French: Bécassine de Strickland **German**: Kordillerenbekassine **Spanish**: Agachadiza Fueguina
Other common names: (Southern/Strickland's) Cordilleran Snipe

Taxonomy. *Gallinago stricklandii* G. R. Gray, 1845, Hermit Island, Cape Horn.
Formerly placed in genus *Chubbia*. Forms superspecies with *G. jamesoni*, with which often considered conspecific. Monotypic.



Distribution. SC Chile and SC Argentina S to Tierra del Fuego.
Descriptive notes. 29-30 cm. Dark and rufous woodcock-like snipe, with broad, rounded wings; small, unmarked throat patch; central belly unbarred buff. Like *G. jamesoni* and *G. imperialis*, lacks clear pale stripes on head and upperparts typical of other snipes; lacks white on wings and tail. Very similar to *G. jamesoni*, but underparts richer buff. Sexes alike. No seasonal variation. Juvenile very similar to adult, but feathers of mantle and scapulars narrowly edged pale buff.
Habitat. Grassy or forested boggy areas with low scrub or rushes; often mosaic of grassy bog, bamboo and lichen-clad dwarf forest, sometimes cushion-plant bogs; occurs from sea-level, in fjordland habitat and on small islands, up to more than 3000 m.
Food and Feeding. Virtually nothing known, but diet includes beetles. Apparently largely nocturnal.
Breeding. Not well known. Nest and chicks found in Dec. Nest sited on elevated ground among short, sparse grasses and rushes. Normally 2 eggs; chick like that of *G. jamesoni*, but brighter, with white spots in pale zones.
Movements. Mostly sedentary, but extreme S including Tierra del Fuego vacated during winter. Rarely occurs on Falkland Is.
Status and Conservation. Not globally threatened. Currently considered near-threatened. No population estimates available; highly secretive habits make possible census work very difficult. Status extremely uncertain; species reported to be common on islands around Cape Horn, but decreasing in numbers towards N.
Bibliography. Blake (1977), Clark (1986), Fjeldså & Krabbe (1990), Hellmayr & Conover (1948), Humphrey *et al.* (1970), Johnson (1965b), Meyer de Schauensee (1966), Narosky & Yzurieta (1987), de la Peña (1992), Reynolds (1935), Scott & Carbonell (1986), Sutton (1981), Tuck (1972), Woods (1988).

23. Andean Snipe
Gallinago jamesoni

French: Bécassine des paramos **German**: Andenbekassine **Spanish**: Agachadiza Andina
Other common names: Northern Cordilleran/Jameson's Snipe

Taxonomy. *Xylocota jamesoni*. Bonaparte, 1855, high Andes of Quito, Ecuador.
Formerly placed in genus *Chubbia*. Forms superspecies with *G. stricklandii*, with which often considered conspecific. Monotypic.
Distribution. Santa Marta Mts (N Colombia) and Andes from W Venezuela S to WC Bolivia.

Descriptive notes. 29-30 cm; 140-224 g. Bulky, woodcock-like snipe. Like *G. stricklandii* and *G. imperialis*, lacks clear pale stripes on head and upperparts typical of other snipes; lacks white on wings and tail. Very similar to *G. stricklandii*, but bill deep at base, tapering and often drooping slightly towards tip; larger unmarked throat patch; underparts colder buff, whiter on belly and more heavily barred; in flight, wings slightly longer and narrower. Sexes alike. No seasonal variation. Juvenile very similar to adult, but wing-coverts warmer buff and less clearly barred, but notched with dark brown and tipped pale tawny buff.
Habitat. Found in variety of habitats from open swampy forest to coastal moorland with dwarf shrubs and miry parts; also in grassy marshland above tree-line, at 2100-3800 m, occasionally 4300 m; typically found on open slopes of *páramo*, especially grassy areas with *Espeletia*.
Food and Feeding. No information available.
Breeding. Gonads of few specimens suggest egg-laying from Mar to early Apr, but species also nests in May and Aug-Nov; display recorded at dusk in mid-Sept, Colombia. Nest is delicate saucer of grass on dry slope, at some distance from bog. Normally 2 eggs; chick tawny buff with bold fuscous pattern and some buff-white stripes on head and back.
Movements. Probably sedentary. In Santa Marta Mts, records at lowest altitudes were at end of dry season.
Status and Conservation. Not globally threatened. No population estimates available; status extremely uncertain, but species probably not rare. Uncommon and perhaps local in Colombia.
Bibliography. Arango (1986), Blake (1977), Butler (1979), Fjeldså & Krabbe (1990), Hellmayr & Conover (1948), Hilty & Brown (1986), Koepcke (1970), Meyer de Schauensee (1966), Meyer de Schauensee & Phelps (1978), Ortiz & Carrión (1991), Parker *et al.* (1982), Remsen & Traylor (1989), Scott & Carbonell (1986), Sutton (1981), Tuck (1972), Vuilleumier (1969).

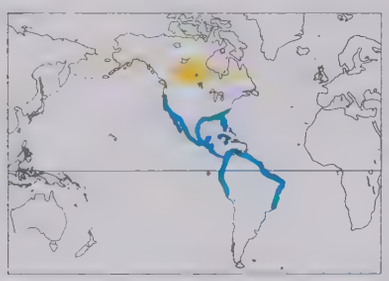
24. Imperial Snipe
Gallinago imperialis

French: Bécassine impériale **German**: Kaiserbekassine **Spanish**: Agachadiza Imperial
Other common names: Banded/Bogota Snipe

Taxonomy. *Gallinago imperialis* P. L. Sclater and Salvin, 1869, Bogotá, Colombia.
Formerly placed in genus *Chubbia*. Monotypic.
Distribution. Isolated sites in Peru, in Piura, Amazonas, La Libertad and Cuzco.

Descriptive notes. 29-31 cm. Large, dark rufous woodcock-like snipe, with very broad, rounded wings and slightly drooping bill; lacks pale stripes on head and upperparts; upperparts barred dark rufous chestnut and black; breast mottled chestnut and dark brown; belly, flanks and undertail-coverts strongly banded dark brown on whitish background; at rest, primaries concealed by tertials. Perhaps more similar to *Scolopax saturata* than to other snipes. Juvenile undescribed, as are any possible sexual and seasonal differences.
Habitat. Occurs in zone around tree-line at 2745-3500 m, where probably mainly restricted to bogs and damp elfin forest intermixed with tree-ferns and tall grass; also glades fringed by bamboo with extensive covering of *Sphagnum* mosses.
Food and Feeding. No information available. Thought to feed on worms and arthropods by probing in layer of thick mosses.
Breeding. Virtually nothing known. Crepuscular aerial display often continues well into darkness; observed in Jul-Aug.
Movements. Probably sedentary.
Status and Conservation. Not globally threatened. Currently considered near-threatened. No population estimate available, and biology virtually unknown; species apparently occurs at very low densities; population apparently very small and localized, although species is difficult to find. Known only from a

few specimens; thought to be extinct for over a century, but rediscovered in 1967, since when has been found at several localities. Survey work and research required to establish limits of range and approximate size of population. Original specimen labelled "Bogotá", but probably not from Colombia; at the time, this was commonly given as locality for birds collected over vast areas of South America.
Bibliography. Arango (1986), Blake (1977), Fjeldså & Krabbe (1990), Hellmayr & Conover (1948), Hilty & Brown (1986), Meyer de Schauensee (1966), Ortiz & Carrión (1991), Parker *et al.* (1982), Rasmussen *et al.* (1996), Sutton (1981), Terborgh & Weske (1972), Tuck (1972).



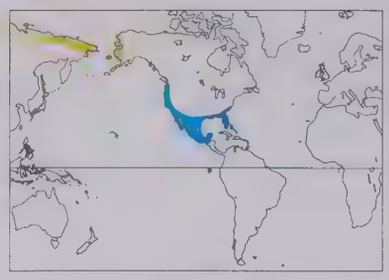
Genus *LIMNODROMUS* Wied, 1833

25. **Short-billed Dowitcher**

Limnodromus griseus

French: Bécassin roux **German**: Kleiner Schlammläufer **Spanish**: Agujeta Gris
Other common names: Common Dowitcher

Taxonomy. *Scolopax grisea* Gmelin, 1789, Long Island, New York.
Forms superspecies with *L. scolopaceus*, with which formerly considered conspecific. Three subspecies recognized.
Subspecies and Distribution.
L. g. caurinus Pitelka, 1950 - S Alaska and S Yukon; winters on Pacific coast from C USA to S Peru.
L. g. hendersoni Rowan, 1932 - EC British Columbia to SE Keewatin and C Manitoba; winters from SE USA to Panama.
L. g. griseus (Gmelin, 1789) - C Quebec and W Labrador; winters on Atlantic coast from S USA to Brazil.



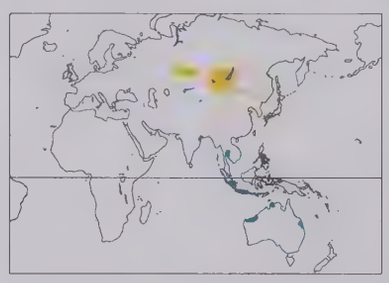
Descriptive notes. 25-29 cm; 65-154 g; wingspan 45-51 cm. Snipe-like bill, godwit-like plumage. Very similar to *L. scolopaceus*, but bill tends to be shorter; foreneck with few or no spots; tail pattern variable, but white bars normally broader than black ones; best separated by call, mellow "tu-tu-tu". Female slightly larger than male. Non-breeding adult has plain grey upperparts and breast, pale supercilium, dark eyestripe and whitish underparts. Juvenile has crown, upperparts and tertials with broad chestnut-buff edges; face, foreneck and breast buffish and white towards rear. Races differ mainly in breeding plumage and size, latter decreasing eastwards; race *caurinus* has very variable underparts, male generally brighter than female, with fewer spots; *hendersoni* lacks white on centre of belly, being uniform rufous below with sparse brown markings on flanks and undertail.
Habitat. Muskegs, wet sedge meadows and bogs with low vegetation, also swampy coastal tundra. On migration, found on both inland and coastal wetlands. In winter, mainly on intertidal mudflats bordered with mangroves and sandy shores; also borders of shallow pools on salt-marshes.
Food and Feeding. On breeding grounds chiefly larvae and pupae of Diptera, also snails, beetles and adult insects and sometimes plant material, particularly seeds. On coast, feeds on marine polychaetes, molluscs and crustaceans. Feeds by rapid, vertical probing, often in water, submerging head. In wintering areas often feeds in large flocks. Diurnal and nocturnal forager.
Breeding. Nests late May to Jul. Monogamous. Nest well hidden in soggy grass or sedge cover, near standing water. Usually 4 eggs (3-5); incubation 19-21 days, by both sexes; care of young mainly by male.
Movements. Long distance migrant. Race *caurinus* moves down Pacific coast, some birds inland through W USA, wintering on coast from California to Peru; *hendersoni* passes E Great Plains, valley of R Mississippi and E coast of USA, S of New York and New Jersey, and winters from the Carolinas round Gulf coast and down both coasts of Central America to Panama; *griseus* moves down Atlantic coast to North Carolina and S through Caribbean to N Brazil, with highest numbers wintering in Surinam. Small number of non-breeders spend N summer on wintering grounds. Females leave breeding grounds from early Jul, before males, and juveniles from late Jul; birds reach N South America from mid-Aug to early Oct. Spring migration early Mar to early Jun.
Status and Conservation. Not globally threatened. Total population exceeds 100,000 birds, possibly several 100,000's; no estimates available for populations of different races. Declining trends evident for races *caurinus* and *griseus*, while population of *hendersoni* seems stable; between 1972 and 1983, numbers staging on Atlantic coast of USA decreased by 46%, and by almost 8% annually in E Canada. No significant trend in numbers in E Canada during period 1986-1991.
Bibliography. Armstrong (1983), Avise & Zink (1988), Bent (1927-1929), Biaggi (1983), Blake (1977), Burton (1972b), Byrkjedal (1987b), Cramp & Simmons (1983), Fjeldså & Krabbe (1990), Haverschmidt (1968), Haverschmidt & Mees (1995), Hicklin & Smith (1979), Hilty & Brown (1986), Howe *et al.* (1989), Howell & Webb (1995a), Jaramillo & Henshaw (1995), Jaramillo *et al.* (1991), Jehl (1963), Jehl & Hussell (1966), Jehl & Smith (1970), Maisonneuve (1993), Mallory & Schneider (1979), Matthiessen (1994), McCollough (1981), McNair (1991), McNeil & Burton (1973), Meyer de Schauensee & Phelps (1978), Miller, Gunn & Harris (1983), Miller, Gunn, Myers & Veprintsev (1984), Monroe (1968), Morrison *et al.* (1994), Mullarney (1988), Napolitano *et al.* (1992), Nehls (1989), Pfister *et al.* (1992), Pitelka (1950), Pittaway (1992), Ridgely & Gwynne (1989), Robert & McNeil (1989), Root (1988), Rowan (1927, 1932), Schneider (1992), Scott & Carbonell (1986), Sick (1985c, 1993), Slud (1964), Snyder (1966), Stiles & Skutch (1989), Tostain *et al.* (1992), Wetmore (1965), Wilds & Newton (1983), Yésou (1982).

26. **Long-billed Dowitcher**

Limnodromus scolopaceus

French: Bécassin à long bec **German**: Großer Schlammläufer **Spanish**: Agujeta Escolopácea

Taxonomy. *Limosa scolopacea* Say, 1823, Council Bluffs, Iowa.
Forms superspecies with *L. griseus*, with which formerly considered conspecific. Monotypic.
Distribution. NE Siberia (R Yana E to Chukotskiy Peninsula), St Lawrence I and coastal W Alaska; N Inuvik and probably also N Yukon. Winters from W & S USA to Guatemala, and uncommonly to El Salvador; also rare S to Panama and French Guiana.



Descriptive notes. 24-30 cm; 90-135 g; wingspan 46-52 cm. Very similar to *L. griseus*, but bill and tarsi generally longer; breeding plumage darker red below with stronger breast and flank barring and no pale belly; on tail, black bands broader than white ones; best separated by call, high-pitched "keek", given 1-6 times. Female averages larger, more so than in *L. griseus*. Non-breeding adult mostly grey, virtually identical to *L. griseus*, but clearer separation between grey breast and white belly. Juvenile darker grey with narrower edges to upperparts.
Habitat. Grassy or sedgy marshes and swamps on Arctic tundra, often on shores of shallow lakes, mainly in floodplains; also moist tundra. On migration and in winter, mainly found at freshwater sites, such as marshes and drying lake shores; also salt-marshes and mudflats.
Food and Feeding. Diptera larvae, beetles, small gastropods, crustaceans, seeds and even mosses or plant fibres, less frequently polychaete worms. Probes in mud while wading, sometimes immersing head entirely. Usually in smaller flocks than *L. griseus*.
Breeding. Nests late May to Aug. Monogamous. Density up to 7-14 pairs/km². Nest usually located in small clump of sedges, typically damp at the bottom. 4 eggs; incubation 20-21 days, initially by both sexes, but later only by male; it has been suggested that only male cares for brood.
Movements. Migratory. Southward migration through North America in Jul-Oct; moves down Pacific coast, though many birds cross interior and along Atlantic coast up to New England; few birds follow W Pacific route and occur in Japan on passage. Juveniles migrate later than adults; females leave breeding area before males. Northward migration in Apr-May; more westerly than autumn route, mainly W of Mississippi and staging in Cheyenne Bottoms (Kansas). Some non-breeders spend summer in USA and Mexico. Regularly sighted in Britain and Ireland, mainly juveniles.
Status and Conservation. Not globally threatened. Total population numbers 50,000-100,000 birds. Breeding range has expanded considerably since 1920; towards W, now stretching beyond Yana Delta; in E Siberia, spreading S into Koryak Highlands; westward expansion may still be continuing. Very high numbers use Cheyenne Bottoms as a staging site during northbound migration.
Bibliography. Armstrong (1983), Avise & Zink (1988), Beaman (1994), Bent (1927-1929), Blake (1977), Brazil (1991), Burton (1972b), Conover (1941), Cramp & Simmons (1983), Elvers (1988), Foster & Greaves (1986), de Groot (1993), Hilty & Brown (1986), Howell & Webb (1995a), Jaramillo & Henshaw (1995), Jehl (1963), Knystautas (1993), Matthiessen (1994), Miller *et al.* (1984), Minton & Campbell (1995), Nehls (1989), de la Peña (1992), Pitelka (1950), Ridgely & Gwynne (1989), Robbins *et al.* (1983), Rogacheva (1992), Root (1988), Slud (1964), Stiles & Skutch (1989), Tomkins (1964), Tomkovich (1992b), Ulrich (1984), Wetmore (1965), White & Mitchell (1990), Wilds & Newton (1983), Wills (1958), Yésou (1982).

27. **Asian Dowitcher**

Limnodromus semipalmatus

French: Bécassin d'Asie **German**: Steppenschlammläufer **Spanish**: Agujeta Asiática
Other common names: Asiatic/Snipe-billed Dowitcher

Taxonomy. *Macrorhamphus semipalmatus* Blyth, 1848, Calcutta.
Formerly placed in genus *Pseudoscolopax*. Separation of W & E breeding populations, with different migration routes and wintering areas, may warrant subspecific status. Monotypic.
Distribution. Disjunct populations from W to E Siberian steppe regions, S into Mongolia and N Manchuria; the eastern areas may be continuous. Winters from E India through SE Asia, SE Sumatra and Java to N Australia.

Descriptive notes. 33-36 cm; 127-245 g; wingspan 59 cm. Face, neck and breast chestnut-red, lower belly and flanks mainly white; upperparts blackish broadly fringed pale brown and chestnut, streaked rather than mottled. Noticeably larger than congeners, with fewer dark markings on neck and breast. Similar in plumage to *Limosa lapponica*, but smaller, with bill straighter, not tapering, differently shaped and mostly black; rump is barred (unlike *Limosa l. lapponica* and *L. l. menzbieri*) and underwing mostly white with fine black streaking; bill normally held at lower angle. Female somewhat duller than male with more white in chestnut areas. Non-breeding adult has pale supercilium, darkish grey-brown upperparts, grey-brown mottled breast and whitish underparts. Juvenile has streaks on buff neck and breast; upperparts black with narrow pale buff fringes.
Habitat. Breeding in extensive freshwater wetlands on lake shores or in deltas and flooded areas of rivers, e.g. flooded meadows and grassy bogs, in steppe and forest-steppe zone, with short vegetation of grasses and sedges; observed feeding in rice fields. During non-breeding season, occurs in sheltered coastal environments, primarily estuarine and intertidal mudflats, muddy lagoons, tidal creeks and salt-works. Roosts, often with *Limosa*, on sandy beaches or in shallow lagoons.
Food and Feeding. Poorly known. On breeding grounds, takes small fish, insect larvae and oligochaetes. Away from breeding grounds feeds on polychaetes, insect larvae and molluscs, following edge of receding or incoming tide. Feeds on damp ground or in shallow water by walking and repeatedly probing deeply into mud, sometimes fully submerging head; feeds with stiff neck and typical wooden "sewing-machine" action; large prey is pulled up slowly with tremendous effort, small prey can be taken quickly. Gregarious, usually in pairs or small flocks, sometimes in large flocks of over 100 birds at roosts and favoured feeding sites.
Breeding. Lays late May to early Jun; timing and location of breeding may vary considerably, depending on water levels. Breeds in small colonies of 6-20 pairs, with nests 4-350 m apart, often mixed with White-winged Terns (*Chlidonias leucopterus*); territorial. Nests in sparsely vegetated parts of breeding area; nest is shallow depression on bare ground or in vegetation, lined with grass, sometimes 8-12 cm above water that is up to 25 cm deep. 2 eggs, rarely 3; single brood; incubation c. 22 days, by both parents; both parents tend chicks. Nests may fail due to flooding (occasionally 75% or more) and trampling by cattle.
Movements. Not well known. On migration occurs in small numbers in Japan, China, Hong Kong, Thailand, Malaysia, Philippines, E Kazakhstan, Uzbekistan, Mongolia and NE India; migration may

occur across interior of C Asia and along SE Asian coast. Largest wintering populations are probably those of E & SE Sumatra and N Java; smaller numbers occur in NW Australia (no more than 500). Westernmost population may, in fact, migrate SW, to winter in Persian Gulf and on coast of Arabian Sea; presumed vagrants have turned up in Arabia, and even in Kenya. Present in wintering areas from early Sept to late Apr. Departs from wintering grounds from Mar, mostly Apr; arrives on breeding grounds early to late May. Small groups remain in winter quarters during boreal summer.

Status and Conservation. Not globally threatened. Currently considered near-threatened. Recent work in Indonesia, mostly in Sumatra, has shown that world population comprises at least 20,000 birds; previously considered rare. Important wintering sites are Banyuasin Delta (Sumatra), where up to 13,000 birds estimated in 1988, and Ujung Pangkah (E Java); significant numbers have been counted in Philippines, India and Thailand; during migration significant numbers occur at Hutan Bakau Pantai Timor and Tanjung Jabung (E Sumatra), Gulf of Thailand and Sheyang Salt-works (Jiangsu, China). During severe droughts in Mongolia and China, large numbers appear in N parts of breeding range, e.g. c. 6000 were breeding at Selenga Delta, L Baikal, in late 1970's. At present reckoned not to be in immediate danger, although dependent on rather a small number of wetlands; drainage or drying out of wetlands reduces area of suitable breeding habitat. Poorly studied; listed as endangered in Russian Red Data Book. Population density everywhere small; numbers difficult to estimate, as typically flocks together with very similar *Limosa lapponica*, hampering counts and easily causing present species to be overlooked.

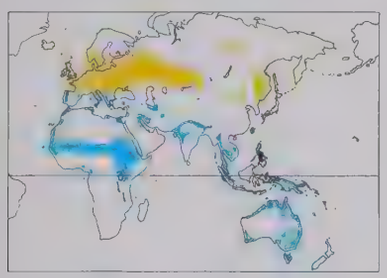
PLATE 42



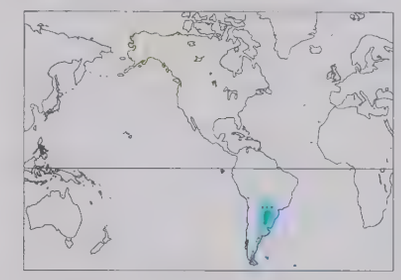
inches 7
cm 18

Subfamily TRINGINAE
Tribe NUMENIINI
Genus *LIMOSA* Brisson, 1760

28. **Black-tailed Godwit**
Limosa limosa

French: Barge à queue noire **German**: Uferschnepfe **Spanish**: Aguja Colinegra

Taxonomy. *Scolopax Limosa* Linnaeus, 1758, Sweden.
Forms superspecies with *L. haemastica*, with which sometimes considered conspecific. Three subspecies recognized.
Subspecies and Distribution.
L. l. islandica C. L. Brehm, 1831 - Iceland, Faeroes, Shetland and Lofoten Is; winters in Ireland, Britain, W France, Spain and Portugal.
L. l. limosa (Linnaeus, 1758) - W & C Europe and Russia E to upper R Yenisey; winters in Mediterranean and sub-Saharan Africa, and E through Middle East to W India.
L. l. melanuroides Gould, 1846 - disjunct populations in Siberia E of R Yenisey, E Mongolia, NE China and Russian Far East; winters from India, Indochina, Taiwan and Philippines S to Indonesia, New Guinea and Australia.



Descriptive notes. 36-44 cm; male 160-440 g, female 244-500 g; wingspan 70-82 cm. Tall, elegant godwit with chestnut breast and upper belly; dark brown barring on belly, with lower belly white; mantle and scapulars blotched pale red, black and grey; long, straightish bill orange pink at base; long legs. Variable numbers of brownish grey feathers in upperparts give untidy, half-moulted look. Combination of distinctive black tail and white uppertail-coverts and wingbar separates from *L. lapponica* and *L. fedoa*, and white underwing separates from *L. haemastica*. Female paler and less red than male, with less barring on underparts; bill averages longer. Non-breeding adult pale grey-brown above, greyish white below, with pale greyish supercilium; lacks chestnut; base of bill fleshy pink. Juvenile as non-breeding adult but upperparts dark grey-brown, with pale chestnut and buff fringes; neck and breast pale cinnamon, more richly coloured in race *islandica*; no barring on white underparts. Races *islandica* smaller than nominate, *melanuroides* smaller still; both are darker red and have shorter bills than nominate; non-breeding *melanuroides* has darker upperparts and breast.
Habitat. Wet grassland with moderately high grass and soft soil, in lowlands; also grassy marshland, raised bogs and moorland, reclaimed areas and damp grassy depressions in steppe. Winters in sheltered estuaries and lagoons with large intertidal mudflats, sandy beaches, salt-marshes, salt-flats, and inland wetlands, such as swampy lake shores, river pools, flooded grassland and irrigated rice fields. Race *limosa* winters mainly in freshwater habitats; *islandica* and *melanuroides* mainly in estuarine habitats.
Food and Feeding. Chiefly invertebrates, most frequently insects and their larvae (especially beetles), annelids, molluscs, ragworms, crustaceans, spiders, fish eggs, and spawn and tadpoles of frogs; also plant material, such as berries and seeds, especially of rice. In winter quarters, race *limosa* feeds mainly on plant material, in parts of W Africa almost 100% rice; also takes chironomid larvae and snails. Feeds by picking and by forward-angled, prolonged probes. Locates food by touch or sight; recorded foot-trembling to disturb prey; sometimes washes food. Usually feeds gregariously in winter and on migration, using communal night-time roosts in shallow water. Chicks on pastures feed very actively on mobile prey in quite tall vegetation.
Breeding. Laying Apr to mid-Jun. Monogamous on long-term basis. Often in loose, semi-colonial groups, up to 3 pairs/ha. High degree of site fidelity, low degree of natal philopatry. Nest in short vegetation, open to rather concealed, lined with thick mat of vegetation. 4 eggs (3-5), with laying interval 1-2 days; single brood, but replacement clutches laid; incubation 22-24 days, by both sexes; chick light pinkish cinnamon with fuscous bands and mottles on back, wing-pads and thighs; both sexes care for young, although brooding primarily by female; fledging 28-34 days. Including failed nests, 49% of eggs hatch; c. 26% of nests in meadows and c. 62% in pastures produce at least 1 hatchling; production on agricultural grasslands c. 0·4 fledglings per breeding pair, but half of these fledglings die without becoming adults; mortality may increase dramatically during cold spells, especially in combination with rain; trampling by cattle, predation and agricultural activities, notably mowing, may cause high losses. Annual adult mortality c. 20%; 1st-year mortality c. 40%. Age of first breeding 1 year, sometimes older.
Movements. Migration on broad front, often overland, characterized by long distance flights between relatively few staging sites and wintering areas. S migration late Jun to Oct, return passage Feb-Apr. Many 1-year-olds spend summer in winter quarters. Race *islandica* migrates via Ireland to coasts of British Is, France, Spain and Portugal, and some to Morocco. Main body of *limosa* population winters in W Africa S of Sahara, Sept-Mar, flying through France and Iberia, and pausing in N Morocco to moult; may have more easterly route back to breeding grounds; populations from C & E Europe and Russia winter in sub-Saharan Africa from Mali and L Chad eastwards; they fly in broad front between Balkans and Black Sea; breeding birds from Kazakhstan winter in India. Origin of wintering birds in E Spain and Tunisia unknown. Race *melanuroides* migrates through Mongolia, Ussuriland, Manchuria, Korea, Japan, Taiwan, Philippines, Hainan and China, some passing through Indochina, SE Asia and Malay Peninsula; staging areas in SE Sumatra used on S migration towards Australia. During N migration, may roost in concentrations of up to 12,000 birds in moist pastures, in Netherlands.
Status and Conservation. Not globally threatened. Total population estimated at 140,000-270,000 pairs, of which over two thirds breed in Europe, with 85,000-100,000 pairs breeding in Netherlands alone; 110,000-120,000 winter in rice fields in Guinea-Bissau (1986) and of 10,000's in Senegambia and Niger inundation zone; minimum of 25,000 winter in SW Asia and minimum 100,000 in SC Asia, with high numbers in Pakistan; Australasian wintering population estimated at 162,000 birds, of which 81,000 in Australia, with SE Gulf of Carpentaria and NE Arnhem Land being most important sites; abundant in Indonesia. Race *islandica* numbers c. 65,000 birds (1989), possibly less, but numbers increasing. Up to 1970's marked increase in W European countries, including Iceland; colonized Finland and Norway, and recolonized Britain during present century. Increase mainly due to ability to adapt to man-made habitats, e.g. fertilized meadows. However, substantial decline occurred in 1970-1990, mainly due to effects of agricultural intensification, e.g. drainage, and earlier and rotary mowing; drought in W African wintering grounds may also have been factor. Numbers in SC Asian wintering grounds are increasing. Preservation of wet grassland in lowlands and regulation of disturbance from certain farming activities are main conservation measures necessary.

29. **Hudsonian Godwit**
Limosa haemastica

French: Barge hudsonienne **German**: Hudsonschnepfe **Spanish**: Aguja Café

Taxonomy. *Scolopax Hæmastica* Linnaeus, 1758, Hudson Bay.
Forms superspecies with *L. limosa*, of which sometimes considered a subspecies. Monotypic.
Distribution. Locally from NW & S Alaska to Hudson Bay. Winters on Atlantic coast of S South America; also Chiloé I, SC Chile.

Descriptive notes. 36-42 cm; male 196-266 g, female 246-358 g; wingspan 66 cm. Darkish godwit with slightly uptilted bill; face and throat whitish; breast, belly and undertail-coverts deep chestnut, irregularly barred; upperparts dark brown with variable buff or cinnamon fringes and notches; in flight, narrow white wingbar and very dark underwing. Structure intermediate between *L. limosa* and *L. lapponica*; extent of barring on underparts variable, but always more than in *L. lapponica*. Female less reddish chestnut; paler on mantle; heavily blotched white below, frequently barred. Non-breeding adult dark, plain grey-brown on breast and upperparts, white on lower belly; white supercilium; bill base brownish. Juvenile has dark upperparts, fringed with buff; neck and breast washed brownish buff; lower belly whitish.
Habitat. Sedgy marshland near tree-line in lowlands, close to coast or river. In winter and on migration, occurs in muddy estuaries, tidal pools, coastal lagoons, flooded grassland, shallow freshwater lakes, rice paddies and salt-works; less often on sandy beaches.
Food and Feeding. On breeding gounds mainly Diptera larvae; also snails, beetles, adult insects and seeds. Diet on wintering grounds not well known; includes worms, insects, molluscs, crustaceans and other small invertebrates; polychaete worms predominate on intertidal mudflats of Tierra del Fuego; sometimes plant tubers in N of range. Feeding behaviour rather similar to that of *L. limosa*; often wades in water 10-15 cm deep. Mostly feeds gregariously.
Breeding. Nests late May to Jul. Nest typically placed on dry hummock at edge of dwarf birch, usually well hidden; saucer-shaped depression in or under edge of prostrate dwarf birches or on top of dry hummock in sedge marsh. Usually 4 eggs; incubation 22-25 days, by female during day, male at night; chick pale buff-grey to buffy brown, with brownish black dorsal stripes and blotches, brownish black crown patch and greyish white underparts; both sexes care for young until just before fledging; fledging c. 30 days.
Movements. Long distance migrant. During late Aug, much of population gathers along S Hudson Bay and James Bay and at certain sites in Saskatchewan and Alberta; crosses W Atlantic and arrives at unknown locations in N South America and stages at Amazon basin, then possibly passes through W Brazil on way to S Argentina; apparently young depart after adults. Birds wintering around Chiloé I may originate from Alaska, and follow different route. N migration probably very rapid, using few or no staging sites in South America; passage through USA more westerly, with many birds crossing Great Plains, Apr-May; rarely on Pacific coast of Guatemala and Costa Rica. Main wintering sites are Tierra del Fuego and areas around Chiloé I in SC Chile.
Status and Conservation. Not globally threatened. Currently considered near-threatened. Total population c. 50,000 birds or perhaps more; on South American wintering grounds 45,500 birds counted (1989), with 19,400 in Bahía de San Sebastian and 10,500 in Bahia Lomas (Tierra del Fuego), and over 12,600 in Chiloé area. Until 1960, species was considered threatened, largely as result of being very poorly known; now considered to be locally common in breeding range. Population thought to be stable.

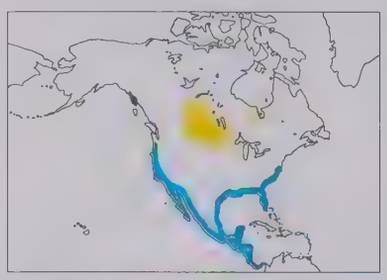
30. Bar-tailed Godwit

Limosa lapponica

French: Barge rousse **German**: Pfuhlschnepfe **Spanish**: Aguja Colipinta

Taxonomy. *Scolopax lapponica* Linnaeus, 1758, Lappland.
Race *menzbieri* sometimes included within race *baueri*. Three subspecies recognized.
Subspecies and Distribution.
L. l. lapponica (Linnaeus, 1758) - Lappland W through Kola and Kanin Peninsulas to Taymyr; winters from North Sea, W Iberia and NW Africa S to W South Africa, and E to Persian Gulf and W India.
L. l. menzbieri Portenko, 1936 - N Siberia, between R Khatanga and Kolyma Delta; winters from SE Asia to NW Australia, and possibly E Australia.
L. l. baueri Naumann, 1836 - NE Siberia, E of R Kolyma, to W Alaska; winters from China to New Zealand and some Pacific Is.



Descriptive notes. 37-41 cm; male 190-400 g, female 262-630 g; wingspan 70-80 cm. Medium-sized godwit with slightly upcurved bill and barred tail; in flight, lacks white wingbar and has white underwing; virtually no barring on underparts; upperparts fringed chestnut; shorter legs and bill, and less upright stance than other godwits. Less white on rufous underparts than *L. limosa*. Female larger with longer bill; much paler. Non-breeding adult has upperparts pale grey-brown, partly edged whitish; breast turns grey, with fine dark streaking; underparts white. Juvenile has neck and breast washed buff with scattered streaks; upperparts dark, with bright buff fringes; belly whitish; bill darker. Rump and uppertail-coverts white in nominate, but heavily barred brown in *baueri*; race *menzbieri* intermediate in plumage between nominate and *baueri*, with lower back and rump fairly strongly barred; bill and tarsus shortest in nominate; *baueri* has relatively long wings and tail.
Habitat. Lowland scrub tundra, forest tundra, rolling uplands, wet river valleys and open larch woodland close to water bodies. After breeding, mainly in intertidal areas, preferably sandy parts of estuaries, inlets, mangrove-fringed lagoons, sheltered bays. Locally at inland wetlands and short-grass meadows.
Food and Feeding. Diet on breeding grounds mainly comprises insects, annelids, molluscs, occasionally seeds and berries. Non-breeding diet mainly *Nereis* and *Arenicola*, and smaller annelids, bivalves, crustaceans in intertidal areas, cranefly larvae and lumbricids in grassland; occasionally tadpoles, small fish and fruits. Feeds by pecking, stitching or probing. Longer-billed females tend to feed in deeper water. Outside breeding season, feeds in flocks, e.g. along edge of tide.
Breeding. Lays late May to Jun. Monogamous. Densities 0·1-1·0 pairs/km². Nest usually on dry, elevated sites, often between clumps of grass; depression lined with bits of vegetation and lichens. 4 eggs (2-5); single brood; incubation 20-21 days, by female at night and male during day; chick pale vinaceous cinnamon to pinkish cinnamon to nearly white on belly, brownish cap and dark brown bands and mottles on back, wing-pads and thighs; both parents tend young, or possibly only male; fledging c. 28 days; adults depart soon after young fledge. Annual mortality 40%. Age of first breeding 2 years.
Movements. Long distance migrant. Race *lapponica* wintering in Europe originates from N Europe and Russia E to Yamal Peninsula; birds breeding further E (to Taymyr) winter in W Africa, Sept-Apr, staging at W European intertidal areas during mid-Apr to May and mid-Jul to Aug; females winter further S than males. Major migration passes through North Sea basin and Baltic, only some through Caspian Sea area, presumably birds wintering in S Africa; inland records suggest continental crossing by SW African wintering birds. In Apr-May, many birds gather in Wadden Sea to moult and fatten. In E Asia, *baueri* and *menzbieri*, commonly migrate through W Kamchatka, Sakhalin, Japan and Korea; probably also use trans-Pacific route, between Korea, Japan and SE China and Australia. Wintering birds in NW Australia are likely to be of race *menzbieri*, while SE Australian birds possibly originate from Alaska. Alaskan birds move down Bering Sea coast and through Pribilof and Aleutian Is. High degree of site fidelity on non-breeding grounds; many non-breeders remain S all year.
Status and Conservation. Not globally threatened. European wintering population fluctuates, but estimated at 115,000 birds (1989), with up to 57,000 in Britain; numbers in Britain and Portugal decreased during 1980's, but may now be increasing; up to 341,000 birds counted staging in Wadden Sea; W & S African wintering population estimated at minimum 700,000 birds (1989); at least 100,000 *lapponica* winter in E Africa and SW Asia. Of race *baueri* and *menzbieri* c. 165,000 birds winter in Australia, with 65,000 in Roebuck Bay and 34,000 on Eighty Mile Beach, 102,000 in New Zealand (1988) and 125,000 in E & SE Asia; numbers increasing in some areas. Species vulnerable due to concentration at a few wetlands in non-breeding season. Land reclamation, pollution and human disturbance have detrimental effects on feeding conditions. Important staging and wintering areas in France, Portugal and Guinea-Bissau are not yet protected. Other important wintering areas may include sites in Oman, Saudi Arabia and Sumatra.

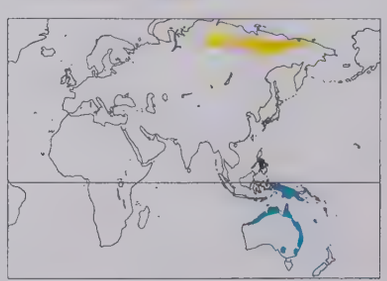
31. Marbled Godwit

Limosa fedoa

French: Barge marbrée **German**: Marmorschnepfe **Spanish**: Aguja Canela

Taxonomy. *Scolopax Fedoa* Linnaeus, 1758, Hudson Bay.
Two subspecies recognized.
Subspecies and Distribution.
L. f. beringiae Gibson & Kessel, 1989 - Alaska Peninsula; winters on Pacific coast of USA from S Washington to C California.
L. f. fedoa (Linnaeus, 1758) - C Alberta and SW Manitoba to SC Montana and W Minnesota, also SW James Bay; winters from California and the Carolinas S to Panama, occasionally occurring S to N Chile, Colombia and Venezuela.

Descriptive notes. 42-48 cm; male 278-365 g, female 312-510 g. Fairly large cinnamon-buff godwit, with cinnamon wingbar and underwing; buff underparts irregularly streaked brown; upperparts with sooty black and reddish buff spotting and barring. Female more sparsely barred than male. Non-breeding adult paler and plainer above; few individuals can turn as pale as *L. lapponica*, but always has longer bill and legs. Juvenile as non-breeding adult, but with buff fringes to upperparts, underparts cinnamon-buff with only a little streaking. Race *beringiae* has shorter bill, wing and tarsus, but appears to be slightly heavier than nominate.
Habitat. Wet meadows and grassland near pools on prairies and coastal marshland. After breeding, largely coastal, occurring in muddy bays and estuaries, coastal pools and salt-marshes, preferably with adjoining wet savannas or grassy borders.
Food and Feeding. Mainly insects, also bivalves. In non-breeding range, takes small molluscs, crustaceans, insects, worms and leeches. Feeding style involves calm pecking and probing. Feeds in flocks on intertidal mudflats.
Breeding. Lays early May to Jun. Often in semi-colonial groups, up to 27 pairs/km². 4 eggs, sometimes 5, with laying interval 1-3 days; incubation 21-23 days, by both sexes; both parents tend chicks; fledging c. 3 weeks. Annual survival c. 87%; oldest ringed bird at least 25 years, 9 months.
Movements. Relatively short distance migrant. Movements in broad front over coast and interior; *beringiae* probably crosses Gulf of Alaska. Birds wintering on Pacific coast of USA (mainly Washington and Oregon) are probably *beringiae*, while *fedoa* presumably moves via W Montana, Idaho and E Oregon to Sacramento/San Joaquin Delta or San Francisco Bay area, and along Pacific coast southwards. During northward migration, high numbers stage at Cheyenne Bottoms (Kansas). High degree of wintering site fidelity. N migration of *beringiae* mainly late Apr and early May, some throughout May; southward Jul-Oct. Casual in West Indies. Traditionally said to winter S to N Chile, but only three records up to 1986, with first in 1852 and second not till 1977; only one record up to 1986 in Colombia, where probably occurs sporadically; also said to occur in Venezuela.
Status and Conservation. Not globally threatened. Total of c. 100,000 birds on Pacific flyway. Numbers apparently stable. Range has contracted considerably in recent decades, but species still moderately common in large part of breeding area; in 1967, total of 37,000 pairs were breeding in North Dakota. Decline at least partly caused by hunting and conversion for agriculture of prairie breeding grounds, on which species is fully dependent.
Bibliography. Argabrite (1988), Armstrong (1983), Bent (1927-1929), Blake (1977), Colwell *et al.* (1995), Cook (1986), Edwards (1989), Gibson & Kessel (1989), Heller (1991), Higgins *et al.* (1979), Hilty & Brown (1986), Horn (1990), Howell & Webb (1995a, 1995b), Igou (1986), Kelly & Cogswell (1979), Knopf (1994), Luckner (1992), Matthiessen (1994), McNeil *et al.* (1985), Mercier *et al.* (1987), Meretsy (1988), Monroe (1968), Nowicki (1973), Ridgely & Gwynne (1989), Root (1988), Ryan (1982), Ryan *et al.* (1984), Schaldach (1963), Slud (1964), Stiles & Skutch (1989), Ulrich (1984), Wetmore (1965), Whittle (1992), Wilbur (1987), Wishart & Spencer (1980).



Genus *NUMENIUS* Brisson, 1760

32. Little Curlew

Numenius minutus

French: Courlis nain **German**: Zwergbrachvogel **Spanish**: Zarapito Chico
Other common names: Little Whimbrel

Taxonomy. *Numenius minutus* Gould, 1841, New South Wales.
Forms superspecies with *N. borealis*, with which formerly considered conspecific. Monotypic.
Distribution. N & C Yakutia, from S slopes of Putorana Mts E to R Anabar, and Verkhoyansk and Cherski Mts on upper R Yana and R Indigirka as far E as R Anyuy, along Siberian coast. Winters in New Guinea and Australia.

Descriptive notes. 28-32 cm; 118-221 g; wingspan 68-71 cm. Smallest curlew, with short bill only slightly and evenly decurved; rounded head and large eye, somewhat reminiscent of *Bartramia longicauda*; head strongly patterned with dark eyestripe, brown crown stripe and buffish supercilium; buffish brown rump and back. Very similar to *N. borealis*, but paler buff rather than cinnamon-coloured, less streaked on flanks and whiter on belly; shorter-winged, and at rest lacks distinct primary projection. Female averages slightly larger. No seasonal variation. Juvenile very similar to adult, but with pale buff spots and fringes on scapulars, and brown coverts broadly edged with buff; less streaking on flanks and breast.

Habitat. Breeds on N montane taiga, often in river valleys; preferably with secondary vegetation, such as fire-damaged areas, or grassy clearings in sparse larch or dwarf birch woodland. In non-breeding zone, found in dry, inland grassland, blacksoil plains, bare cultivation, often on artificial short-grass flats; always near fresh water, such as swamps, pools, lakes or flooded ground; rare on coast.
Food and Feeding. Mainly insects, including grasshoppers, crickets, weevils, beetles, caterpillars and ants; also spiders and vegetable matter, including seeds, rice husks and berries. Feeds mostly by picking and shallow probing. In winter quarters, occurs in dense flocks of several hundreds, sometimes thousands. Feeds in morning, and gathers near water to roost during warmest part of day, to resume foraging at mid-afternoon; forms roosting flocks again before night.
Breeding. Breeds late May to early Aug. Forms loose colonies. Nest is shallow depression lined with grass, in open ground. 4 eggs, sometimes 3; single brood; incubation 22-23 days, by both parents; fledging 5 weeks.
Movements. Migratory; primarily continental. Occurs on passage (mid-Aug to Oct) in S Siberia, Mongolia, Japan, China and E Indonesia and New Guinea; presumably moves in narrow front to and down coasts of Yellow and East China Seas; route S of China lies E of Borneo; presumably non-stop from China to S New Guinea and N Australia, and same route back. Main winter quarters, S New Guinea and N Australia, are reached in early Sept. Erratic movements within Australia depending on rainfall; once dry grassland becomes wet at start of monsoon (Nov-Dec), moves further inland, being most abundant on Barkly Tableland (Northern Territory) during main wet season (Jan to early Apr); in some years, reaches S Australia and Tasmania, rarely New Zealand. Flocks move N from early Apr, primarily through unflooded grasslands near Broome (CN Western Australia) and Karumba (NW Queensland). Departs N Australia late Mar to late Apr, probably non-stop to China. Moves in flocks of up to 1000 birds. 1st-year birds presumably leave Australia during non-breeding season.
Status and Conservation. Not globally threatened. CITES I. Total population c. 200,000 birds; abundant in N Australia, with 180,000 birds; 250,000 birds recorded at Humpty Doo, near Darwin, N Australia, in 1966, but possibly an overestimate; important areas are Alligator Rivers area with c. 180,000 birds, Roebuck Plains with c. 50,000, and Anna Plains with c. 12,000. In 1992, total of 324 birds reported to be wintering in China. No threats in wintering area, as favoured habitat is very extensive in N Australia. In Australia, has benefited from provision of watering points and large areas of grassland for livestock, and maybe from control of numbers of feral water buffalo (*Bubalus bubalis*), though in some areas this has led to denser vegetation cover, leaving less suitable habitat for shorebirds. Agricultural intensification and pesticides could affect population. Species formerly considered rare, but breeding range is much more extensive than formerly believed. Listed by CITES due to very similar appearance to Critically Endangered *N. borealis*.
Bibliography. Andersson, G. (1971), Artyukhov (1988), Bamford (1989, 1990), Barter (1992c), Beaman (1994), Beehler *et al.* (1986), Blakers *et al.* (1984), Boswall & Veprintsev (1985), Brazil (1991), Butyev (1983), Coates (1985), Cramp & Simmons (1983), Crawford, D.N. 33. **Eskimo Curlew**

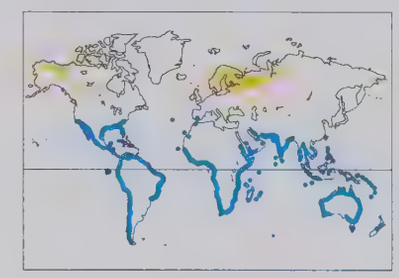
Numenius borealis

French: Courlis esquimau **German**: Eskimobrachvogel **Spanish**: Zarapito Esquimal

Taxonomy. *Scolopax borealis* J. R. Forster, 1772, Fort Albany, Hudson Bay.
Forms superspecies with *N. minutus*, with which formerly regarded as conspecific. Monotypic.
Distribution. CN Canada, on S shore and inland of Amundsen Gulf along Coppermine R to Point L; possibly also N Alaska. Winters in Uruguay and Argentina and possibly also in Chile.



Descriptive notes. 29-34 cm. Tiny curlew with rather short bill and legs; dark eyestripe and black crown streaked with pale buff; upperparts with brown-buff notches; underparts buff-cinnamon with streaks on breast and Y-shaped marks on flanks. Somewhat larger and more cinnamon-coloured than *N. minutus*; more heavily marked below; wings longer and more pointed; bill longer and more decurved. Female averages slightly larger. No seasonal variation. Juvenile as adult, but underparts more buff and upperparts with neat pale buff fringes and spotting.
Habitat. Barren Arctic tundra, just N of tree-line and lowlands along coast. In Maritime Provinces of Canada, frequents areas covered in ripening bushes of crowberry (*Empetrum nigrum*) on tundra hillsides; these were on occasion called "curlew-berry" as a consequence. On migration, occurs on prairies and coastal grassland; winters on *pampas* grassland.
Food and Feeding. On breeding grounds, takes ants, grubs and freshwater insects; also large proportions of crowberries. On southward migration, feeds mainly on field crickets and grasshoppers and also other insects, snails and worms; on northward migration apparently chiefly grasshopper egg pods. In past, was highly gregarious in foraging.
Breeding. Not well known. Laying probably in Jun, and birds seen on nesting grounds from late May to early Aug. Nest is mere hollow in barren ground, lined with few leaves. 3-4 eggs, with highly variable camouflage pattern; hatching peaks from late Jun to mid-Jul; downy chicks undescribed.
Movements. Migratory; leaves breeding grounds late Jul to early Aug; moves via Canadian Maritime Provinces and New England; departs from Labrador and Newfoundland on a direct oceanic flight to N South America, a distance of 4000-5000 km, late Aug to early Sept; some birds follow route along W shores of Hudson and James Bays, SE across Quebec and then down over WC Atlantic. Chief wintering grounds probably in Uruguay and Argentina, and possibly also in Paraguay and Chile; may occur S to S Argentina. Return migration starts late Feb to early Mar, and follows route farther W, moving through Yucatán across Gulf of Mexico to Texas coast, and continuing N along W Mississippi Basin and Prairie Provinces of Canada to breeding grounds. Arrives on breeding grounds from mid-May.
Status and Conservation. CRITICALLY ENDANGERED. CITES I. World population estimated at 50 birds in 1992. Apparently very abundant before 1850, although perhaps not as abundant as often suggested; subsequently, serious decline due to excessive shooting on Atlantic seaboard and along R Mississippi; there is no evidence for suggested shooting on wintering grounds. Habitat loss on Argentinian *pampas* and at stopover sites on North American prairies may have been significant factors in decline. However, many wintering areas in Argentina and Uruguay still provide excellent shorebird habitat. As population never recovered after hunting stopped, some important ecological factor may have been operating. Species now very close to extinction and only occasionally reported: 18 times between 1982 and 1987. Report of a nest in Canada in 1992 now considered likely to have been referable to *N. phaeopus*, as thorough searches have revealed no further sightings. In 1987 a recovery plan was devised, and in 1990 an advisory group was formed. Species is legally protected in USA, Canada, Argentina and Mexico.
Bibliography. Anon. (1995k, 1995l, 1995m), Banks (1977), Bent (1927-1929), Blanco, D.E *et al.* (1993), Blake (1977), Canevari & Blanco (1994), Chebez (1994), Collar & Andrew (1988), Collar, Crosby & Stattersfield (1994), Collar, Gonzaga *et al.* (1992), Daniels (1972), Dinsmore (1988), Emanuel (1962), Eubanks & Collins (1993), Faanes (1990a), Faanes & Senner (1991), Farrand (1977), Gollop (1988), Gollop *et al.* (1986), Hagar & Anderson (1977), Hayes (1995), Howell & Webb (1995a), Iversen (1976, 1989a, 1989b, 1995), Johnson (1965b), King (1978/79), Lahrman (1972), MacKay (1996), Matthiessen (1994), Michelutti (1991), de la Peña (1992), Sick (1993), Tostain *et al.* (1992), Wege & Long (1995), Weston & Williams (1965), Williams (1988).

34. **Whimbrel**

Numenius phaeopus

French: Courlis corlieu **German**: Regenbrachvogel **Spanish**: Zarapito Trinador

Taxonomy. *Scolopax phæopus* Linnaeus, 1758, Sweden.
Four subspecies recognized.
Subspecies and Distribution.
N. p. phaeopus (Linnaeus, 1758) - Iceland, Faeroes and N Scotland through Scandinavia to R Yenisey and SW Taymyr; winters from extreme SW Europe and Africa through Middle East to W India, Sri Lanka and Andaman and Nicobar Is.
N. p. alboaxillaris Lowe, 1921 - steppes N of Caspian Sea; winters on islands and coasts of W Indian Ocean.
N. p. variegatus (Scopoli, 1786) - NE Siberia, from Verkhoyansk Mts. and perhaps SE Taymyr, to basins of R Kolyma and R Anadyr; winters from E India to Taiwan, and S through Philippines and Indonesia to Australasia.
N. p. hudsonicus Latham, 1790 - W & N Alaska, E to W Yukon and NW Mackenzie, and also W Hudson Bay; winters from S USA to S South America.

Descriptive notes. 40-46 cm; male 268-550 g, female 315-600 g; wingspan 76-89 cm. Medium-sized curlew showing blackish brown crown with pale central stripe, conspicuous pale supercilium and medium-sized bill; upperparts greyish brown with pale spotting; neck and breast finely streaked. Generally darker and greyer above than other *Numenius*; differs from larger curlews and generally paler *N. tenuirostris* by dark loral stripes and crown stripe; from very similar *N. tahitiensis* by smaller, paler markings on upperparts, more extensive markings on underparts, and different colour of rump and uppertail-coverts. Female averages slightly larger. No seasonal variation. Juvenile as adult, but upperparts brown with buff fringes and spots and underparts more buff; juvenile *hudsonicus* browner above and more buff below. Race *alboaxillaris*, like nominate, has unbarred white lower back and rump, and white underwing, which is almost unbarred in paler *alboaxillaris*; *variegatus* and *hudsonicus* have underwing brown; *hudsonicus* richer buff overall, with lower back and rump brown.
Habitat. Boreal, subarctic and subalpine moorland, birch forest and tundra near tree-line, open montane forest and river valleys. On migration, occurs in wetlands, on tidal flats and dry to wet grassland; in spring, prefers heathland with crowberries (*Empetrum*) and farmland; during migration often visits inland grassland to feed. In winter, essentially coastal, occupying exposed reefs, muddy, rocky or sandy beaches, tidal mudflats and mangrove swamps. Roosts communally in mangroves; may perch high up in mangrove trees; uses night-time communal roosts in shallow water during migration.
Food and Feeding. Inland diet includes insects (beetles and Orthoptera, and cranefly larvae), spiders, millipedes, earthworms, snails and slugs; on arrival at breeding grounds, also berries; on southward migration, also seeds and leaves. On coast, diet includes crabs and other crustaceans, molluscs, large polychaetes and rarely fish, reptiles and birds. Usually feeds more by pecking than by probing; feeds on crabs by probing in burrows. Generally forages in small groups or singly; individuals may defend feeding territory on wintering grounds.
Breeding. Laying May to mid-Jun. Monogamous and solitary, in densities of 1-11 pairs/km². Nest is depression filled with fragments of vegetation, usually in exposed location. 4 eggs (2-5); single brood; incubation 22-28 days, by both sexes, but more by female; chick warm buff above clouded with blackish brown, dark crown with buff mid-line, and creamy buff belly; both parents care for young; fledging 35-40 days. In NE Lapland, 60% of eggs hatched, 74% in Shetland, 67% in race *hudsonicus*. Annual mortality may be as high as 31%. Age of first breeding usually 2 years.
Movements. Migratory. Moves over broad front, in spring with relatively few staging areas, often inland, e.g. in Hungary and Netherlands; in autumn no concentrated staging. Most N European and NW Russian *phaeopus* migrate to coastal W Africa; return migration sometimes involves long diagonal Sahara crossing from W African coast and some transcontinental migration in S Africa. Icelandic birds fly over W Britain and some make long flights over water, directly to Africa. Birds in E & SE Africa include *alboaxillaris*, which migrate via Middle East. Race *variegatus* moves through Japan, coastal China, Korea, Hong Kong and Taiwan to wintering grounds in SE Asia and Australasia. Alaskan *hudsonicus* migrates down Pacific coast; Canadian populations over broad inland front to Canadian Maritime Provinces and New England and then S down coast, mainly to N & W South America. Migrates through NW Europe early Jul to late Aug, and late Apr to late May; arrives in Africa and E Australia late Jul to early Oct and departs from Apr. Many non-breeders remain in winter quarters all year, and all 1-year-olds probably do so.
Status and Conservation. Not globally threatened. E Atlantic flyway population numbers 600,000-700,000 birds, although figure of only 83,000 was estimated from counts in wintering areas; high numbers probably feed within mangroves where they are overlooked, or perhaps major wintering sites have yet to be found; numbers of W Siberian breeders and SE African winterers unknown; breeding population of Fenno-Scandia estimated at 62,500-123,000 pairs in 1993, and that of Iceland at 200,000 pairs in 1985; species is not generally numerous in Russia, although locally abundant in C Siberia. Wintering population of race *phaeopus* in SW Asia exceeds 25,000 birds; in SE Asia and Australasia 40,000 birds of race *variegatus*, of which 10,000 in Australia in 1993. Population size of race *alboaxillaris* unknown. Race *hudsonicus* comprises 25,000-100,000 birds; numbers apparently declined by 61% on Atlantic staging sites between 1972 and 1983. Probably the most abundant curlew, due to extremely extensive breeding range.

35. Bristle-thighed Curlew

Numenius tahitiensis

French: Courlis d'Alaska **German**: Borstenbrachvogel **Spanish**: Zarapito del Pacífico

Taxonomy. *Scolopax tahitiensis* Gmelin, 1789, Tahiti.
Monotypic.

Distribution. W Alaska, from Seward Peninsula to Yukon Delta. Winters from Marshall and Hawaiian Is, S to Santa Cruz, Fiji, Tonga, Samoa, Marquesas, Tuamotu Is and Pitcairn I.

Descriptive notes. 40-44 cm; male 254-553 g, female 372-796 g; wingspan 82-90 cm. Medium-sized curlew with broadly striped head; cinnamon-buff spotted upperparts; dark underwing; bristle-like extensions on some flank and thigh feathers, rarely visible in field. Differs from very similar *N. phaeopus* by generally warmer buff and more cinnamon plumage; head characteristically appears more flattened; less densely streaked below, with undertail-coverts unmarked; in flight, conspicuous unmarked cinnamon patch on rump and uppertail. Female averages heavier, with longer wings and shorter bill. No seasonal variation. Juvenile, as adult but upperparts have bold, large, cinnamon-buff spots; more buffish breast lightly streaked.

Habitat. Exposed montane shrub-meadow tundra and shrub-tussock tundra. Winters exclusively on oceanic islands, where most birds prefer vegetated interior of island, while some birds use beaches; also tidal mudflats, exposed reefs, salt-pans, grassy fields, narrow channels between islets and in and around seabird colonies.

Food and Feeding. Diet in breeding range not well known, but known at least to include berries. Highly opportunistic on wintering grounds, taking vegetable matter, crustaceans, insects, spiders, gastropods, and even scorpions; also seabird carrion and fish regurgitated by seabirds and lizards; occasionally takes eggs of various seabirds, opening them with bill or by dropping them on hard surfaces, some birds even using stone tools. Usually feeds singly or in small groups.

Breeding. Probably starts laying in late May, and eggs have been found in Jun. Nest is simple, almost bare, depression in mossy vegetation. 4 eggs; both sexes incubate and tend young, but most females desert brood before young fledge; hatchlings and parents often move to wet sedge meadows to feed. Just after fledging several broods (c. 11) merge into groups tended by 1-5 adults; attending birds are, at least occasionally, non-parental adults. Age of first breeding at least 3 years. Annual survival 85-90%, and over 90% for non-migrating subadults once they have arrived at wintering grounds. Oldest ringed bird at least 23 years, 10 months.

Movements. Makes long distance, non-stop migrations of at least 4000 km over open ocean. After breeding, adults and juveniles gather on Alaskan coast prior to migration; juveniles migrate unaccompanied by adults. Occurs on passage on Pribilof, Aleutian, Hawaiian and Marquesas Is. Failed breeders start migrating S from late Jun, successful breeders and juveniles from early Aug; adults and juveniles arrive in wintering areas late Aug to early Sept, and adults depart early May. During moult on wintering grounds c. 50% of adults become flightless for c. 2 weeks. Immature birds spend all of their pre-breeding years on wintering grounds. Migrates in small flocks. Shows no diurnal pattern in timing of departures. Possibly birds wintering in C & S Pacific overfly Hawaiian Is on both migrations, flying distances of over 6000 km, relying on aid of tailwinds.

Status and Conservation. VULNERABLE. Total population 10,000 birds; breeding population 7000 birds (1992), and possibly decreasing. Designated a "Category 2" candidate by US Fish & Wildlife Service: species is rare and presumed to be in danger, but little is known. Low numbers and restricted breeding range are reasons for concern. Only two continental breeding areas known, at Seward Peninsula and floodplain of Yukon and Kuskokwim Deltas; other breeding grounds may yet await discovery; few birds may breed on Chukotskiy Peninsula, at least intermittently. Owing to moult-induced flightlessness on wintering grounds, numbers have probably declined through predation by introduced cats and dogs and possibly pigs. Potential threats on breeding grounds are off-road hunting and gold-mining activities; nest may suffer predation by Arctic Skuas (*Stercorarius parasiticus*), Common Ravens (*Corvus corax*) and foxes. On Tuamotu Is, species has traditionally been trapped for food; as possesion and use of firearms in Tuamotu Is is now restricted, greatest threat comes from introduced predators.

Bibliography. Allen & Kyllingstad (1949), Armstrong (1983), Bent (1927-1929), Brazil (1991), Collar & Andrew (1988), Collar *et al.* (1994), Ehrlich *et al.* (1992), Gill & Redmond (1992), Gill, Lanctot *et al.* (1991), Gill, McCaffery & Tobish (1988), Handel & Dau (1988), Holyoak & Thibault (1984), Konyukhov & McCaffery (1993), Kyllingstad (1948), Lanctot *et al.* (1995), Marks (1992, 1993), Marks & Hall (1992), Marks & Redmond (1994a, 1994b), Marks & Underhill (1994), Marks *et al.* (1990), Matthiessen (1994), McCaffery & Gill (1992), McCaffery & Peltola (1986), Meijer (1995), Pratt *et al.* (1987), Pyle (1991), Rosair (1995b), Tobish & Isleib (1992), Veitch (1974), Viliná *et al.* (1992), Widrig (1983b).

36. Slender-billed Curlew

Numenius tenuirostris

French: Courlis à bec grêle **German**: Dünnschnabel-Brachvogel **Spanish**: Zarapito Fino

Taxonomy. *Numenius tenuirostris* Vieillot, 1817, Egypt.
Monotypic.

Distribution. SW Siberia and N Kazakhstan, precise breeding range virtually unknown. Winters in NW Africa, and probably also Iraq.

Descriptive notes. 36-41 cm; 255-360 g; wingspan 80-92 cm. Very pale curlew, with shortish, slim, pointed bill; white or pale buff ground colour of head, neck and breast; lower back, rump, undertail and underwing white; uppertail-coverts white with sparse brown markings; typically has rounded or heart-shaped dark markings on breast and flanks. Similar to *N. phaeopus*, but paler; lacks dark crown stripe. Female averages larger with longer bill. Non-breeding adult has fewer marks on flanks. Juvenile like adult, but flanks streaked brown.

Habitat. Breeds in extensive peat bogs with some small willow (*Salix*) and birch (*Betula*) trees, in habitat transitional from bog to forest. On migration, occurs in coastal lagoons and adjoining salt-marshes, estuaries, inland soda- or salt-lakes or (drained) fishponds in steppe area. Winters in coastal bays and lagoons with salt-marshes and temporary inland marshes. Few birds observed in Morocco appear to be habitat generalists, occurring on seashore, in saline and brackish lagoons and estuaries, in temporary and permanent lakes with adjoining marshes, on mudflats, and in sandy grassland and arable fields.

Food and Feeding. Outside breeding season, takes annelids, molluscs, snails, crustaceans and small insects, such as grasshoppers, earwigs and beetles. Probes in soft mud and soil or pecks from surface; observed taking insects from scrubby bushes.

Breeding. Very little known. Eggs found in May; may apparently breed in small colonies, with nests 2-3 m apart, up to 10-15 m apart; nest in dense growth on dry areas within bogs, constructed of dry grass. 4 eggs (variation unknown).

Movements. SW-WSW migration towards Mediterranean, mainly ending up in Atlantic Morocco and in Tunisia; chiefly via Turkmenistan, Caspian steppes, Ukraine, Bulgaria, Romania, former Yugoslavia, S Hungary, Greece and Italy; a second migration route may lead from breeding grounds to Middle East, where winters in Iraq and also reported to occur in Iran, Saudi Arabia and Oman. Records from Morocco mainly Nov-Mar; formerly irregular migrant in NE Africa late Jul to Aug and Apr-May. Status in Turkey uncertain, as many records of *N. arquata orientalis* have been erroneously attributed to present species; 2 skins exist of birds thought to have been shot in Istanbul area in late 19th or early 20th century. Status in Azerbaijan also uncertain; definite record of bird shot in Aug 1988, and species said to pass through regularly in very small numbers. Reported to have been seen in Argentina, but these reports now discounted.

Status and Conservation. CRITICALLY ENDANGERED. CITES I. Population estimated at 50-270 birds in 1994. Has only been recorded breeding in Tara region N of Omsk in SW Siberia, but no breeding records since 1925. Until early 1890's probably very abundant in Morocco, Algeria and Tunisia, but since then numbers have declined dramatically and probably still dropping, so species seriously threatened; only regularly used wintering site is Merja Zerga, NW Morocco. In 1964, as many as 600-900 birds were counted in SW Morocco, but almost all recent sightings in entire non-breeding range usually involve only 1-3 birds; in S Italy, c. 20 birds reported to be seen regularly during Jan-Mar 1995; surprising report of 50 birds from Iran in 1994. Species used to stage in steppes, and its decline may be due to massive loss of this particular habitat; also hunting, particularly on migration, and drainage of staging areas may have been significant. Breakdown of social behaviour patterns in a species which formerly migrated in large flocks may also constrain recovery. It has recently been suggested that the main breeding areas may not have been located in W Siberia but in steppe zone, which has been cultivated on large scale, thus perhaps explaining rapid decline of species. Area N of Caspian Sea, between R Volga and R Ural has been suggested as potential breeding location.

Bibliography. Albrecht (1989), Allport (1995), Anon. (1989c, 1993b), Baccetti (1991, 1995), Belik, V.P. 37. Eurasian Curlew

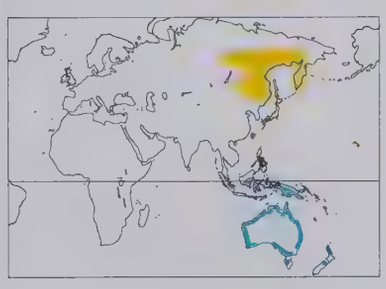
Numenius arquata

French: Courlis cendré **German**: Großer Brachvogel **Spanish**: Zarapito Real
Other common names: Common Curlew

Taxonomy. *Scolopax Arquata* Linnaeus, 1758, Sweden.
Racial variation clinal; W populations of *orientalis* have on occasion been separated as race *sushkini*. Two subspecies recognized.

Subspecies and Distribution.
N. a. arquata (Linnaeus, 1758) - British Is and France across W Europe (N to Arctic Circle) and E to R Volga and Urals; winters from Iceland and British Is S to Mediterranean and NW Africa, and E to Persian Gulf and W India.
N. a. orientalis C. L. Brehm, 1831 - R Volga and Urals E through C Russia and N Kazakhstan to C Manchuria; winters in W, E & S Africa, and from S Caspian Sea S to Persian Gulf and E through S Asia to E China and S Japan, and S to Philippines and Greater Sundas.

Descriptive notes. 50-60 cm; male 410-1010 g, female 475-1360 g; wingspan 80-100 cm. Large greyish brown curlew with long bill and plain head pattern; head, neck, breast and upperparts buffy brown with dark streaking, although plumage variable; pale underwing, white rump and lower back; belly white, flanks streaked. Most similar to *N. madagascariensis*, but bill less massive and normally shorter; underparts whiter. Female averages larger, especially with longer bill. Non-breeding adult has breast and upperparts grey-brown and underparts whiter. Juvenile has breast more buff and flanks less streaked; upperparts with buff spot-



ting and fringes. Race *orientalis* usually paler, with underwing-coverts and axillaries largely unmarked; lower rump may be more barred and inner wing paler, but considerable overlap.
Habitat. Breeds on peat bogs, fens, upland moors, damp grassland, grassy or boggy open areas in forest, extensive farmland, swampy and dry heathland, dune valleys and coastal marshes; increasing numbers breed in meadows. In non-breeding period, chiefly on muddy coasts, bays and estuaries; also regularly on muddy shores of inland lakes and rivers. During migration, also found on wet grassland and arable fields. Males are more likely to feed in inland grassland than females.
Food and Feeding. Throughout year, diet includes annelids, arthropods, crustaceans, molluscs, berries and seeds; occasionally vertebrates, including small fish, amphibians, lizards, young birds (and possibly eggs), small rodents; chiefly terrestrial insects and earthworms, especially in summer. Feeds by pecking, jabbing or deep probing in mud or damp soil. Occasionally takes food from conspecifics or other wader species. Some birds territorial on wintering grounds, others feed gregariously. Long-billed females tend to forage more on intertidal flats, feeding on molluscs, crabs and polychaetes, while shorter-billed males tend to feed more on lumbricids on cultivated grassland.
Breeding. Lays Apr to early Jul. Monogamous. High degree of site fidelity. Densities of up to 10 pairs/km². Nest typically in open, often in grass or sedge cover. 4 eggs (2-5), with laying interval 1-2 days; single brood; incubation 27-29 days, by both sexes; chick pale ochraceous buff above clouded with blackish brown, black crown and creamy buff on belly; both parents care for young; fledging 32-38 days. Including unsuccessful clutches, production c. 1·7 hatchlings/pair, and 0·25-1·4 fledlings/pair; reproductive success is higher in semi-natural habitats than in farmland, and lowest on intensively cultivated land; on farmland, nest failure caused by predation and farming practices; fledgling survival until maturity c. 30%. Annual mortality 66% in 1st year, deceasing to 18% until 3rd year. Age of first breeding 2 years. Oldest ringed birds at least 32 years.
Movements. Mostly migratory; some birds resident in W of range, especially in British Is and Ireland. Small numbers regularly winter in Iceland and Faeroes. Scandinavian and Baltic populations move SW to W European coast. The subspecies mix in Balkans after breeding, and probably in winter quarters from Mediterranean to W India. Nominate *arquata* presumably winters as far S as Banc d'Arguin (Mauritania), Morocco, Algeria and Italy, with *orientalis* occupying rest of African wintering grounds, e.g. birds wintering in Guinea-Bissau originate from C Siberia. Some transcontinental migration in Africa, e.g. across Sahara. Most birds winter at moulting grounds, with little evidence of post-moulting movements. High fidelity to wintering grounds. Southward migration Jun-Nov, starting with non-breeders and adult females; return starts Feb, but mainly Mar-Apr; migration to Fenno-Scandian and Russian breeding grounds mainly mid-Apr to early May. Many 1st-year birds remain in winter quarters all year.
Status and Conservation. Not globally threatened. E Atlantic wintering population estimated at 348,000 birds, plus probably c. 80,000 birds inland (1989), with c. 250,000 birds wintering in Europe; up to 227,000 birds have been counted on Wadden Sea. Breeding population of Europe, excluding Russia, comprises 125,000-147,000 pairs (1986-1993), mostly in Scandinavia and British Is; has occasionally bred in Spain, e.g. in 1993. Most European breeding populations have declined, except in Russia, Finland and Britain; numbers of wintering populations have dropped even more. Numbers of *orientalis* wintering in SW Asia and E Africa exceed 28,000 birds; 15,000-20,000 counted in Iran in 1970's; SC, SE & E Asia hold c. 25,000 birds each. Decline of nominate race probably due mainly to loss of breeding habitat and loss and fragmentation of grassland, caused by agricultural intensification, e.g heavy egg and chick mortality occurs if grassland is cut, and predation is high in agriculturally improved habitats; "improvement" of marginal grassland shown to reduce breeding population. In Ireland, afforestation of moorlands has led to decline in breeding pairs. Wintering populations affected by disturbance and building developments on high tide roosts, by pollution, and locally by intensive hunting. Recommended conservation measures are protection of wintering sites and reductions in intensive farming.

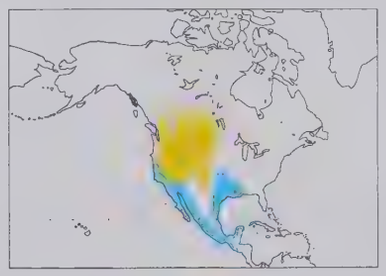
38. Far Eastern Curlew

Numenius madagascariensis

French: Courlis de Sibérie **German**: Isabellbrachvogel **Spanish**: Zarapito Siberiano
Other common names: Eastern/Australian/Long-billed/Red-rumped Curlew

Taxonomy. *Scolopax madagascariensis* Linnaeus, 1766, Madagascar; error = Macassar, Sulawesi. Monotypic.
Distribution. E Siberia, from upper reaches of R Nizhnyaya Tunguska E through Verkhoyansk Mts to Kamchatka, and S to NE Mongolia, Manchuria and Ussuriland. Winters in Taiwan, Indonesia and New Guinea, but most birds migrate to Australia and a few reach New Zealand. Never recorded in Madagascar.



Descriptive notes. 53-66 cm; 390-1350 g, male averaging 110 g lighter than female; wingspan 110 cm. Largest curlew with very long, heavy bill; female has longest bill of any wader (184 mm). Plain head pattern; upperparts have dark feather centres and buff notches and fringes; breast and flanks finely streaked; underwing densely barred brown. Differs from *N. arquata* in dark rump, back and underwing; longer, heavier bill. Female averages larger, especially with longer bill. Non-breeding adult lacks rufous tinge on upperparts. Juvenile has more extensive whitish edging on upperparts when plumage fresh; streaking on underparts finer.
Habitat. Breeds in open mossy or transitional bogs, moss-lichen bogs and wet meadows, and on swampy shores of small lakes. In non-breeding season essentially coastal, occurring at estuaries, mangrove swamps, salt-marshes, intertidal mudflats or sandflats, particularly those with extensive seagrass (*Zosteraceae*) meadows; sometimes on beaches; very rarely inland near large wetlands. Often roosts in salt-marshes behind mangroves, or on sandy beaches.
Food and Feeding. Diet on breeding grounds includes insects, such as larvae of beetles and flies, and amphipods. During autumn migration berries also consumed. In non-breeding areas, marine invertebrates, mainly crabs and small molluscs, but also other crustaceans and polychaete worms. Probes bill down burrows, or pecks from surface, detecting prey by sight or touch; prefers soft-sediment intertidal mudflats. Feeding action slow and deliberate. Manipulates large prey, swallowing it piece by piece; sometimes washes prey. Sexual differences in length of bill can lead to corresponding differences in diet: females feed solitarily on burrow-living shrimps and defend feeding territory; males feed in loose flocks (up to 100's) on crabs. Diurnal and nocturnal.
Breeding. Nests early May to late Jun. Often in small colonies of 2-3 pairs. Nest lined with dry grass and twigs, on small mound in swampy ground, often close to areas with wild berries growing. Usually 4 eggs. Probably delays maturity longer than most shorebirds, perhaps not breeding until 3-4 years old.
Movements. Long distance migrant; moves down coasts of Kuril Is, Sakhalin, Ussuriland, Korea, Japan, parts of Philippines, E Sumatra and Borneo; less common in transit in E China, Hong Kong and New Guinea. Fewer birds appear in continental Asia in autumn than in spring, vice versa in Japan. NW & E Australia reached as early as Jun, but mainly in late Aug, followed by gradual southward movement; most birds reach S Australia in Nov. Northbound migration up coast of E Australia occurs mainly Feb-Apr, but birds from SE Australia seem to bypass E coast sites. More females seem to migrate farther S. Non-breeding birds spend boreal summer in N & NW Australia and Victoria, and possibly do so until late in their 3rd year.
Status and Conservation. Not globally threatened. Currently considered near-threatened. At present, world population reckoned to number 21,000 birds at most, with Australia holding 19,000 birds in boreal winter; in Philippines, 457 birds counted in 1992, and 75 in 1993; up to c. 370 recorded in Sumatra. Small numbers apparently wintering in China in recent years, with 64 birds counted in 1992, and 10 in 1993. Has declined mainly through loss of habitat and disturbance, and possibly persecution (Tasmania) and decrease of available food through pollution (South Korea); hunting may also have been significant at breeding grounds, on migration and in S Australia. Easily disturbed at feeding and roosting sites. Potential threat may be that females probably tend to migrate farther S, to S Australian wetlands, which are more at threat than those in N Australia. Over last 30-60 years, numbers have fallen significantly in some areas in Australia, Tasmania and New Zealand; this may be due to population decline or to change in non-breeding range. In Western Port Bay, SC Victoria, dramatic loss of seagrasses on intertidal mudflats caused substantial decline in mid-1970's, but population now seems to be recovering.
Bibliography. Alcorn (1988), Barter (1990), Beehler *et al.* (1986), Blakers *et al.* (1984), Brazil (1991), Bregulla (1992), Brouwer & Garnett (1990), Chambers (1989), Close & Newman (1984), Coates (1985), Congdon & Catterall (1994), Dickinson *et al.* (1991), Étchécopar & Hüe (1978), Garnett (1993), Knystautas (1993), Kragh *et al.* (1986), Lane & Davies (1987), MacKinnon & Phillipps (1993), Marchant & Higgins (1996), van Marle & Voous (1988), Medway & Wells (1976), Meyer de Schauensee (1984), Minton (1993), Parish & Howes (1989), Perennou *et al.* (1994), Piersma (1986e), Pook (1992), Rogacheva (1992), Rogers, K.G. (1982, 1995), Scott (1989), Silvius (1986), Starks & Lane (1987), Tolchin (1980), Vinter (1980), Watkins (1993), White & Bruce (1986), Williams, M.D. (1986), Yi *et al.* (1994).

39. Long-billed Curlew

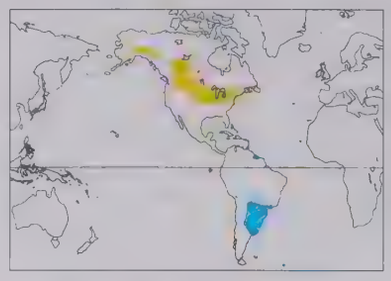
Numenius americanus

French: Courlis à long bec **German**: Rostbrachvogel **Spanish**: Zarapito Americano

Taxonomy. *Numenius americanus* Bechstein, 1812, New York.
Race *parvus* formerly labelled *occidentalis*; type specimen of latter lost. Two subspecies recognized.
Subspecies and Distribution.
N. a. parvus Bishop, 1910 - SC British Columbia E to S Manitoba, and S to California and South Dakota; winters from California and Louisiana S to Mexico.
N. a. americanus Bechstein, 1812 - Nevada E to South Dakota and S through Utah and NW Oklahoma to N Texas; winters from California, and Texas S to Mexico and Guatemala.

Descriptive notes. 50-65 cm; males 445-792 g, females 630-951 g. Large cinnamon-coloured curlew with droplet-shaped bill tip; fairly large eye; upperparts speckled black and cinnamon-buff; strong barring on tertials; mostly unstreaked cinnamon underparts. Much more richly coloured than congeners, including rich cinnamon underwing. Female averages larger, especially with longer bill. Non-breeding adult has duller upperparts. Juvenile almost identical to adult, but upperparts buffer, especially wing-coverts. Race *parvus* smaller.
Habitat. Prairies, including damp meadowland, grain fields, grazed mixed grass and drier short-grass areas, especially on gravelly soils in rolling terrain. After breeding, occurs in moist upland environments, shallow estuaries, inland waters and open parts of marshes; some move to farmland.
Food and Feeding. Adult and larval insects. During non-breeding season often feeds on burrow-dwelling crustaceans (e.g. mud crabs and shrimps), also on molluscs, worms, toads, adult and larval insects, and sometimes berries. Occasionally preys on nesting birds. Feeds by pecking and probing, striding rapidly over substrate; in non-breeding habitat, often feeds in flocks.
Breeding. Laying Apr-May. Density 0·6-2·4 pairs/km², up to 9 pairs/40 ha. Low degree of natal philopatry, only 4%. Nest sited in flat area, with short grass cover and well spaced grass clumps, often close to object such as rock or dried cow dung. 4 eggs (3-5), laying interval 1-2 days; incubation 27-28 days, by both parents; during first weeks young cared for by both parents, later only by male; fledging 41-45 days. Nest success 44-69%, 28-44% of young survive till fledging; 10-16% of nests destroyed by mammalian and avian predators; productivity adversely affected by grazing and dragging. Age of first breeding unknown, but some birds return to breeding grounds as 1-year-olds.
Movements. Relatively short distance migrant, which arrives on breeding grounds early, mid-Mar, and departs by mid-Aug. Mostly moves across interior W half of USA, and also fairly common to uncommon across inland Mexico. Most non-breeders spend all year in winter range. Rarely winters S to N South America.
Status and Conservation. Not globally threatened. Population size of race *americanus* unknown; that of *parvus* numbers c. 6500 birds (1992) and apparently in continuing decline. Formerly bred in several states of Midwest, but breeding range has contracted westwards during present century, due to constant

loss of open prairies to agriculture. Was heavily hunted in late 19th and early 20th centuries. Species now benefits from full protection and overall numbers may now be stable.
Bibliography. Allen (1980), Bayer (1994), Bent (1927-1929), Bicak (1977), Blake (1977), Cochran & Anderson (1987), Fitzner (1978), Forsythe (1970, 1972, 1973), Goater & Bush (1986, 1988), Graul (1971), Grinnell (1921), Hardee (1988), Hertzel (1990), Howell & Webb (1995a), Knopf (1994), Krych (1992), Matthiessen (1994), Monroe (1968), Pampush & Anthony (1993), Paton & Dalton (1994), Redmond (1986), Redmond & Jenni (1982, 1986), Redmond *et al.* (1981), Ridgely & Gwynne (1989), Ritchie (1990), Root (1988), Salder & Maher (1976), Schon (1988), Shackford (1994), Silcock (1991), de Smet (1992), Stenzel *et al.* (1976), Stiles & Skutch (1989), Wilson (1988).



Genus *BARTRAMIA* Lesson, 1831

40. **Upland Sandpiper**

Bartramia longicauda

French: Maubèche des champs **German**: Prärieläufer **Spanish**: Correlimos Batitú
Other common names: Bartram's Sandpiper, Upland Plover

Taxonomy. *Tringa longicauda* Bechstein, 1812, North America. Monotypic.
Distribution. C Alaska, Yukon and S Mackenzie; British Columbia and Alberta E through Great Plains to S Quebec and New Brunswick, and S to NE Oregon, NC Texas, C Missouri, West Virginia and Maryland. Winters in Surinam and from Paraguay and S Brazil to C Argentina.
Descriptive notes. 26-32 cm; 98-226 g; wingspan 64-68 cm. Curious sandpiper, reminiscent of small curlews; elegant, with short yellow bill, large dark eye, long neck and small, rounded head; upperparts olive brown with extensive dark barring and pale buff fringes; neck and breast pale buff with dark streaking, rest of underparts white; in flight, conspicuous black rump. Recalls *Numenius minutus* but has shorter, much straighter bill, yellowish legs and longer tail; paler than *N. borealis*, with whitish underwing and axillaries densely barred blackish. Female averages slightly longer in wings and tail. No seasonal variation. Juvenile has dark brown scapulars and upperparts with pale buff fringes; flanks less streaked.
Habitat. Inland, on primary or restored prairie grasslands, locally extensive tracts of wet meadows, domestic hay fields, retired croplands and marginal habitats. In non-breeding season uses similar habitats in *pampas*, frequenting alfalfa fields, pastures, rough grassland, areas of short grass including golf courses and airfields, even suburban lawns, and sometimes wet shorelines; vegetated sand banks in Amazon zone. Commonly perches on posts or even in trees.

Food and Feeding. Diet chiefly consists of terrestrial insects such as grasshoppers, crickets and weevils, larvae of beetles and Lepidoptera, also centipedes, millipedes, spiders, snails, earthworms and seeds. Feeding style is sometimes plover-like, alternating short runs with sudden stops; forages singly or in small groups.
Breeding. Laying May-Jun. Density 5-22 pairs/km², but 25-75 pairs/km² reported in 1930's; sometimes in loose colonial groups. Nest usually well hidden in tussock 5-20 cm high. 4 eggs (2-5), laid at intervals of c. 26 hours; incubation 24 days (21-28), by both sexes; chick brownish above with buffy feather tips; roles of sexes in tending chicks not clear; fledging 32-34 days. 41-74% of nests successful; major cause of nest failure is predation.
Movements. Long distance migrant. Main wintering areas seem to be located in Argentina and Uruguay. Migrates through Great Plains, Mexico, Central America, across Gulf of Mexico and most of South America E of Andes; some movement across W Atlantic; no evidence of Atlantic crossing during northward migration. Leaves breeding areas late Aug to early Sept, arriving in non-breeding areas late Sept to Oct; return passage starts mid-Feb, birds reaching breeding grounds early Apr to Jun.
Status and Conservation. Not globally threatened. Total population size unknown; estimated c. 2000 birds in Canada. Enormous numbers once bred on grasslands in Great Plains. After eastward expansion following deforestation, numbers declined dramatically due to hunting and cultivation of prairies during late 19th and early 20th centuries. Still fairly abundant in some parts of breeding range, although part of range has contracted. Numbers breeding on grasslands increased by 3·5% annually during period 1961-1991, although species declining locally. In Pacific Northwest, only tiny relict populations remain; these are in real danger of extinction. Species is a good indicator species for undisturbed grasslands.
Bibliography. Ailes (1976, 1980), Ailes & Toepfer (1977), Amos (1991), Armstrong (1983), Belton (1984), Bent (1927-1929), Blake (1977), Bowen, B.S. & Kruse (1993), Bowen, D.E. Tribe TRINGINI

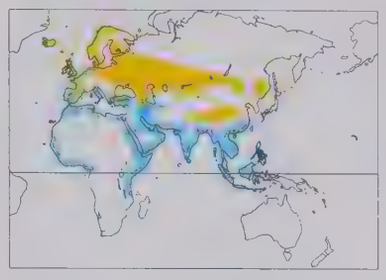
Genus *TRINGA* Linnaeus, 1758

41. Spotted Redshank

Tringa erythropus

French: Chevalier arlequin **German**: Dunkler Wasserläufer **Spanish**: Archibebe Oscuro
Other common names: Dusky Redshank

Taxonomy. *Scolopax erythropus* Pallas, 1764, the Netherlands.
Monotypic.
Distribution. N Scandinavia and NW Russia across N Siberia to Chukotskiy Peninsula. Winters from W Europe through Mediterranean to equatorial Africa, and E through Persian Gulf and India to SE Asia, SE China and Taiwan.



Descriptive notes. 29-32 cm; 97-230 g; wingspan 61-67 cm. Elegant wader, with long neck, legs and bill; entirely black, with white dots on upperparts, and often variable amounts of whitish on underparts; in flight, shows white wedge on back and white underwing. Female slightly larger and generally paler, with white tips on crown feathers and more white fringes on underparts. Non-breeding adult has contrasting dark eyestripe and white supercilium, ash grey upperparts with white fringes, plain grey breast and white underparts; rather similar to *T. totanus*, but has longer darker red legs; longer, finer bill, lower mandible basally red; white above lores. Juvenile darker than non-breeding adult; upperparts, head and breast brownish with dense white marks; underparts paler, densely barred.
Habitat. Open wooded tundra, swampy pine or birch forest near tree-line, and also more open areas such as heathland and shrub tundra. After breeding, occurs in variety of freshwater or brackish wetlands, including sewage farms, irrigated rice fields, brackish lagoons, salt-marshes, salt-pans and sheltered muddy shores along coast.
Food and Feeding. Chiefly aquatic insects and their larvae, terrestrial flying insects, small crustaceans, molluscs, polychaete worms, fish and amphibians, rarely up to 6-7 cm length. When feeding on fish, may forage socially in dense flock of conspecifics or mixed with other tringines, moving erratically while pecking at prey or running synchronously in one direction, while each bird sweeps bill through water. Often found in water, and occasionally swims while feeding in deep water; may immerse head and neck completely. Pecks, probes, jabs or sweeps bill through water from side to side. Mostly in small flocks, occasionally up to several 100's, sometimes singly. Diurnal and nocturnal feeder.
Breeding. Laying mid-May to late Jun. Monogamous; apparently sometimes polyandrous. Rather patchy dispersion, in densities of 2-3 pairs/km² (maximum 15). Nest usually in grass tussocks or moss, sparsely lined with plant material. 4 eggs (3-5); laying interval and incubation period unknown; chick pale drab grey finely marked with fuscous black above, dark cap and dirty white on chin and belly; fledging 28 days; male undertakes most of incubation and tends brood largely on his own; most females often leave before eggs hatch (mid-Jun). Oldest ringed bird 6 years 1 month.
Movements. Migratory. Passage overland on broad front, although also important route down W coast of Europe. Movements characterized by long flights between staging areas, such as Wadden Sea, Dutch delta region, S Hungary, SE Greece, C Turkey, Black and Caspian Seas, C Kazakhstan, L Baikal, Chang L (Ussuriland), C Yakutia, Sakhalin, Japan and Korea. Birds wintering in Sahel and N savanna zones evidently cross Sahara, e.g. to Mali, Nigeria and Chad. Adults moult in staging areas before moving to wintering grounds. Present in tropics mainly Oct-Apr. Migrates N along European coast late Apr to mid-May; females move S from early Jun, males during Jul, and juveniles in Aug-Sept. Few birds oversummer in tropics, but most non-breeders spend summer just S of breeding grounds.
Status and Conservation. Not globally threatened. European and W African population numbers 75,000-150,000 birds (1994); 23,000-40,000 birds breed in Fenno-Scandia (1993); further E, in Russia, breeds in fairly high numbers. Total of c. 25,000 birds winter in Egypt, E Africa and SW Asia, 10,000-25,000 birds in SC Asia and similar number in SE & E Asia. Number of wintering birds in NW Europe was fairly stable over period 1971-1977.
Bibliography. (1990), Smythies (1986), Taverner (1982), Urban *et al.* (1986), Williams, M.D. (1986).

42. Common Redshank

Tringa totanus

French: Chevalier gambette **German**: Rotschenkel **Spanish**: Archibebe Común
Other common names: Redshank

Taxonomy. *Scolopax Totanus* Linnaeus, 1758, Sweden.
Increasing evidence for separation of population of British Is and Netherlands as race *britannica*, as was earlier suggested. Birds from S portions of European range have sometimes been awarded race *bewickii*. Six subspecies currently recognized.
Subspecies and Distribution.
T. t. robusta (Schiøler, 1919) - Iceland, Faeroes and possibly Scotland; winters in British Is and W Europe.
T. t. totanus (Linnaeus, 1758) - Orkney, Shetland and N Scandinavia S to Iberian Peninsula, N Italy, Tunisia and Turkey, and E to W Siberia; winters from Mediterranean to tropical Africa, India and Indonesia.
T. t. ussuriensis Buturlin, 1934 - S Siberia and Mongolia E to N Manchuria and Russian Far East; winters from E Mediterranean and E Africa through Red Sea, Persian Gulf and Arabia to W India, and probably also farther E.
T. t. terrignotae R. & A. C. Meinertzhagen, 1926 - S Manchuria; winters in SE & E Asia.
T. t. craggi Hale, 1971 - NW Xinjiang (NW China); wintering grounds unknown, but probably in E China.
T. t. eurhinus (Oberholser, 1900) - Pamirs, N India and C & S Tibet; winters in India.

Descriptive notes. 27-29 cm; 85-155 g; wingspan 59-66 cm. Ashy brown upperparts, head and breast, streaked and spotted with black and dark brown; white secondaries conspicuous in flight. Differs from non-breeding *T. erythropus* by shorter, orange-red legs, shorter bill, indistinct supercilium and redder bill. Female often has paler upperparts than male, at least in race *totanus*. Non-breeding adult has greyer upperparts, without streaks or spots, but some narrow white fringes; underparts paler, breast finely streaked. Juvenile has warm brown upperparts with buff fringes and bill dull red at base. Races generally vary only in small details of plumage and size; *robusta* and *ussuriensis* more cinnamon.
Habitat. Wide diversity of coastal and inland wetlands, including coastal salt-marshes, inland wet grasslands, grassy marshes and swampy heathlands. After breeding, chiefly in coastal habitats including rocky, muddy and sandy shorelines, salt-marshes and open mudflats, salt-lakes, freshwater lagoons, salt-works and sewage farms; sometimes at inland waters or flooded grasslands.
Food and Feeding. Insects, spiders and annelids; non-breeders also consume molluscs and crustaceans, particularly amphipod *Corophium volutator*; on occasion, feeds on small fish or tadpoles. Like diet, feeding method varies seasonally; uses typical brisk walk while pecking; occasionally probes, jabs or sweeps bill through water; often wades, and occasionally swims. When feeding on fish, may forage socially in dense flock, often mixed with other tringines: birds move erratically while pecking at prey or running synchronously in one direction, ploughing or scything bills through water. Feeds diurnally and nocturnally. Mostly in small flocks, occasionally many 100's, sometimes singly. May defend feeding territory.
Breeding. Laying Apr-Jun. Monogamous. Moderate degree of natal philopatry and, especially in experienced and successful breeders, of site faithfulness and mate fidelity. Solitary or in loose colonies; on coast up to 100-300 pairs/km², but inland usually below 10 pairs/km². Nest typically at base of tall clump of grass, with leaves covering overhead. 4 eggs (3-5), laying interval 38 hours (35-43); replacement clutches laid; incubation 23-24 days, by both sexes; chick has creamy or greyish buff upperparts with black-brown lines, buff suffused breast and whitish underparts; both parents initially tend young; but later on often only male, and brood sometimes split up between sexes; fledging 23-35 days. Hatching success c. 14%; from hatching to fledging 20-50%; mortality may increase dramatically during cold spells, especially in combination with rain; other important causes of nest loss are trampling by cattle, predation and agricultural activities, notably mowing. Mortality of 1st-year birds 55%, of adults c. 30%. Age of first breeding 1-2 years. Oldest ringed bird 17 years.
Movements. Chiefly migratory, although some birds in Iceland and W Europe virtually resident. Much overlap between subspecies in winter range, but in general smallest birds (N Scandinavia) winter farthest S (typically W Africa), while largest (Iceland) winter on average farthest N (Iceland to North Sea). Migration through Europe is SW-SSW, except for Atlantic Is; presumably on broad front over land and along coast; birds wintering in W Africa may cross Sahara on passage. In Asia, movements noted through Japan, Mongolia, E China (Chihli Plains), Hong Kong and Korea (scarce); breeders of Altai and Novosibirsk area and probably C Siberia winter in India. A few birds remain in winter quarters all year. Occurs annually in small numbers in NW & N Australia. In nominate race, W African winterers migrate N from late Apr to May, when S breeders already incubating; these S birds migrate S in Jul (adults) and mid-Jul to early Aug (juveniles); N breeding birds of races *totanus* and *robusta* migrate S in Jul (adults) and mid-Aug to early Sept (juveniles).
Status and Conservation. Not globally threatened. W Palearctic breeding population has declined since 1970, and estimated at 50,000-100,000 pairs of race *robusta* (1993) and 145,000-185,000 pairs of race *totanus* (1986-1993). Counts along E Atlantic flyway yield estimates of 177,000 birds of race *totanus* and 109,000 of *robusta* (1989), with highest numbers in British Is, Guinea-Bissau and Mauritania; considering breeding numbers, these must be underestimates. In Egypt 8000-10,000 birds, in SW Asia (mainly *ussuriensis*) c. 55,000 birds, in SC Asia (*ussuriensis* and *eurhinus*) probably c. 100,000 birds, and in SE & E Asia (mainly *terrignotae*) also in order of 100,000 birds; no figures available for race *craggi*. Decline of W Palearctic population mainly due to loss of winter and breeding habitats, agricultural intensification, wetland drainage, flood control, afforestation, land reclamation, industrial development and encroachment of *Spartina* on mudflats; severe cold spells on W European wintering grounds may also have had disastrous effects. Improvement of marginal grassland may result in declining density of breeding pairs by up to 80%. Currently, winter population of E Atlantic flyway seems rather stable.

43. Marsh Sandpiper

Tringa stagnatilis

French: Chevalier stagnatile **German**: Teichwasserläufer **Spanish**: Archibebe Fino

Taxonomy. *Totanus stagnatilis* Bechstein, 1803, Germany.
Monotypic.

Distribution. W Russia and E Ukraine to EC Siberia; isolated populations in Ussuriland and W Heilongjiang (NE China). Winters from Mediterranean and sub-Saharan Africa through Persian Gulf and S Asia to Indonesia and Australia.

Descriptive notes. 22-26 cm; 43-120 g; wingspan 55-59 cm. Small body, long legs and straightish, needle-like bill; looks like small, fine *T. nebularia*; wings dark, rump and back white, face pale; upperparts strongly spotted and blotched with greyish cinnamon and black-brown; foreneck, breast and flanks with black markings. Female averages slightly larger. Non-breeding adult has plain grey upperparts with narrow white fringes and contrasting dark wing-coverts; face and underparts white. Juvenile as non-breeding, but upperparts browner with buff spots and fringes.

Habitat. Steppe and boreal wetlands, deep inland, preferably in open marshland with fresh grassy cover; brackish shallow marshes; less frequently around salt-lakes. Outside breeding season, occurs typically at margins of inland fresh to brackish wetlands, including paddyfields, swamps, salt-pans, salt-marshes, sewage farms, estuaries, lagoons and intertidal mudflats; avoids open beaches. On migration often feeds alongside *T. nebularia*.

Food and Feeding. Diet not well known, but includes at least small fish, crustaceans, molluscs and many insects, mostly aquatic, sometimes terrestrial; occasionally plant material. Often feeds in shallow water, pecking from water surface, while walking steadily and briskly; may glean from vegetation; sometimes probes, jabs or sweeps bill through water; rarely swims. When feeding on fish, may forage socially in dense flock of conspecifics or mixed with other tringines, moving erratically while pecking at prey or running synchronously in one direction while ploughing or scything bill through water; also recorded following ducks, egrets and other waders, feeding on prey disturbed by activity of other birds. Feeds singly or in flocks of up to several 100's.

Breeding. Laying late Apr to Jun. Probably monogamous. Solitary or in loose colonies; frequently together with marsh terns (*Chlidonias*), *T. totanus*, *Vanellus vanellus* or *Limosa limosa*. Nest placed on mound, in short vegetation, close to water; usually filled with dry grass. 4 eggs (3-5); both sexes incubate and tend brood; chick creamy buff above with blackish brown markings, face, chin and belly almost white. Age of first breeding 1 year or older.

Movements. Migratory. Generally scarce at stopover sites and many birds fly long distances overland on broad front. Main passage from USSR occurs E of Black Sea, through Kazakhstan and Middle East towards E & S Africa; few birds cross Slovakia, Hungary, Balkans, Italy and E Mediterranean; less commonly, though regularly, through W Europe. Nile Valley in Sudan frequently used as stopover, whereafter Sahara is crossed diagonally to W & WC African wintering grounds, where species present Sept to mid-Apr. In E Asia, passes through C Mongolia, C, NE & coastal China (Yellow R Delta), Korea (only on S migration), Japan, Hong Kong, Myanmar, Malaysia and Sumatra. In E Australia, may move away from coast after rains, and, as in C Australia, disperse among temporary inland wetlands. Most non-breeders stay in winter quarters or at intermediate sites during N summer.

Status and Conservation. Not globally threatened. Population of W African and Palearctic winterers c. 100,000 birds; in E Africa and SW Asia 25,000-100,000 birds; SC Asia in order of 100,000 birds, with important sites in SW India and Sri Lanka; E & SE Asia c. 90,000 birds; estimated 9000 birds in Australia, where SE Gulf of Carpentaria is the most important site, with 1150 birds. Little known about population trends, but breeding range in W Palearctic has shrunk, and species has even disappeared as breeding bird in E Europe, Belarus and Moldova, as result of losses of steppe habitat due to agricultural intensification; egg-collecting might also have played a role. Since 1960's, northward expansion of breeding range in Russia, although recently some Russian breeding populations declining in Caspian and Aral Sea regions, e.g. around Volga-Kama confluence and Orenburg. In E Russia, breeding range has expanded S as result of agricultural development. In Kharkov, NE Ukraine, amount of rain in spring affects numbers of breeding birds.

44. Common Greenshank

Tringa nebularia

French: Chevalier aboyeur **German**: Grünschenkel **Spanish**: Archibebe Claro
Other common names: (Greater) Greenshank

Taxonomy. *Scolopax nebularia* Gunnerus, 1767, district of Trondheim, Norway.
Possible race *glottoides* proposed for E populations, on grounds of larger size range and details of non-breeding plumage. Monotypic.

Distribution. N Scotland and Scandinavia E through C Asia to E Siberia and Kamchatka. Winters from W Europe through Mediterranean to Africa, and E through Middle East to S Asia, Indonesia and Australasia.

Descriptive notes. 30-35 cm; 125-290 g; wingspan 68-70 cm. Largest *Tringa* with long, robust, slightly uptilted bill and dull green legs; upperparts spotted and streaked black-brown, lesser wing-coverts browner; head, neck and upper-breast streaked brown-black; in flight, shows dark wings, white back and rump. Paler above than *T. guttifer* and *T. melanoleuca*, with longer legs than former. Female averages slightly larger. Non-breeding adult has feathers of upperparts rather uniform grey, without dark markings; breast, foreneck and face white; stronger contrasting dark wing-coverts. Juvenile resembles non-breeding adult, but upperparts browner with buff fringes and neck and breast somewhat more streaked.

Habitat. Taiga zone, in forest clearings, woody moorland or open bogs and marshes, including blanket bog; characteristic of northern and middle taiga. On migration, occurs at inland flooded meadows, dried-up lakes, sandbars and marshes. Winters in variety of freshwater and marine wetlands, including estuaries, sandy or muddy coastal flats, salt-marshes, mangroves, swamps and lakes; also on artificial wetlands, such as sewage farms, salt-works and inundated rice crops; less often on open coast, sometimes along quiet stretches of rivers.

Food and Feeding. Chiefly insects and their larvae, especially beetles, but also crustaceans, annelids, molluscs, amphibians and small fish; reported also rodents. Usually pecks and probes in shallow water walking with steady pass, sometimes running with erratic changes of direction; when feeding on fish may forage socially in dense flocks of conspecifics or mixed with other tringines, moving erratically while pecking at prey or running synchronously in one direction, ploughing or scything bill through water. Singly, or in small to large flocks of up to 100's. Feeds diurnally and nocturnally.

Breeding. Lays late Apr to Jun. Usually monogamous, though some males bigynous. High degree of site fidelity, but no natal philopatry. Densities 1·4-10 birds/km of riverbed (R Yenisey). Nest is shallow scrape lined with some plant material, on ground in the open, typically placed next to piece of dead wood. 4 eggs (3-5), with laying interval of 30-72 hours; single brood; incubation 24 days (22-26), by both sexes, but males with two mates normally do little incubation; chick pale grey marked above with fuscous black, white belly; often one parent leaves brood before fledging; fledging 25-31 days. On average, 74% of eggs hatch, 32% of hatchlings fledge. Age of first breeding unknown, but some return to breeding grounds as 1-year-olds. Oldest ringed bird 11 years, 11 months.

Movements. Mostly migratory, though some populations move only short distances. Migrates overland on broad front, but largest numbers pass through coastal sites. Movements over Europe mainly SSW-SW. Wadden Sea used by many Fenno-Scandian birds as stopover and moulting site from late Apr to mid-May; some move to Morocco. Most Palearctic birds are trans-Saharan migrants. Some non-breeders remain S all year. Spring migration more direct, without large coastal concentrations. Birds from Russia wintering in Africa are presumed to cross E & S Europe. In E Asia, passes through Kuril Is, Commander Is, Korea, Japan, NE China and New Guinea, mainly to coastal N Australia. Females start S migration in late Jun, but most adults arrive in Wadden Sea in Jul, followed by juveniles in Aug. Arrives in S Africa and Australia Aug-Sept, and begins N migration as early as Mar; arrival in W Australia may perhaps be followed by movement towards E & S; numbers in SE Australia continue to increase until Mar.

Status and Conservation. Not globally threatened. In Europe and W Africa probably several 100,000's of birds, although only 25,000 actually counted in coastal Europe and W Africa; in E Africa and SW Asia probably c. 100,000 birds; in SC Asia probably c. 25,000 birds; in E & SE Asia and Australasia c. 20,000 birds each. Scotland holds 400-900 breeding pairs; Fenno-Scandia 50,000-90,000 pairs (1993); locally abundant on Russian breeding grounds. Overall population considered secure due to extensive breeding range.

45. Nordmann's Greenshank

Tringa guttifer

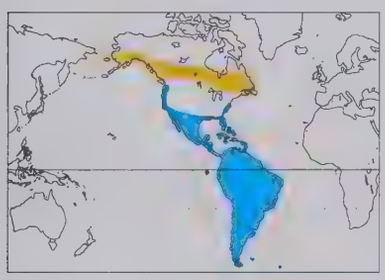
French: Chevalier tacheté **German**: Tüpfelgrünschenkel **Spanish**: Archibebe Moteado
Other common names: Spotted Greenshank

Taxonomy. *Totanus guttifer* Nordmann, 1835, Okhotsk.
Formerly separated in monospecific genus *Pseudototanus*. Monotypic.

Distribution. Sakhalin and W Sea of Okhotsk; possibly also N Sea of Okhotsk and Kamchatka. Winters in NE India, Bangladesh, Myanmar and Hainan S to Malay Peninsula; may also be regular in South Korea, perhaps E Sumatra and elsewhere.

Descriptive notes. 29-32 cm; 136-158 g. Heavily built *Tringa*; dark brown upperparts with whitish spots and fringes; head and neck densely spotted and streaked dark brown; breast and flanks spotted blackish. Very similar to *T. nebularia*, but legs short and yellowish; bill almost straight and two-toned. Sexes alike. Non-breeding adult has dull grey upperparts with whitish fringes, contrasting dark brown lesser wing-coverts; head and neck much paler; breast and flanks lack spots. Juvenile as non-breeding, but crown and upperparts browner, with buff spots and streaks; wing-coverts have pale buff fringes; breast with brown wash.

Habitat. On breeding grounds, occupies coastal lowland swamps and sparse larch forests around marshy pools, close to shallow bays. After breeding, mostly at large, coastal mudflats or sandflats, deltas, shallow lagoons, occasionally with mangroves or beds of seagrass; also swamps, willow beds, mossy meadows near streams, salt-pans and rice paddies.



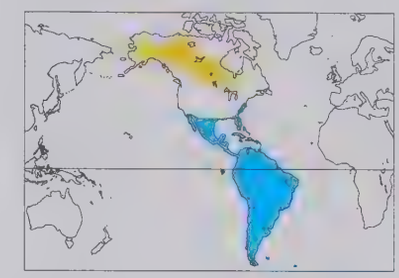
Food and Feeding. On breeding grounds takes small fish, especially sticklebacks; also polychaetes, small crustaceans and insects, especially aquatic beetles. Outside breeding areas, shows preference for crabs, but also other aquatic invertebrates, molluscs, insect larvae and small fish. Large crabs shaken until legs come off, and body and legs swallowed separately; small crabs swallowed whole. Takes multiple and single pecks with slightly opened bill, moving head from side to side; also runs after prey with bill held low, probably chasing fish. Feeds during low tide on tidal flats, prefering the tide-line. Roosts at high tide, preferably in shallow water.
Breeding. Laying in Jun. Monogamous; nests in scattered single pairs or in colonies of 3-10 pairs. Nest placed in low larch tree at height of 2·3-4·5 m; formed of larch twigs, lichen and moss; unlike other *Tringa*, nest is built by the birds themselves; both female and male birds collect material from the ground and pull twigs from trees. 4 eggs; single brood; both sexes incubate. Reported predators include Carrion Crow (*Corvus corone*) and foxes.
Movements. Not well known; has been recorded widely as a migrant or winter vistor in Ussuriland, Japan, North and South Korea, China, Taiwan, Hong Kong, Vietnam, Thailand, Sumatra, Philippines and S India. Adults leave Sakhalin breeding grounds late Jul to mid-Aug, juveniles from late Aug to mid-Sept; species migrates through Japan and Korea in Sept. Returns to breeding grounds from mid-May.
Status and Conservation. ENDANGERED. CITES I. Total population comprises perhaps c. 1000 birds (1989), but both breeding and winter distributions poorly known. Breeding population on Sakhalin (Chaivo Bay and Dogy Bay) estimated at 30-40 pairs (1985-1988); urbanization, increased crow predation, human disturbance and increased hunting pressure are major threats for this population. At least 36 pairs counted in bays of W Sea of Okhotsk in 1990/91. Main wintering grounds seem to be located in Bangladesh (Nijhum Dweep and Maulavir Char), Thailand (Krabi Bay) and perhaps also in South Korea, where over 50 birds may occur; c. 300 birds reported from Bangladesh in winter 1988/89; up to 27 birds staging in Sheyang Saltworks, Jiangsu, CE China, in Aug-Sept 1991. Winter distribution still very poorly known, and may regularly include E Sumatra, where flock of 21 birds seen in 1988; total of 25 birds in Karnataka, S India, in 1992. In general, rarely seen and not well known; apparently in process of disappearing from its highly restricted range.
Bibliography. Ali & Ripley (1980), Austin & Kuroda (1953), Bijlsma & de Roder (1986), Borodin *et al.* (1984), Brazil (1991), Collar & Andrew (1988), Collar *et al.* (1994), Dickinson *et al.* (1991), Étchécopar & Hüe (1978), Howes (1988), Howes & Lambert (1987), Howes & Parish (1989), Kennerley & Bakewell (1987, 1991), King (1978/79), Knystautas (1993), Kuroda (1936b), Lekagul & Round (1991), Lim Kimseng (1994), MacKinnon & Phillipps (1993), van Marle & Voous (1988), Medway & Wells (1976), Nechaev (1978, 1982, 1989), Neufeldt & Vietinghoff-Scheel (1983), Perennou *et al.* (1994), Ripley (1982), Scott (1989), de Silva (1992), Silvius (1986), Smythies (1986), Swennen & Park (1991), Verheugt *et al.* (1993), Wang Hui (1992).

46. Greater Yellowlegs

Tringa melanoleuca

French: Grand Chevalier **German**: Großer Gelbschenkel **Spanish**: Archibebe Patigualdo Grande

Taxonomy. *Scolopax melanoleuca* Gmelin, 1789, Chateaux Bay, Labrador.
Monotypic.
Distribution. S Alaska and British Columbia E to Labrador, Newfoundland I, Anticosti I and NE Nova Scotia. Winters from British Columbia and the Carolinas through Mexico, Central America and West Indies to South America, S to Tierra del Fuego.



Descriptive notes. 29-33 cm; 111-235 g; wingspan 70-74 cm. Large *Tringa* with long legs and longish bill; head and neck heavily streaked dark brown; breast, flanks and upper belly with blackish spots; white rump, dark back. Larger and heavier than *T. flavipes*, with longer, stout, straight or slightly uptilted bill; more heavily marked below; dark secondaries fringed whitish. Sexes alike. Non-breeding adult has grey-brown upperparts with white spots and fringes, and grey streaking on breast and flanks. Juvenile as non-breeding, but has buff spots and brown on breast usually forming a breast band.
Habitat. Muskeg forest with low and sparse undergrowth, scattered trees, marshy ponds and open areas; also on hills near swamps, subarctic tundra and subalpine scrub; generally in fairly flat terrain. After breeding, occurs at freshwater or brackish wetlands, especially ponds with emergent vegetation, flooded rice fields and rain pools; also mangrove stands, muddy coasts, salt-marshes, intertidal flats and man-made reservoirs. On wintering grounds, most abundant on intertidal flats and lagoons. On occasion, found in dry areas such as pastures and dunes, and small numbers at streams and pools at medium to high altitudes, up to 4600 m.
Food and Feeding. Diet includes small crustaceans, fish, worms, aquatic insects and their larvae, also terrestrial insects, such as small grasshoppers, ants and flies. Feeding techniques include skimming water surface for food, picking, and dashing through shallow water after small fish; often wades and sometimes swims. Outside breeding season, feeds singly or in small flocks; often defends feeding territory. Diurnal and nocturnal forager, at night scything (side-sweeping with bill through water) to catching small fish.
Breeding. Poorly known. Season starts May. Nest is usually next to branch or log, on dry hard substrate on ridge, close to water. 4 eggs (variation unknown); incubation 23 days; chick-care, and presumably also incubation, by both parents.
Movements. Migration through interior North America and along coasts, on both passages. Few birds overfly W Atlantic between Canadian Maritime Provinces and Lesser Antilles, but most birds on E coast pass along Atlantic seaboard, or from Florida across Great Antilles to South America. Spring return flight presumably non-stop from the Guianas to USA, some via Lesser Antilles, then majority across C North America and up Atlantic coast. Largest winter numbers recorded in Surinam and, to lesser extent, in Guyana and French Guiana. Possibly faithful to wintering sites. Many non-breeders, presumably immatures, remain S all year.
Status and Conservation. Not globally threatened. Total population reckoned at c. 20,000 birds in 1994, but very few precise data available; population seems to be stable.

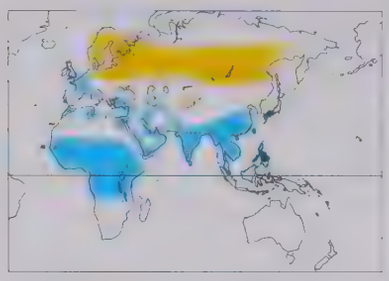
47. Lesser Yellowlegs

Tringa flavipes

French: Petit Chevalier **German**: Kleiner Gelbschenkel **Spanish**: Archibebe Patigualdo Chico
Other common names: Yellowshank

Taxonomy. *Scolopax flavipes* Gmelin, 1789, New York.
Monotypic.
Distribution. Alaska to SC Canada, E to James Bay. Winters from S USA through Mexico, Central America and West Indies to South America, S to Tierra del Fuego.



Descriptive notes. 23-25 cm; 48-114 g; wingspan 59-64 cm. Slim, medium-sized *Tringa* with relatively short, straight, thin, pointed bill; blackish upperparts with white spots and grey-brown wing-coverts; head, neck and breast heavy blackish streaked. Very similar to *T. melanoleuca*, but smaller with shorter bill; sparser dark markings on underparts; dark secondaries unmarked. Female averages slightly longer-winged. Non-breeding adult paler grey with pale spots on inner greater coverts and tertials. Juvenile as non-breeding, but upperparts brown with buff spots; breast washed brownish grey with little streaking.
Habitat. Swampy muskeg habitat, clearings within tall, open woodland with sparse undergrowth, sometimes close to marshy or grassy ponds, grassy meadows and bogs; usually drier and more sheltered than breeding habitat of *T. melanoleuca*. Outside breeding season occurs in variety of inland and coastal wetlands, usually with emergent vegetation, including inundated farmland and grassland, mangrove stands, sewage beds, shallow prairie sloughs, man-made reservoirs, marshes, lagoons, mudflats and salt-marshes. On wintering grounds, most abundant on intertidal flats and in lagoons.
Food and Feeding. On breeding grounds, takes cranefly larvae, beetles, Diptera eggs and larvae, snails and spiders. Non-breeding diet includes variety of terrestrial and aquatic insects and their larvae (Diptera, beetles), worms, crustaceans, gastropods and small fish. Often wades in shallow, belly-deep water, and also walks on floating water weeds; pecks from water or mud surface, rarely probes, skims, or dashes after prey like *T. melanoleuca*. In wintering range, often defends feeding territory. Diurnal and nocturnal forager, using sweeping technique at night.
Breeding. Breeds May-Aug. Often up to 3-4 pairs/km². Nest often on ridge, at base of tree stump under bush, usually situated close to water. 4 eggs (3-5); incubation 22-23 days; both sexes incubate and care for chicks; fledging probably 23-25 days. Oldest ringed bird 5 years, 11 months.
Movements. Migratory. Moves through E Canada, E of breeding range, and (mid-Jul to mid-Sept) interior USA between Rocky and Allegheny Mts; also down Atlantic coast, S of Gulf of St Lawrence. Some may fly direct, or via Bermuda, to Lesser Antilles and N South America; others move S down Atlantic seaboard; commonly stages at W Amazonian lakes and rivers. Uncommon transient in Central America. Few birds winter on W coast USA, more in S USA, majority in West Indies and N South America, where most abundant in Surinam, and high numbers in Guyana and French Guiana. Fair numbers remain S in N summer. In spring, return migration across W Caribbean and Gulf of Mexico, and North America; in USA, most birds move through interior, fewer up Atlantic coast.
Status and Conservation. Not globally threatened. Total population comprises at least 100,000 birds; 91,000 yellowlegs counted during aerial survey of South American coasts, with large proportion probably of present species. Few precise data available, but numbers are apparently declining.

48. Green Sandpiper

Tringa ochropus

French: Chevalier cul-blanc **German**: Waldwasserläufer **Spanish**: Andarríos Grande

Taxonomy. *Tringa Ocrophus* [sic] Linnaeus, 1758, Sweden.
Monotypic.
Distribution. Scandinavia and E Europe through C Asia to E Siberia; isolated population in Kyrgyzstan and NW Xinjiang. Winters in Mediterannean and tropical Africa, and from Turkey through Middle East and Indian Subcontinent to S Japan, E China, Philippines and N Borneo; small wintering populations in W & WC Europe, and in sheltered valleys of Tien Shan zone.
Descriptive notes. 21-24 cm; 53-119 g; wingspan 57-61 cm. Medium-sized, dark sandpiper; foreneck, breast and upper flanks streaked grey-brown, underparts white; rump white, tail white with thick black bars. Very similar to *T. solitaria*, but larger and darker; head greyer, spots on upperparts whiter and more distinct, white rump; bill generally heavier and longer, wings broader. Resembles *Actitus hypoleucos* and *T. glareola*, but larger; generally darker above, with dark underwing. Female averages larger. Non-breeding adult has less spotted upperparts and face, foreneck and centre of breast whiter, and no streaking on flanks. Juvenile like breeding adult, with buff spots on upperparts, paler breast and no streaks on flanks; white eye-ring very distinct.

Habitat. Damp wooded areas, in old, swampy woodland and montane forest; preferably pine woods, but also in spruce or alder, in vicinity of rivers, streams, swamps or lakes. Outside breeding season less attracted to vicinity of trees, in variety of inland fresh waters, such as marshes, riverbanks, sewage farms, small ponds and narrow ditches, often with protective vegetation. Scarce in intertidal areas, and then only in channels of salt-marshes.

Food and Feeding. Feeds on aquatic and terrestrial insects, mainly adults and larvae of beetles, Diptera and Trichoptera, but also dragonfly larvae, ants, water-bugs and moth larvae; annelids, small crustaceans, spiders, fish and plant fragments. Mainly pecks food from shallow water and from surface of ground and plants; rarely probes; sometimes uses trampling to stir up food. Sometimes wades or swims, and even dives, while feeding. Normally feeds singly, sometimes in small, scattered groups of up to 30 birds.

Breeding. Laying late Apr to Jun. Monogamous. Densities normally 1-8 birds/km², but 11-19 birds/km² recorded and under 0·5 birds/km² in extreme N taiga. Usually uses old tree nests of other bird species, especially thrushes (*Turdus*) or Common Woodpigeon (*Columba palumbus*), normally with little modification; sometimes on natural platform; up to 20 m high; occasionally nests on ground. 4 eggs, sometimes 3; incubation 20-23 days, by both sexes, but mainly female; chick pale drab grey marked fuscous black, with dark line across and along crown and long tail; both sexes tend chicks at first, but female may leave before fledging; fledging c. 28 days. Oldest ringed bird 9 years, 8 months.

Movements. Moves overland on broad front, generally in low concentrations on passage and at stop-over sites; many passage records at Saharan oases. N European population probably moves S & SW to wintering grounds. In mild winters some birds stay in S Scandinavia. Southward movements from Jun to early Nov; species present in N and equatorial Africa late Aug to early Apr and in S Africa Oct-Mar; return passage late Feb to mid-May. At least locally very faithful to wintering areas. Few birds remain in wintering areas during breeding season.

Status and Conservation. Not globally threatened. Possibly more than 1,000,000 breeding birds in Europe; numbers wintering in E Africa and SW Asia unknown; in S Asia and E & SE Asia probably 100,000 to several 100,000's of birds. Breeding range in Poland has probably decreased, although species colonized Denmark in 1950's and recent northward expansion in Finland. Fenno-Scandian breeding population estimated at 123,000 pairs in 1986. Breeding population of Ukraine has declined due to habitat changes.

49. **Solitary Sandpiper**

Tringa solitaria

French: Chevalier solitaire **German**: Einsamer Wasserläufer **Spanish**: Andarríos Solitario

Taxonomy. *Tringa solitaria* Wilson, 1813, Pocono Mountains, Pennsylvania.
Formerly considered conspecific with *T. ochropus*. Two subspecies recognized.

Subspecies and Distribution.
T. s. cinnamomea (Brewster, 1890) - C & S Alaska through W Northwest Territories and N British Columbia to NE Manitoba; winters from N South America S to C Argentina.
T. s. solitaria Wilson, 1813 - E British Columbia through SC Canada to Quebec and Labrador; winters from Central America and West Indies to South America S to Argentina, and occasionally in S USA.

Descriptive notes. 18-21 cm; 38-69 g; wingspan 55-59 cm. Adult has dark upperparts with pale spots; head and breast finely streaked dark brown; the only *Tringa* with combination of dark rump and underwing. Closely resembles *T. ochropus*, but smaller and appears more slender; bill generally shorter and finer; at rest, primaries clearly longer than tail; rump dark. Female averages slightly larger. Non-breeding adult has head, neck and upperparts greyer; upperparts less spotted; clear white eye-ring. Juvenile has pale spots on upperparts; breast washed dark, often forming lateral patches; clear white eye-ring. Race *cinnamomea* averages slightly larger, with slightly paler, warmer brown spotting on upperparts; juvenile has upperparts dotted buff, rather than whitish.

Habitat. Wet boreal muskeg forest, usually in rather open terrain with scattered trees. Outside breeding season, most abundant in savannas, in enclosed inland fresh waters, often in isolated ditches and temporary tiny stagnant pools; also man-made reservoirs, wet meadows, quiet streams and swamps in woodlands; often found near human settlements; rare at coast.

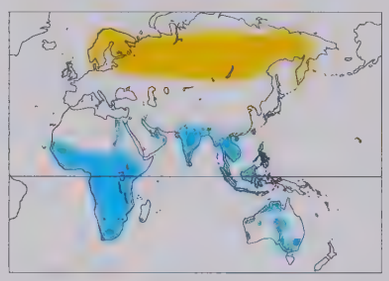
Food and Feeding. Diet includes aquatic insects and their larvae, small crustaceans, spiders, terrestrial insects (e.g. grasshoppers) and even small frogs. Often wades in shallow water, vibrating leading foot to disturb and catch aquatic invertebrates. On wintering grounds defends feeding territory.

Breeding. Often uses old tree nests of passerines, such as thrushes (*Turdus*) up to 12 m high, usually in coniferous trees; also on ground in areas above tree-line. 4 eggs; probably both sexes incubate; incubation and fledging periods unknown.

Movements. Migratory, overland on broad fronts, extending right across North America, but main passage E of Rocky Mts. Race *cinnamomea* migrates mainly through region from mountains of W USA E to Montana and Colorado, on occasion E to Mississippi Valley; race *solitaria* moves through region from Montana and Utah E to Atlantic states of USA. In autumn, some birds apparently pass over W Atlantic, directly from Canadian Maritime Provinces to N South America. Races mix in winter quarters; species is common migrant and short-term resident along lakes and rivers in W Amazon area. Seldom migrates in flocks. Some birds oversummer in Neotropics.

Status and Conservation. Not globally threatened. Population of *cinnamomea* numbers less than 10,000 birds; no figures available for nominate race. Thought to have suffered little from hunting, probably due to solitary habits; cutting of boreal forests may be threat in some areas. Commonest shorebird in inland Brazil, occurring on almost all water bodies.

Bibliography. Amos (1991), Armstrong (1983), Aspinwall *et al.* (1995), Belton (1984), Bent (1927-1929), Biaggi (1983), Blake (1977), Conover, H.B. (1944), Contreras *et al.* (1990), Cramp & Simmons (1983), Fjeldså & Krabbe (1990), Haverschmidt (1968), Haverschmidt & Mees (1995), Hayes (1995), Hayes & Fox (1991), Hilty & Brown (1986), Howell & Webb (1995a), Lethaby (1995), Matthiessen (1994), Meyer de Schauensee & Phelps (1978), Monroe (1968), Moskoff (1995), Navas & Bo (1993), Oring (1968, 1973), de la Peña (1992), Ridgely & Gwynne (1989), Root (1988), Scott & Carbonell (1986), Shelley (1933), Sick (1985c, 1993), Slud (1964), Snyder (1966), Stiles & Skutch (1989), Street (1923), Tallman & Tallman (1986), Tostain *et al.* (1992), Webber (1968), Wetmore (1965).



50. **Wood Sandpiper**

Tringa glareola

French: Chevalier sylvain **German**: Bruchwasserläufer **Spanish**: Andarríos Bastardo

Taxonomy. *Tringa Glareola* Linnaeus, 1758, Sweden. Monotypic.

Distribution. N Europe through C Siberia to Anadyrland, Kamchatka and Commander Is; occasionally Aleutian Is. Winters mainly in tropical and subtropical Africa, across S Asia to S China, Philippines, Indonesia and Australia.

Descriptive notes. 19-23 cm; 34-98 g; wingspan 34-37 cm. Small, graceful sandpiper; head, neck and breast finely streaked grey-brown; supercilium and throat white; upperparts black-brown with white spots, underparts white. Similar to *T. ochropus*, but paler, less bulky and longer-legged; underwing much paler. Has longer neck and legs than more uniform *Actitis hypoleucos*. Female averages slightly larger. Non-breeding adult has browner and less spotted upperparts; breast washed grey and less streaked; supercilium more distinct. Juvenile like non-breeding adult, but warmer brown above with buff spots; breast washed grey-brown, finely streaked brown.

Habitat. Peatlands, open swampy areas in boreal forest, especially scrubland between tundra and coniferous forest, wet heathlands with or without scattered conifers, and marshlands with deciduous bushes. Outside breeding season, generally not associated with woodlands; found in more open areas than those favoured by *T. ochropus*, including open margins of inland fresh waters, muddy marshes, grassy stream banks, sewage farms, wet paddyfields, tiny temporary pools and streams; only rarely in coastal habitats, such as channels of salt-marshes and mangrove swamps.

Food and Feeding. On breeding grounds chiefly takes small, especially aquatic, insects, up to 2 cm long, e.g. beetles, Hemiptera, larvae of Diptera. Elsewhere, aquatic and terrestrial insects and their larvae, worms, spiders, crustaceans, molluscs, small fish (up to 2 cm) and even frogs; sometimes plant matter (seeds). Gleans, pecks, probes or sweeps bill through water; also able to catch flying insects from air. Feeds in shallow water or on mud; occasionally swims. Often feeds singly, but also in pairs or scattered groups. May defend feeding territories.

Breeding. Lays May to mid-Jul. Monogamous. Solitary; normally 1-10 pairs/km², but up to 50 birds/km² in forest tundra. Nest is scrape lined with moss, stems and leaves, on ground among dense cover; also frequently in trees, in old nests of other species. 4 eggs, sometimes 3, with laying interval 1-2 days; single brood; incubation 22-23 days, by both sexes; chick pale buff to pale cream marked fuscous black and mottled greyish brown to cinnamon on upper back, with wide dark cap and white belly; from 7-10 days after hatching, care of young usually only by male; fledging 28-30 days. Annual adult mortality 46%, 1st-year mortality 83-88%. Oldest ringed bird 9 years, 2 months. Age of first breeding 1 year.

Movements. Migratory. Many birds move to sub-Saharan Africa and India, few to Australia. On migration, scarce in W Europe, especially during N migration in May, commoner Aug to mid-Sept. Migration across Europe and Middle East overland on broad front, predominantly S-SSW; scarce in Britain and Ireland; many stop over in N Mediterranean, especially France (Camargue) and Italy, whereafter they overfly Sahara, chiefly in SW direction to W Africa; common on passage through C Chad. Spring migration probably more easterly, with briefer pauses. Birds wintering in E & S Africa originate from former USSR; birds wintering in India from breeding zone in Siberia between Tyumen and R Kolyma. Many E Siberian breeders pass through S Ussuriland, Japan, Korea, Taiwan, E China and Hong Kong to SE Asian wintering grounds, with only small fraction continuing to Australia, where mainly in NW; also movements through N China and Tibet. In spring, large numbers pass W Aleutians.

Status and Conservation. Not globally threatened. European breeding population estimated at up to 1,400,000 pairs, representing probably around one fifth to quarter of total world population (1994). Possibly over 1,000,000 birds wintering in SW Asia and E & C Africa, where 250,000-500,000 in Sudan, 30,000 on W shore of L Edward, Zaire; 100,000's in SC Asia and in E & SE Asia. Australian non-breeding population estimated at 6000 birds; has benefited from irrigation schemes and construction of open sewage ponds. Breeding population has declined in some European countries, especially Finland, where currently 200,000-300,000 pairs; decline mainly due to exploitation, destruction or drainage of peatlands for forestry and agriculture; decline noted in S Sweden, Germany and Poland, possibly due to climatic changes. Populations in Sweden, Norway and European Russia currently fairly stable; status of population E of Urals poorly known.

Bibliography. Akriotis (1991), Ali & Ripley (1980), Amos & Wingate (1983), Armstrong (1983), Beehler *et al.* (1986), Benson & Benson (1975), Blakers *et al.* (1984), Blitzblau (1990), Boyd (1962), Brazil (1991), Chattopadhyay & Chattopadhyay (1988), Chattopadhyay *et al.* (1994), Chojnacki & Stawarczyk (1988), Coates (1985), Cramp & Simmons (1983), Deignan (1945), Dickinson *et al.* (1991), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Étchécopar & Hüe (1964, 1978), Evans (1994), Ferguson-Lees (1971), Fjeldså (1977), Galbraith & Thompson (1981, 1982), Gavrilov (1988), Ginn *et al.* (1989), Glutz von Blotzheim *et al.* (1977), Goodman *et al.* (1989), Gore (1990), Grimes (1987), Hoath (1994), Hockey & Douie (1995), Hoffmann (1957), Hoogerwerf (1964), Hüe & Étchécopar (1970), Kirchner (1978), Knystautas (1993), Kolmodin & Risberg (1994), Lambert (1984), Lane & Davies (1987), Lekagul & Round (1991), Leuzinger & Jenni (1993), MacKinnon & Phillipps (1993), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Madoc (1976), Marchant & Higgins (1996), van Marle & Voous (1988), Medway & Wells (1976), Neill (1987), Ostergaard (1986), Pakenham (1979), Patrikeev (1995), Paz (1987), Pearson (1974), Perennou *et al.* (1994), Phillips (1978), Piersma (1986b), Pinto (1983), Pulliainen & Saari (1991), Raju (1978), Rands *et al.* (1987), Ripley (1982), Roberts, T.J. Genus *XENUS* Kaup, 1829

51. **Terek Sandpiper**

Xenus cinereus

French: Chevalier bargette **German**: Terekwasserläufer **Spanish**: Andarríos del Terek

Taxonomy. *Scolopax cinerea* Güldenstädt, 1774, Terek River, Caspian Sea.
Often placed in *Tringa*; *Tringa terek* is synonym. In past, occasionally split into two subspecies, with recognition of *australis*; based on differences noted at winter quarters, but variation poorly understood. Monotypic.
Distribution. S Finland; NW Russia and Ukraine E through C Siberia to Anadyrland, mainly in boreal taiga zone, extending N into subarctic tundra and S to steppe fringes. Winters from SW, S & E Africa through Middle East, S Asia and Indonesia to N & W Australia.

Descriptive notes. 22-25 cm; 50-126 g; wingspan 57-59 cm. Distinctive, rather small sandpiper with long upcurved bill and short orange to greenish yellow legs; grey-brown upperparts with almost black centres to feathers, particularly distinct on scapulars; streaked crown, hindneck, cheeks and sides of breast; broad white trailing edge to wings. Some birds have shorter bills, not very obviously upcurved. Female averages slightly larger. Non-breeding adult plainer; brownish grey above with pale fringes; paler head. Juvenile as breeding adult, but upperparts darker and browner with narrow buff fringes; black scapular lines less prominent.
Habitat. Breeds in lowland valleys, especially on floodplains with alternation of tall grasses and scrub willows; most typical on northern taiga and forest tundra. Outside breeding season, on tropical coasts, especially open intertidal mudflats and estuaries, also coral reefs, sandy beaches, sandbars or mudflats at mouths of rivers, and coastal swamps and salt-pans; sometimes up to 10 km inland, around brackish pools and riverbeds. Often roosts communally on branches of mangroves. During migration, occasionally inland on freshwater wetlands.
Food and Feeding. On breeding grounds, diet consists mainly of adult and larval midges, as well as seeds. Elsewhere, variety of insects, small molluscs, crustaceans including crabs, spiders and annelid worms. Rapid feeding action, with abrupt changes of direction; often teeters; pecks at sand or water surface; chases mobile prey on surface, also uses avocet-like sideways sweeping action; frequently probes; often washes prey in water's edge. Usually feeds during low tide, but may also feed during high tide around embedded seaweed high on beach. Scattered when feeding, in groups of 5-25 birds.
Breeding. Breeds May-Jul. Semi-colonial. Nest is shallow depression sparsely lined with grass and debris, in open or short vegetation, close to water. 4 eggs (2-5), with laying interval 1-2 days; single brood; incubation 23-24 days, starting with 3rd egg; role of sexes unclear; chick greyish brown or rusty grey above finely stippled and mottled dusky, with black mid-line across crown and back and white chin, throat and underparts; fledging 15 days. Oldest ringed bird at least 14 years, 11 months.
Movements. Migratory. Moves S from late Jul to Oct, N in Apr-May. In E Asia migrates along coasts of Ussuriland, Japan, Korea, NE China, Taiwan, Hong Kong, Philippines and W Micronesia. Birds wintering in N Australia and E Indonesia probably breed farther N than those wintering in SE Asia and W Indonesia. On E coast of Australia two southbound waves of migration occur, one in Sept, the other in Nov. Return passage probably non-stop from NW Australia to Philippines or Taiwan. In W Asia birds pass S through Caspian region and Middle East to Africa; Finnish birds fly across E Europe, probably crossing Mediterranean and Sahara non-stop. Strong site tenacity. Many non-breeders spend N summer on wintering grounds.
Status and Conservation. Not globally threatened. In Africa and SW Asia minimum 44,000 wintering birds (1991); in SC Asia probably c. 25,000 birds; in E & SE Asia in order of 100,000 birds, with highest concentrations on W coast of Peninsular Malaysia and in Banyuasin Delta of SE Sumatra; Australian non-breeding population estimated at 18,000, with most important sites at Eighty Mile Beach with 6100 birds, SE Gulf of Carpenteria with 2800, and Great Sandy Strait with 2494. Finnish breeding population comprises only c. 20 pairs; on Russian nesting grounds, common to abundant. Common to abundant in Pakistan. Increasingly sighted in W Europe, W Africa and New Zealand. In tropical Australia no immediate threats to habitat.

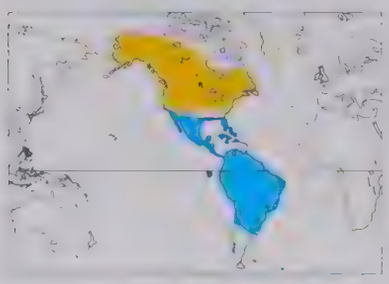
Genus *ACTITIS* Illiger, 1811

52. **Common Sandpiper**

Actitis hypoleucos

French: Chevalier guignette **German**: Flußuferläufer **Spanish**: Andarríos Chico
Other common names: Eurasian Sandpiper

Taxonomy. *Tringa Hypoleucos* Linnaeus, 1758, Sweden.
Sometimes placed in genus *Tringa*. Occasionally considered conspecific with *A. macularia*. Monotypic.
Distribution. Europe E across C Asia to Kamchatka, Sakhalin and Japan. Winters from W Europe and Africa through Middle East and S Asia to Indonesia and Australia; irregularly on islands of W Pacific.



Descriptive notes. 19-21 cm; 33-84 g; wingspan 38-41 cm. Small, short-legged sandpiper, with pale eye-ring; greenish brown upperparts, white underparts with dark lateral breast patches; dark brown streaks and marks on upperparts; in flight, shows dark rump and white wingbar. Resembles non-breeding *A. macularia*, but slightly larger, with more obvious wingbar in flight; at rest, tail much longer than wings; legs normally greener or greyer, less yellow. Female averages slightly larger than male. Non-breeding adult has faintly barred olive brown upperparts; less streaking on head. Juvenile resembles non-breeding adult, but feathers of upperparts have buff tips and bars; more heavily buff and sepia barred wing-coverts.
Habitat. Prefers margins of water bodies, mostly riverbanks, preferably with pebbles, sand or rocks and patches of dry meadows; also small ponds, lake shores, sheltered sea coasts. Outside breeding season, in wide variety of habitats, such as coastal shores, estuaries, salt-marshes, inland wetlands, riverbanks, pools and tidal creeks in mangroves; sometimes on grassland, along roadsides or in urbanized areas; large coastal mudflats are not favoured.
Food and Feeding. Adult and larval insects (e.g. beetles, Diptera), spiders, molluscs, crustaceans and annelids, sometimes frogs, tadpoles or small fish; occasionally plant material. During breeding season, adults and young chicks frequently feed on grassland. Prey located visually; feeds mainly by pecking and stabbing, free stalking and dashing, rarely by probing; runs quickly, frequently pausing with tail moving up and down and head bobbing; insects often caught from surface, or pulled out from rocks or mud; sometimes washes prey before eating it. Mostly forages singly, defending feeding territory, but sometimes in small parties. Mainly diurnal forager; forming night-time roosts occasionally of over 100 birds.
Breeding. Laying May-Jun. Monogamous. In scattered single pairs, in optimal habitat 60-70 m apart. High degree of site fidelity and low degree of natal philopatry. Nest in sheltered depression, sometimes among shrubs and trees. 4 eggs (3-5), with laying interval 1-2 days; incubation 21-22 days, by both sexes; chick greyish brown, above faintly stippled dusky and with fuscous black mid-line on crown and back, and narrow eyeline; brood tended by both sexes, but one parent, often female, usually leaves before young fledge; fledging 22-28 days. Around 85% of eggs hatch, but lifetime reproduction may be as low as 1·5-3·5 fledglings/female; 1st-year survival 21%, annual adult survival 75-79% but much lower during adverse spring weather. Age of first breeding 1 year or older. Oldest ringed bird 12 years.
Movements. Migratory. Many move to S wintering areas, though some stay in N maritime climatic zone (British Is, Mediterranean, Japan). Moves overland on broad fronts, even across deserts and mountains, usually singly or in small flocks. European population mainly winters in W Africa, and basically moves SSW-SW from mid-Jul to Aug, juveniles following one month later; moves N from late Mar to Apr. Many Norwegian birds cross Britain, Swedish birds cross W Germany, Finnish cross E Germany. Wintering populations in E, C & S Africa presumably originate from CIS. E Asian birds move through Korea, Japan (especially during S migration), Hong Kong (both migrations), Peninsular Malaysia, Wallacea and New Guinea. Many immatures remain in N wintering quarters all year. Migrates at night.
Status and Conservation. Not globally threatened. European breeding population comprises 885,000 pairs (1986), of which 96% found in Fenno-Scandia, the rest mainly in Britain and Ireland (22,000-25,000 pairs); this should yield more than 2,000,000 African wintering birds; 100,000's winter in SC Asia and similarly in E & SE Asia and Australasia (1991), with mangroves in W Peninsular Malaysia holding large numbers; numbers wintering in E Africa and SW Asia unknown. Numbers declined in C Europe, Britain and Ireland, particularly in 1930's and 1950's; European population currently believed to be declining. Numbers greatly underestimated in wintering areas, possibly due to habit of frequenting inaccessible mangroves.

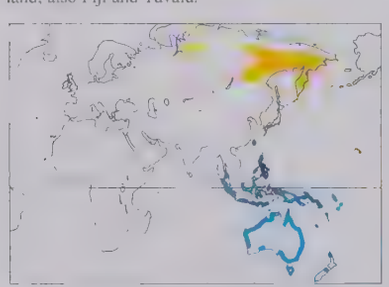
53. **Spotted Sandpiper**

Actitis macularia

French: Chevalier grivelé **German**: Drosseluferläufer **Spanish**: Andarríos Maculado

Taxonomy. *Tringa macularia* Linnaeus, 1766, Pennsylvania.
Sometimes placed in genus *Tringa*. Occasionally considered conspecific with *A. hypoleucos*. Some authors have recognized two subspecies, with *rava* (W North America) and nominate (E North America), but generally considered invalid. Monotypic.
Distribution. Alaska across Canada to Newfoundland, S to SC California, N Texas and North Carolina. Winters from S USA through Central America and West Indies to South America S to S Brazil; in most years, also Galapagos.
Descriptive notes. 18-20 cm; 19-64 g; wingspan 37-40 cm. Smallish size and neatly spotted underparts distinctive; greenish brown upperparts with dark barring; bill pink to orange with black tip, legs often pinkish. Female averages slightly larger; usually has larger, blacker spots on underparts. Non-breeding adult has plainer upperparts and lack spots on underparts; bill mostly dark brown but paler at base; similar to *A. hypoleucos*, but smaller, with greyer upperparts and normally yellowish legs; white wingbar less obvious. Juvenile as non-breeding adult, but upperparts greyish with narrow buff fringes; wing-coverts with distinct buff and brown fringes.

Habitat. Nesting habitat similar to that of *A. hypoleucos*, in wide variety of habitats, preferably in open terrain with freshwater pools, lakes, streams, rivers, marshes and impoundments, from sea-level up to over 2000 m. Outside breeding season occupies similar habitats, and also found along coast, e.g. sandy beaches, muddy edges, lagoons and mangroves.
Food and Feeding. Mainly aquatic and terrestrial insects, e.g. adult, larval and pupal Diptera, mayflies, Orthoptera, beetles and caterpillars; also spiders, annelids, small crustaceans, molluscs and even small fish (e.g. trout fry). Typically feeds at water margin rather than by wading, with rapid downward pecking movements; also by slow approach followed by quick forward thrust of head. Sometimes washes prey before swallowing. Mainly feeds solitarily; often defends feeding territory on migration and in winter.
Breeding. Laying mid-May to Jun. Sex role reversed, with female larger and socially dominant over male. Yearling sequentially resource-defence polyandrous; 2-year-old primarily simultaneously resource-defence and mate-access polyandrous; older females primarily simultaneously resource-defence polyandrous and c. 26% monogamous; female mates with up to 3 (rarely 4) males per season. Females can store sperm for long periods, cuckolding later mates. High degree of site fidelity in successful breeders and of natal philopatry, with siblings from same nest returning more frequently. Solitary, sometimes nests clustered, especially on small islands. Nest-site on ground, usually in sparse vegetation; nest is shallow depression lined with plant material. 4 eggs (3-5), with laying interval of 1 day, occasionally 2; several clutches laid over short periods; incubation 19-24 days; chick pale drab grey, finely mottled and stippled dusky with black eyeline and mid-line on crown and back, white underparts; fledging 18-21 days. Male incubates and broods young; female never broods, but helps males in rearing chicks, primarily playing defence role; female helps last mate of season more than others, but may also help earlier mates until she goes on to another mate. Of 119 eggs laid, 62% of eggs hatched, with mean 3·36 young per nest. Mice, mustelids and birds are nest predators.
Movements. Migrates on broad fronts all across North America, after breeding presumably moving SE down Atlantic states, though some may use direct transoceanic passage from New England to E South America, including W Amazonian rivers. Females precede males and juveniles southwards, and also arrive first at breeding territories. In Venezuela, unlike many other wader species, more numerous in N spring than in autumn. N migration from South America more westerly, suggesting more use of interior route through USA and absence of transoceanic movement then. Usually migrates singly. Not infrequent vagrant to Europe, and has nested in Scotland.
Status and Conservation. Not globally threatened. No population estimate available; most widely distributed breeding scolopacid in North America, with more than 50,000 birds in Canada, at least. Roosts of up to 1000 birds occur at mouth of R Amazon. Population apparently stable. Overall abundance was not severely affected by hunting around turn of present century, basically because species is usually solitary, which prevented hunters from killing large numbers with single shot. Current tendency to turn estuaries into shrimp ponds in Central and South America represents serious threat to species.
Bibliography. Alberico *et al.* (1991, 1992), Amos (1991), Armstrong (1983), Belton (1984), Bent (1927-1929), Biaggi (1983), Blake (1977), Brown (1987), Colwell & Oring (1989a), Contreras *et al.* (1990), Cramp & Simmons (1983), David (1991), Fivizzani *et al.* (1987), Fjeldsa & Krabbe (1990), Gochfeld (1971a), Haverschmidt (1968), Haverschmidt & Mees (1995), Hayes (1995), Hayes & Fox (1991), Hays (1972), Heidemann & Oring (1976), Helbig *et al.* (1991), Hilty & Brown (1986), Johnson (1965b), Kuenzel & Wiegert (1973), Lawrence (1993), Lissak & Willy (1991), Matthiessen (1994), Maxson & Oring (1980), Meyer de Schauensee & Phelps (1978), Miller & Miller (1948), Monroe (1968), Murray (1991), Oring (1988), Oring & Knudson (1972), Oring & Lank (1982), Oring, Colwell & Reed (1991), Oring, Fleischer *et al.* (1992), Oring, Lank & Maxson (1983), Oring, Reed & Alberico (1994), Oring, Reed, Colwell *et al.* (1991), Oring, Reed & Maxson (1994), de la Peña (1992), Pickett *et al.* (1988), Reed & Oring (1992, 1993), Ridgely & Gwynne (1989), Root (1988), Rowan (1927), Schmolz (1991), Scott & Carbonell (1986), Sick (1985c, 1993), Slud (1964), Snyder (1966), Stiles & Skutch (1989), Tostain *et al.* (1992), Varty *et al.* (1986), Wetmore (1965), Willis (1994), Wilson (1976)



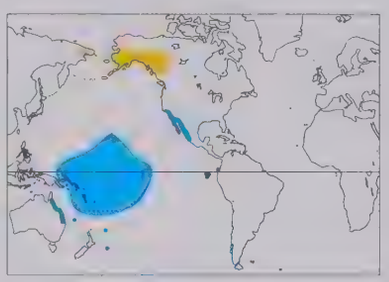
Genus *HETEROSCELUS* Baird, 1858

54. Grey-tailed Tattler

Heteroscelus brevipes

French: Chevalier de Sibérie **German**: Grauschwanz-Wasserläufer **Spanish**: Playero Siberiano
Other common names: Grey-rumped/Grey-tailed Sandpiper, Polynesian/Siberian Tattler

Taxonomy. *Totanus brevipes* Vieillot, 1816, Timor.
Sometimes placed in genus *Tringa*. Forms superspecies with *H. incanus*, with which sometimes considered conspecific. Monotypic.
Distribution. NC & NE Siberia in Putorana Mts, and from Verkhoyansk Mts and Transbaikalia E to Anadyrland; probably also Kamchatka and N Kuril Is. Winters from Taiwan, Malay Peninsula and Philippines through Indonesia, New Guinea and Solomon Is to Australia, a few reaching New Zealand; also Fiji and Tuvalu.



Descriptive notes. 23-27 cm; 80-162 g; wingspan 51 cm. Short yellow legs and darkish grey upperparts. Very similar to *H. incanus*, but slightly paler and shorter-winged; barred paler grey on neck, breast and flanks, with more white on belly and vent; shorter nasal groove and scutellated rear edge to tarsus; best identified by flight call, a whistle of two notes. Female averages larger. Non-breeding adult has greyish white flanks. Juvenile like non-breeding adult, but with whitish spots on upperparts.
Habitat. Breeds in N montane taiga and forest tundra, along rivers and streams and on stone or pebble shorelines of lakes. In non-breeding season found on sheltered coasts with reefs and rock platforms or with intertidal mudflats; also shores of rock, shingle, gravel or shells; often roosts in mangroves, and may perch for roosting; prefers areas with dense beds of seagrass. On migration may occur at inland wetlands, such as paddyfields; exclusively coastal in Australia. Frequents a wider range of environments than *H. incanus*.
Food and Feeding. Food on breeding grounds includes insects, e.g. beetles, mosquitoes, springtails and aquatic larvae of flies. Crabs form large part of non-breeding diet; also other crustaceans, polychaetes, molluscs, insects and occasionally fish. Often teeters and runs during feeding; mostly pecks, sometimes probes in shallow water; large prey detected visually. Crabs often washed on water's edge. Usually forages singly or in loose groups.
Breeding. Breeds late May to late Aug. Nest is shallow depression, often on stony riverbed; sometimes in deserted nests in trees. Usually 4 eggs; sexes share care of young.
Movements. Migratory. Migration mainly coastal, but sometimes on inland wetlands. On passage, occurs in W Aleutian Is, Kuril Is, Korea, Japan, NE China, Hong Kong and Philippines; some birds cross Mongolia and C China; also some movement across SW Pacific; probably two migration routes into Australia, on either side of New Guinea. Migrates in Jul-Oct and Mar-May. Some birds estimated to be capable of flying non-stop from NW Australia to Philippines or S China. Most departures from N Australia late Mar to late Apr. Most 1st-year birds remain S during N summer.
Status and Conservation. Not globally threatened. Total population maximum 100,000 birds. Wintering population in Australia estimated at 36,000 birds; in 1989, total of 22,052 individuals recorded at Moreton Bay, SE Queensland; high numbers occur on Eighty Mile Beach and in Great Sandy Strait. Some 100's winter in Philippines. Species apparently in no danger at present.
Bibliography. Andreev (1980a), Beaman (1994), Beehler *et al.* (1986), Blakers *et al.* (1984), Brazil (1991), Bregulla (1992), Chambers (1989), Coates (1985), Dementiev & Gladkov (1951b), Dickinson *et al.* (1991), Étchécopar & Hüe (1978), Haward & Barter (1991), Keast (1949), Knystautas (1993), Lane & Davies (1987), Leonovitch & Kretzschmar (1966), MacKinnon & Phillipps (1993), Marchant & Higgins (1996), Medway & Wells (1976), Melville (1977), Neufeldt *et al.* (1961), Paulson (1986), Perennou *et al.* (1994), Piersma (1985), Pook (1992), Prater & Marchant (1975), Rogacheva (1992), Scott (1989), Smythies (1981), Stenning & Hirst (1994), Watkins (1993), White & Bruce (1986), Williams, M.D. (1986).

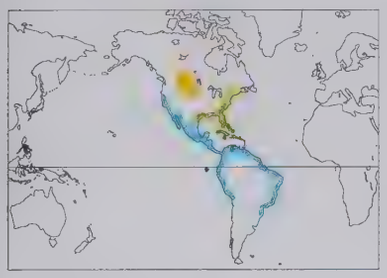
55. Wandering Tattler

Heteroscelus incanus

French: Chevalier errant **German**: Wanderwasserläufer **Spanish**: Playero de Alaska
Other common names: American Grey-rumped Sandpiper

Taxonomy. *Scolopax incana* Gmelin, 1789, Moorea (Eimeo), Society Group, Pacific Ocean.
Sometimes placed in genus *Tringa*. Forms superspecies with *H. brevipes*, with which sometimes considered conspecific. Monotypic.
Distribution. Extreme NE Siberia and S Alaska E to Yukon R and NW British Columbia. Winters in SW USA and W Mexico, Ecuador and Galapagos Is; also Hawaiian Is, C & S Pacific Is to E New Guinea and NE Australia.

Descriptive notes. 26-29 cm; 72-213 g; wingspan 54 cm. Short yellow legs and dark grey upperparts. Very similar to *H. brevipes*, but slightly darker, with longer wings; broader, more extensive dark barring on underparts including central undertail-coverts; distinctive flight call is rippling trill of ten notes. Female averages larger. Non-breeding adult has plain dark grey upperparts, neck, breast and flanks; supercilium only clear above lores. Juvenile as non-breeding adult, but with pale fringes to feathers of upperparts.
Habitat. Similar to that of *H. brevipes*, but variety of wintering habitat narrower. Breeding habitat restricted to alpine zone, along often fast-flowing mountain streams. Outside breeding season found on coral reefs or rocky coast with platforms and piers, and on offshore islands. One of most typical waders of isolated oceanic islands. Incidentaly occurs on adjacent beaches or inland freshwater pools, only on migration; rarely on estuarine mudflats.
Food and Feeding. Breeding season diet mainly aquatic insects and their larvae. In winter and on migration, feeds on crustaceans, polychaete worms, molluscs, insects and fish. When feeding, bobs and teeters almost continuously; moves rapidly over rocky substrates, probing into mats of mussels, barnacles and algae, or picking prey from surface. Usually singly or in small groups.
Breeding. Present in breeding area from late May to Aug, with incubation starting around mid-Jun. Nest is simple depression on gravel shores of mountain streams, or compact structure of twigs and roots. Usually 4 eggs; single brood; incubation 23-25 days, by both parents; both parents tend young. Fledging period unknown, but parents return to rocky ocean shores soon after young fledge.
Movements. Migratory. Passage oceanic towards Hawaiian Is, but many birds move along outer coast and islands of British Columbia and Washington; some birds pass Kuril Is, Japan and Korea on migration, but probably most reach Australia directly across Pacific, some via New Guinea; stragglers reach N New Zealand. 1st-year birds often remain S during breeding months. Spring migration Apr-May; autumn migration mid-Jul to mid-Oct. Probably high fidelity to breeding site.
Status and Conservation. Not globally threatened. Total population estimated at maximum of 25,000 birds. No immediate threats identified, although status very poorly known.
Bibliography. Armstrong (1983), Beehler *et al.* (1986), Bent (1927-1929), Blaber (1993), Blake (1977), Blakers *et al.* (1984), Brazil (1991), Bregulla (1992), Chambers (1989), Coates (1985), Dixon (1933), Doyle *et al.* (1985), Étchécopar & Hüe (1978), Fjeldså & Krabbe (1990), Hilty & Brown (1986), Holyoak & Thibault (1984), Howell & Webb (1995a), Knystautas (1993), Lane & Davies (1987), Marchant & Higgins (1996), Matthiessen (1994), Monroe (1968), Murie (1924), Paulson (1986), Prater & Marchant (1975), Ridgely & Gwynne (1989), Robbins *et al.* (1983), Root (1988), Sibson (1965), Stiles & Skutch (1989), Wecden (1959, 1965), Wizeman (1972).



Genus *CATOPTROPHORUS* Bonaparte, 1827

56. Willet

Catoptrophorus semipalmatus

French: Chevalier semipalmé **German**: Schlammtreter **Spanish**: Playero Aliblanco

Taxonomy. *Scolopax semipalmata* Gmelin, 1789, New York.
Two subspecies recognized.
Subspecies and Distribution.
C. s. inornatus (Brewster, 1887) - C Alberta and SW Manitoba S to N Colorado and W Nebraska; winters from coastal S USA to N South America, mainly on Pacific coast, S to N Chile.
C. s. semipalmatus (Gmelin, 1789) - S New Brunswick, Atlantic and Gulf coasts of USA, and West Indies; winters from Atlantic and Gulf coasts of USA and Mexico through Central America and West Indies S to S Brazil.

Descriptive notes. 33-41 cm; 173-375 g. Medium-sized, tall wader resembling *Tringa*; heavy bill, long legs; pale eye-ring, white above lores; in flight, striking black and white patterns on both upperwing and underwing. Female averages larger. Non-breeding adult has brownish grey upperparts with narrow white fringes; head, throat, neck and breast washed grey. Juvenile as non-breeding, but upperparts grey-brown with dark barring and broad buff fringes. Race *inornatus* paler, with more sparsely streaked and barred neck, breast and flanks.
Habitat. Races differ in habitat preferences: *inornatus* associated with prairie marshes; *semipalmatus* mainly coastal, in salt-marshes with short vegetation. Around temporary pools and lakes of wide range of salinities, preferably more alkaline. In non-breeding season, near seashore, on salt-marshes, intertidal mudflats especially when bordered with mangroves, and sandy or rocky beaches.
Food and Feeding. While breeding, feeds on small molluscs, fish fry, marine worms and aquatic insects. Outside breeding season often takes small crabs, especially fiddler crabs; also small fish, molluscs, marine annelids, isopods and aquatic insects. Pecks or probes, and stalks larger prey in water; also runs while ploughing bill through water or while scything (continuously moving bill from side to side) to catch fish. May defend feeding territory on wintering grounds. Feeds singly or in flocks. Diurnal and nocturnal forager.
Breeding. Laying Apr-Jun. Probably monogamous. Often in loose colonies. Nest usually well concealed in heavy grass, sometimes placed on open sand and almost completely exposed. 4 eggs, with laying interval 1-4 days; incubation 21-29 days, mainly by female, male taking over at night; both parents tend young; fledging period unknown. Age of first breeding 2 years.
Movements. Race *inornatus* strongly migratory, but nominate fairly sedentary around Gulf of Mexico and in Caribbean. Race *inornatus* moves S in three main directions: almost due E to Atlantic coast of New York and New England; SE & S to Atlantic and Gulf coasts, with some moving into Caribbean and reaching Surinam; fairly small numbers migrate SW to Pacific coast, from Oregon to N Peru, scarcely S to N Chile; regular migrant to Galapagos in small numbers. Nominate race moves S down Atlantic coast into Caribbean and to N South America, where occurs mainly in NC Brazil and Surinam.
Status and Conservation. Not globally threatened. No population estimate available, but W Pacific flyway supports at least 70,000 birds; in South America 44,400 counted on aerial surveys in 1989. Population of race *inornatus* declined due to conversion of wetlands and grassland to small grain and row crops, but no notable change in numbers since 1970. In 1967, estimated 41,000 pairs bred in North Dakota. Still moderately abundant over much of original range, perhaps because of considerable tolerance for human activities such as modification and burning of marshes. Numbers of both races apparently fairly stable at present.
Bibliography. Bent (1927-1929), Biaggi (1983), Blake (1977), Burger & Shisler (1978a), Custer & Mitchell (1991), Fjeldså & Krabbe (1990), Haverschmidt (1968), Haverschmidt & Mees (1995), Higgins *et al.* (1979), Hilty & Brown (1986), Howe (1974, 1982), Howell & Webb (1995a, 1995b), Johnson (1965b), Kelly & Cogswell (1979), Llinas & Galindo (1990), Matthiessen (1994), McNeil & Rodriguez (1990), McNeil & Rompré (1995), Meyer de Schauensee & Phelps (1978), Monroe (1968), Ridgely & Gwynne (1989), Rompré & McNeil (1994), Root (1988), Ryan & Renken (1987), Scott & Carbonell (1986), Sick (1985c, 1993), Slud (1964), Snyder (1966), Sordahl (1979), Stenzel *et al.* (1976), Stiles & Skutch (1989), Tomkins (1965), Tostain *et al.* (1992), Wells & Vickery (1990), Wetmore (1965), Wilcox (1980).

Tribe PROSOBONIINI

Genus *PROSOBONIA* Bonaparte, 1850

57. **Tuamotu Sandpiper**

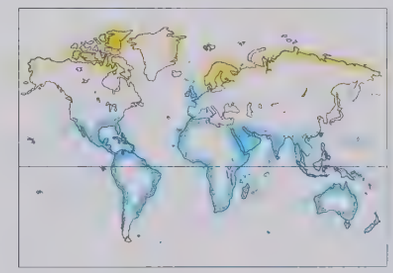
Prosobonia cancellata

French: Chevalier des Touamotou **German**: Südseeläufer **Spanish**: Andarríos de Tuamotu

Taxonomy. *Tringa cancellata* Gmelin, 1789, Kiritimati (Christmas Island), Line Islands, Pacific Ocean. Formerly placed in genus *Aechmorhynchus*. May have formed superspecies with extinct *P. leucoptera* and *P. ellisi* (see page 484). Population of Tuamotu sometimes separated as *parvirostris*, awarded subspecies or even species status; in latter arrangement, extant birds would become *P. parvirostris* and name *P. cancellata* restricted to extinct form of Kiritimati; however, available information probably too scanty to enable firm conclusions. Monotypic.
Distribution. Tuamotu Is (French Polynesia).
Descriptive notes. 15-17 cm; 32-44 g. Small, very dark brown wader with very short, thin bill; ashy white supercilium; upperparts have extensive buff spots and feather edges; breast, flanks and undertail spotted or barred brown; legs yellowish brown to greyish; in flight, very rounded wings. Sexual and seasonal differences and juvenile undescribed.
Habitat. Tiny atolls, mainly in habitats such as open coastal shoreline, lagoon beaches and areas of bare gravel or open shingle; also among vegetation.
Food and Feeding. Very poorly known. Mainly insects: at least 4 species of ant, leafhoppers and a wasp were found in stomach contents. Plant matter also consumed.
Breeding. Breeding season quite prolonged; on one island breeding in Aug, on another in May; unclear whether season is synchronized on different islands. Nest constructed from bits of shell, coral debris and plant fragments; on shoreline, usually on pebbly rather than sandy substrate. One nest contained 2 eggs. No further information available.

Movements. Probably sedentary as a rule, although recent records on Nakutavaké and Rangiroa presumably represent visitors from other islands.
Status and Conservation. ENDANGERED. Population currently in decline. On Morane 150-200 birds (1990), on Anuanu Raro 30-40 birds (1990) and on Tahanea 12-15 birds (1989). Former range spanned 3700 km of C Pacific. Since c. 1965 reported from 11-12 islands, while c. 26 atolls have not yet been surveyed. Decline probably due to introduction of mammalian predators, particularly rats and cats; populations do best on islands free of introduced predators, and without permanent human populations. Species now in severe danger of extinction, but at present no conservation measures have been taken; proposed measures include total protection of atolls on which species still known to occur, with special efforts recommended to prevent introduction of cats and rats.
Bibliography. Bruner (1972), Collar & Andrew (1988), Collar *et al.* (1994), Ferguson-Lees & Faull (1992), Greenway (1967), Hay, R. (1984, 1986), Holyoak (1973), Holyoak & Thibault (1984), King (1978/79), Lacan & Mougin (1974), Lovegrove *et al.* (1989), Pratt *et al.* (1987), Rosair (1995e), Seitre & Seitre (1991), Thibault (1973, 1988), Walters (1993), Wragg & Weisler (1994), Zusi & Jehl (1970).

Subfamily ARENARIINAE



Genus *ARENARIA* Brisson, 1760

58. **Ruddy Turnstone**

Arenaria interpres

French: Tournepierre à collier **German**: Steinwälzer **Spanish**: Vuelvepiedras Común
Other common names: Turnstone

Taxonomy. *Tringa Interpres* Linnaeus, 1758, Gotland, Sweden.
Two subspecies recognized.
Subspecies and Distribution.
A. i. interpres (Linnaeus, 1758) - Axel Heiberg I and Ellesmere I (N Canadian Arctic), Greenland, N Eurasia and NW Alaska; winters on coasts of W Europe, Africa, S Asia, Australasia and S Pacific islands, with some also on Pacific coast of North America, from California to at least Mexico.
A. i. morinella (Linnaeus, 1766) - NE Alaska and most of Arctic Canada; winters from South Carolina and Gulf of Mexico to SC Chile and N Argentina.

Descriptive notes. 21-26 cm; 84-190 g; wingspan 50-57 cm. Robust shorebird with short legs; black and white head, throat, neck and breast; upperparts rufous-chestnut with black-brown patches; underparts white; distinctive pattern in flight, with white back, rump, uppertail-coverts, wingbar and patch on inner wing contrasting with otherwise dark upperparts. Female has more extensive streaking on crown; brownish nape; somewhat duller upperparts; some pale flecking on breast patch. Non-breeding adult much duller, with upperparts dark greyish brown and blackish; head mostly dark grey-brown; black areas of neck and breast replaced with dark grey-brown. Juvenile like adult non-breeding, but browner above with buff fringes and paler on head. Race *morinella* slightly smaller, with less dark streaking on crown; more extensive deep chestnut-red on scapulars and upperwing-coverts.
Habitat. Stony coastal plains, marshy slopes and flats in lowlands, and tundra; always close to areas that remain moist until late summer. Outside breeding season, chiefly coastal; occurs inland only on migration, on short-grass salt-marshes and along dykes; rocky, shingly, and stony shores and breakwaters, sandy beaches with washed-up seaweed, sheltered inlets, estuaries, mangrove stands, exposed reefs and mudflats, preferably with beds of mussels or cockles; also lake shores.
Food and Feeding. In breeding season, mainly Diptera (especially adult and larval midges), also Lepidoptera larvae, Hymenoptera, beetles and spiders; some vegetable matter taken early in season; probing and jabbing are main techniques during breeding. Non-breeding diet diverse, including insects, crustaceans, molluscs, annelids, echinoderms, small fish, carrion such as dead fish or mammals, discarded human food, and birds' eggs. On staging areas in E USA, takes large quantities of horseshoe crab (*Limulus polyphemus*) eggs. Flips over objects such as stones, shells and seaweed with quick jerking movements; prey underneath is pecked at or chased; sometimes pushes larger object with breast; frequently scavenges, occasionally even for bread from people. Age-related differences in foraging rate, and individuals may specialize. Often in rather close flocks, especially on tidal roosts, of 10-100+ birds.
Breeding. Laying mid-May to early Jul, primarily mid-Jun in Canada. Monogamous and solitary. In Taymyr 0·1-12·5 birds/km², in high Arctic Greenland up to 3·8 pairs/km². Nest placed in wet or dry hummocky sites; may be concealed in or under vegetation, or in fully open sites; nest is slight depression lined with various amounts of plant material. 4 eggs (2-4), with laying interval of 1 day, sometimes 2; incubation 22-24 days (22-27), by both sexes, although male much less; chick has buffish grey to cinnamon-buff upperparts, faintly striped and mottled grey or blackish and lacking white tips to down, with face and underparts pale grey; chicks cared for by both sexes for 1-2 weeks, whereafter female leaves; fledging 19-21 days; male departs soon after chicks fledge. 26-88% of eggs hatch, 50-74% of chicks fledge; 1st-year annual mortality 42-55%; adult annual mortality 22-34%. Age of first breeding 2 years. Oldest ringed bird 19 years, 8 months.
Movements. Migratory. Breeding range divisible into 5 populations: (1) birds of Axel Heiberg I, Ellesmere I and Greenland move to W Europe, mainly from Irish and North Seas to Iberia, with vagrants S to Mauritania; direct trans-Atlantic crossing or stopover in Iceland or SW Norway; (2) Fenno-

Scandian and W Russian birds move along coastlines of Baltic and W Europe (May and mid-Jul to mid-Sept) to Morocco and W Africa; (3) birds breeding from White Sea to C Siberia probably move through Kazakhstan lakes and Caspian and Black Seas to winter in E Mediterranean, Red Sea, Persian Gulf, coasts of Indian Ocean and S Africa; on southward migration locally frequent inland in Africa; (4) birds from E Siberia and W Alaska, wintering in SE Asia, Australia, W Pacific and locally on W coast of Mexico and California; possibly two routes to Australia, first with movement to E Australia and New Zealand across Pacific, returning N via E coast of Asia, and second with movement to and from W Australia along E Asian coasts; arrives Australia Aug-Nov and departs Mar-Jun; (5) race *morinella* moves to Pacific and Atlantic coasts of Central and South America, staging in large numbers in Delaware Bay, and with highest numbers wintering in N South America. Most immature birds spend summer S of breeding grounds. High fidelity to wintering sites. Juveniles migrate S c. 1 month later than adults, i.e. mid-Aug to early Sept. Migrates in flocks of 10's of birds.

Status and Conservation. Not globally threatened. Estimated numbers of wintering birds: 67,000 in Europe, including estimated 50,000 in Britain, but excluding Iceland, S Norway and Ireland, all important sites; 43,000 birds in W Africa (1988) and 34,000 in S Africa (1989); 50,000-100,000 birds in E Africa and SW Asia; 10,000-100,000 birds in SC Asia; probably 25,000-100,000 birds in E & SE Asia and Australasia, of which 14,000 in Australia; 30,000-100,000 birds in America, with significant proportion wintering on N coast of Brazil and significant numbers staging at Delaware Bay on northward migration. At least 15,000-30,000 pairs breed in Fenno-Scandia (1993) and c. 25,000 pairs in high Arctic Greenland and Ellesmere I (1985). European wintering population probably increased slightly during 1970's and 1980's. Winter populations in W Palearctic, W & S Africa and America considered stable.

59. **Black Turnstone**

Arenaria melanocephala

French: Tournepierre noir **German**: Schwarzkopf-Steinwälzer **Spanish**: Vuelvepiedras Oscuro

Taxonomy. *Strepsilas melanocephalus* Vigors, 1829, north-west coast of North America. Monotypic.

Distribution. W & S Alaska. Winters from SE Alaska to NW Mexico.

Descriptive notes. 22-25 cm; 98-148 g. Large white spot at base of bill; small white spotting on crown, sides of neck, breast and greater coverts; dark spotting on flanks. Always darker than *A. interpres*, with dark chin and all dark breast; greyer legs; in flight, shows similar pattern on upperparts. Female averages slightly larger; has smaller white spot at base of bill. Non-breeding adult lacks spotting on head, nape and breast; flanks less marked. Juvenile as non-breeding, but dark feathers browner and upperparts with buffish fringes.

Habitat. Salt grass, graminoid and dwarf shrub meadows; also tidal marshes; mostly within 2 km of coast. In non-breeding season on rocky coasts, jetties, isolated rocky outcrops, and barnacle-covered reefs, especially those on offshore islands; sometimes on adjacent sandy beaches or mudflats.

Food and Feeding. Diet on breeding grounds not studied, but probably similar to that of *A. interpres*. Non-breeding diet primarily crustaceans (especially barnacles) and molluscs (especially limpets); also herring eggs in Prince William Sound, on N migration. Turns up patches of seaweed, sometimes follows receding breakers, or gleans from surface; moves slowly and steadily over rocks. Opens shells by inserting bill into gap, or by hammering at shell; only swallows soft part. In small flocks of up to few dozen birds.

Breeding. Lays May-Jun. Solitary or semi-colonial; densities of 40-111 birds/km², highest in coastal salt grass meadows. Nest usually quite close to water; simple depression in dead grass, or sometimes in bare mud, sparsely lined. 4 eggs; incubation 21 days, by both sexes. No further information available.

Movements. Less migratory than *A. interpres*. Migrates down Pacific coast, as far S as Sonora, W Mexico. Vagrant to inland areas of coastal provinces and states. Some non-breeders remain S all year.

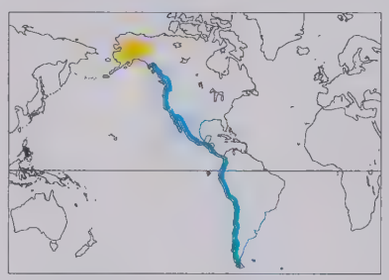
Status and Conservation. Not globally threatened. Total breeding population estimated at 76,000-114,000 birds (1991) of which 85% nest on C floodplain of Yukon and Kuskokwim Deltas, SW Alaska. Decline noted in recent years in population wintering in S British Columbia and NW USA.

Bibliography. Anderson & Bellin (1988), Armstrong (1983), Bent (1927-1929), Brandt (1943), Campbell (1975), Connors (1977), Conover (1926), Denny (1992), Edwards (1989), Gill & Handel (1990), Gill *et al.* (1983), Handel (1982), Handel & Gill (1992a), Howell & Webb (1995a), Matthiessen (1994), Norton *et al.* (1990), Paulson & Erckmann (1993), Roe (1990), Root (1988), Wilbur (1987).

Subfamily CALIDRINAE

Genus *APHRIZA* Audubon, 1839

60. **Surfbird**



Aphriza virgata

French: Bécasseau du ressac **German**: Gischtläufer **Spanish**: Correlimos de Rompientes

Taxonomy. *Tringa virgata* Gmelin, 1789, Prince William Sound, Alaska.

Formerly classified within subfamily Arenariinae, with superficially similar turnstones, but clearly belongs very close to genus *Calidris*, in which occasionally placed (see page 445). Monotypic.

Distribution. C & S Alaska and C Yukon. Winters on Pacific coast of America, from Alexander Archipelago (SE Alaska) S to Straits of Magellan.

Descriptive notes. 23-26 cm; 121-193 g. Large sandpiper, recalling *Arenaria* but also reminiscent of *Calidris tenuirostris*; strongly streaked head, neck and upperparts, bold markings on lower breast and flanks; largest scapulars are bright buff with bold black marks. Sexes apparently similar. Non-breeding adult has plain brownish grey upperparts, head, neck and breast; chin whitish; flanks with some spots. Juvenile like non-breeding, but buff fringes on both upperparts and brownish breast.

Habitat. Rocky ridges in mountains, alpine tundra, typically with vegetation of moss, avens and heather, interspersed with mosses and lichens. Non-breeding habitat includes seaweed-covered rocky coasts, and jetties; sometimes on adjacent sandy beaches, rarely on mudflats; often together with *Arenaria interpres*, *A. melanocephala* or *Calidris ptilocnemis*.

Food and Feeding. On breeding grounds, takes insects, mainly Diptera, also beetles; caught by stealth or by active chase. In winter quarters and on migration, feeds on barnacles, bivalves (e.g. mussels), periwinkles and limpets, normally under 12 mm long; also herring eggs in Prince William Sound on northward migration, and decopods on sandy beaches. Tugs or hammers on prey; pecks from surface. Shells are crushed in gizzard. Gregarious feeder, in flocks of 20-100 birds.

Breeding. Not well documented. Lays late May to early Jun. Probably monogamous. Nest is natural depression lined with few bits of lichen and moss. 4 eggs, sometimes 3; both sexes probably incubate; fledging period under 1 month.

Movements. Strongly migratory; mainly along coast, but few birds may overfly W USA during northward movement from head of Gulf of California; main wintering areas located in Chile and Peru. Non-breeders may remain in some parts of wintering range all year.

Status and Conservation. Not globally threatened. Breeding population 50,000-70,000 birds. Large proportion of total population may stop in Prince William Sound, SC Alaska, during spring migration, with over 18,000 staging in Rocky Bay. Vulnerable to oil spills.

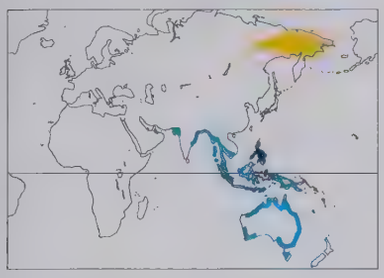
PLATE 44



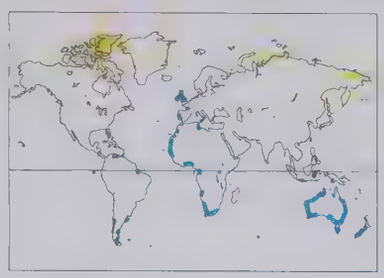
Genus *CALIDRIS* Merrem, 1804

61. Great Knot

Calidris tenuirostris

French: Bécasseau de l'Anadyr **German**: Großer Knutt **Spanish**: Correlimos Grande
Other common names: Eastern/Greater Knot, Great Sandpiper

Taxonomy. *Totanus tenuirostris* Horsfield, 1821, Java.
In past, genus *Calidris* was on occasion reserved for present species and *C. canutus* only. Monotypic.
Distribution. NE Siberia, from Verkhoyansk Mts E to Magadan, Koryak Highlands and S Chukotskiy Peninsula; distribution poorly known. Winters mainly in SE Asia and Australia; also in Arabia, Pakistan, NW & NE India and Bangladesh.



Descriptive notes. 26-28 cm; 115-248 g; wingspan 58 cm. Largest *Calidris*; breast and flanks heavily spotted black; scapulars with large chestnut spots and blackish tips; uppertail-coverts mostly white. Different proportions from *Aphriza virgata*, especially longer bill. Female averages larger, with less chestnut in scapulars. Non-breeding adult has paler grey upperparts and breast; upperparts, head and neck finely streaked dark grey; breast streaked, flanks lightly streaked; faint white wingbar; white rump and uppertail-coverts; similar in shape to *C. canutus* but larger, with longer bill, and at rest wings project beyond tail. Juvenile like non-breeding, but darker and browner; upperparts with narrow pale fringes; dark crown and breast suffused with brown-buff.
Habitat. Breeds in subarctic, on plateaux or gentle slopes with montane tundra at 300-1600 m, in habitats ranging from gravelly areas covered by lichens and patches of herbs and heather to areas with a continuous thick layer of lichen and scattered depressed larch (*Larix*) or dwarf pine (*Pinus pumila*), or both. Non-breeding habitat includes sheltered coasts with large intertidal mudflats and sandflats, e.g. in inlets, bays, harbours, estuaries and lagoons; also on ocean beaches; rarely on inland swamps and lakes or at river mouths.
Food and Feeding. During breeding season primarily plant material, mainly berries, also kernels of dwarf pine trees; only small chicks feed exclusively on insects, such as Diptera larvae, beetles, and spiders. Contrary to previous reports, does not feed in bogs. In non-breeding season feeds mainly on bivalves, up to 36 mm long, buried in soft sediment; also gastropods, crustaceans, annelids and sea cucumbers. Searches mainly by probing in mud, also by pecking and gleaning. Feeds in large flocks of c. 100 to 1000's, often in company of *C. canutus*, *Limosa lapponica* or *Heteroscelus brevipes*. Nocturnal and diurnal forager.
Breeding. Lays late May to late Jun. Monogamous. Territorial; density 13 pairs on 9·5 km² of suitable habitat; highly faithful to site. 4 eggs (sometimes 3), laid over 5 days; single brood; incubation 21 days, by both parents; female leaves area after hatching, leaving male to care for chicks; chick similar to that of *C. canutus*; fledging 20-25 days, varying between years depending on weather; young independent several days after fledging. 2·3-2·5 fledglings per brood; chick survival till fledging at least 47%. Oldest ringed bird at least 10 years.
Movements. Long distance migrant, mainly along coast, probably with few stopovers. Females leave breeding grounds early Jul, males and young late Jul. N & S migration routes quite different. Most birds migrate via coast of Sea of Okhotsk (only on S migration), Ussuriland, South Korea (especially N migration), and E China (stopover, at least in N migration); straggler to New Zealand. Arrival in NW Australia late Aug and early Sept, 1st-year birds in Oct; Gulf of Carpentaria not reached until Dec; N migration occurs in Mar-Apr, and departure from NE Australia occurs late Mar to mid-Apr; probably flies non-stop to S China; arrival on breeding grounds late May to early Jun. Small numbers, with highest count 1193 birds, winter in or pass through Arabia, particularly Oman, United Arab Emirates and Saudi Arabia; birds wintering in Pakistan and India may cross Tibetan Plateau. Some 1st-years spend first boreal summer, and maybe longer, in non-breeding range, others migrate at least N to Sakhalin.
Status and Conservation. Not globally threatened. Australian wintering population estimated at 270,000 birds; in E & SE Asia 50,000 birds; less than 10,000 birds wintering in SW & SC Asia. Common on Borneo before 1940, but has declined since. Currently one of most abundant shorebirds in Australia, although species was considered rare, endangered or uncommon till 1970's, as world population was estimated at 10,000-20,000 birds. Important sites in Australia are Eighty Mile Beach, Roebuck Bay, NE Arnhem Land, Roper R area, and SW & SE Gulf of Carpentaria. Hunting and habitat loss in stopover zone in China may constitute major threats. Australasian wintering population seems to be in decline, but no immediate threats evident.

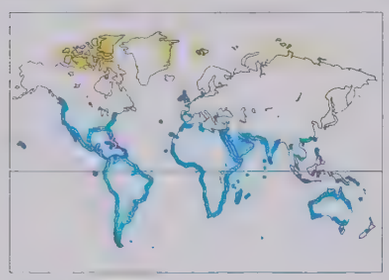
62. Red Knot

Calidris canutus

French: Bécasseau maubèche **German**: Knutt **Spanish**: Correlimos Gordo
Other common names: (Lesser/European) Knot

Taxonomy. *Tringa Canutus* Linnaeus, 1758, Sweden.
In past, genus *Calidris* was on occasion reserved for present species and *C. tenuirostris* only. Races *islandica*, *rogersi* and, until recently, *roselaari* formerly included within nominate *canutus*. Five subspecies currently recognized.
Subspecies and Distribution.
C. c. canutus (Linnaeus, 1758) - CN Siberia, in Taymyr Peninsula, New Siberian Is and possibly Yakutia; winters in W & S Africa and probably Australasia.
C. c. rogersi (Mathews, 1913) - Chukotskiy Peninsula and possibly areas farther W; winters in Australasia.
C. c. roselaari Tomkovich, 1990 - Wrangel I and NW Alaska; probably winters in Florida, S Panama and N Venezuela.
C. c. rufa (Wilson, 1813) - Canadian low Arctic; winters in NE & S South America.
C. c. islandica (Linnaeus, 1767) - islands of Canadian high Arctic and N Greenland; winters in W Europe.

Descriptive notes. 23-25 cm; 85-220 g; wingspan 45-54 cm. Distinctive large *Calidris*, with rich rusty chestnut underparts; upperparts mainly blackish mixed with pale to rufous chestnut. Female has underpart coloration broken with white feathers; more white on rear belly. Non-breeding adult plain grey above with narrow white fringes on larger feathers; underparts white, with grey barring on breast and flanks; recalls larger *C. tenuirostris*, but rump white barred grey appearing uniform grey with rest of upperparts, and white wingbar more marked. Juvenile like non-breeding adult, but breast washed buffish, upperparts brownish grey and wing-coverts and scapulars with buff fringes and dark subterminal bars. Race *islandica* paler below with yellowish fringes on upperparts; *rogersi* similarly paler, with more white on rear belly; *rufa* palest below with most white on rear belly; *roselaari* has more richly coloured belly and undertail-coverts.
Habitat. High Arctic, occupying tundra and upland glacial gravel, marshy slopes and flats in foothills, close to streams or ponds, usually near coast. In non-breeding range, strictly coastal; rarely inland on migration, in W Africa; prefers large tidal mudflats or sandflats; also on sandy beaches of sheltered coasts, rock shelves, bays, lagoons and harbours; occasionally on ocean beaches and saline wetlands near coast.
Food and Feeding. Insects, mainly adult and larval Diptera, also Lepidoptera, Trichoptera, beetles and bees; spiders, small crustaceans, snails and worms. Away from breeding grounds, feeds on small range of intertidal invertebrates, chiefly bivalve and gastropod molluscs, less frequent crustaceans, annelids and insects, rarely fish and seeds. During N migration on staging areas in E USA, feeds primarily on horseshoe crab (*Limulus polyphemus*) eggs. Probes in soft sediment; sometimes pecks. Highly gregarious, often in dense flocks of 300-10,000 birds. Diurnal and nocturnal feeder.
Breeding. Lays Jun. Monogamous. Solitary, territory not important for feeding; normally c. 1 pair/km². Nest on open vegetated tundra or stone ridge, often close to clump of vegetation. 3-4 eggs, with laying interval 1-2 days; incubation 21-22 days, by both sexes; chick mottled dull blackish brown above with some buff and with rows of white or cinnamon-buff tips to down, underparts white to buffish white; females depart immediately after hatching, leaving male to tend young alone; fledging 18-20 days. In one sample of 26 eggs, 54% hatched, 27% fledged; annual adult mortality 32%. Age of first breeding probably 2-3 years. Oldest ringed bird 16 years, 1 month.
Movements. Long distance migrant, with relatively few stopover sites. Race *islandica*, from Canada and W Greenland, crosses Greenland icecap, N Atlantic, often Iceland (probably not used by birds from E Greenland), to NW Europe; some move down SW Norway and Denmark, mainly juveniles, only in autumn; spring migration more synchronized, passing through Iceland and N Norway. Race *canutus* probably has 3 migration routes: birds from Yakutia perhaps move overland to Gulf of Finland, through Baltic and W Europe to W Africa (mainly Banc d'Arguin, Mauritania) and S Africa; Taymyr population presumably halts in W Europe; N migration of both groups along same route, many also stopping over in W France; birds from New Siberian Is probably move down E coast of Asia to Australasia. Most *rufa* cross W Atlantic from NE North America to coast of the Guianas, whereafter most continue to Patagonia and Tierra del Fuego; birds wintering in Florida traditionally ascribed to this race, but probably referable to *roselaari*; on way N, most birds stage at Delaware Bay. Race *rogersi* may perform loop migration to Australasia, moving S non-stop across W Pacific, via Sea of Okhotsk, and down E Asian coast (Shanghai and Korea); arrives in N Australia from late Aug, in New Zealand arrives from late Sept, and departs late Mar to early Apr; possibly flies non-stop from NW & SE Australia to SE China. Migration route of *roselaari* not clear, but assumed to winter in W Florida, S Panama and N Venezuela. Adults depart breeding grounds before young. Degree of site fidelity to wintering grounds unclear. Many immatures remain in winter quarters all year.
Status and Conservation. Not globally threatened. Population estimates: *islandica* 345,000-500,000 birds (1989), of which 253,000 winter in the British Is; *canutus* 520,000 birds (1989), of which c. 362,000 winter on Banc d'Arguin, Mauritania, and c. 144,000 in Archipélago dos Bijagós, Guinea-Bissau, in 1992, although only 31,000 estimated in 1992/93; *rogersi* 255,000 birds (1993), including c. 153,000 birds wintering in Australia and 88,000 in New Zealand, with most important wintering sites at Eighty Mile Beach and SE Gulf of Carpentaria, and Farewell Spit and Firth of Thames; *roselaari* at least 20,000 birds; *rufa* 100,000-150,000 birds, of which 53,000 winter in Tierra de Fuego (1989), mostly in Bahía Lomas, while 10,000 birds in Florida are, in fact, probably referable to *roselaari*. Population of *rufa* declined in 1972-1983, possibly due to cold breeding seasons; *islandica* declined from 609,000 birds in early 1970's, perhaps due to severe weather in Arctic; *canutus*, *islandica* and *rufa* currently considered to be stable. Vulnerable to extensive land reclamation projects, encroaching on relatively few staging areas, especially in W Europe, where virtually the entire adult population of race *canutus* and most of population of *islandica* stage in Wadden Sea, where up to 433,000 birds counted at one time; significant numbers of *rufa* (c. 80% of population) stage in Delaware Bay on N migration. Human overexploitation of shellfish stocks in the Wadden Sea directly leads to reduction of food supply and indirectly to alterations in sediment characteristics, which reduce prey availability. Disturbance outside breeding season from recreational activities and overflying aircrafts reduces size of foraging areas. In New Zealand, some illegal shooting persists.



On following pages: 63. Sanderling (*Calidris alba*); 64. Semipalmated Sandpiper (*Calidris pusilla*); 65. Western Sandpiper (*Calidris mauri*); 66. Red-necked Stint (*Calidris ruficollis*); 67. 63. Sanderling
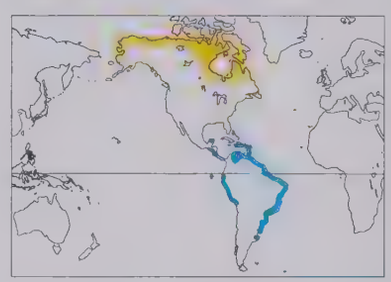
Calidris alba

French: Bécasseau sanderling **German**: Sanderling **Spanish**: Correlimos Tridáctilo

Taxonomy. *Tringa alba* Pallas, 1764, coast of North Sea.
Formerly placed in monospecific genus *Crocethia*. Monotypic.
Distribution. Canadian Arctic, Greenland and Svalbard to Severnaya Zemlya Is, Taymyr Peninsula, Lena Delta and New Siberian Is; small numbers in N Alaska. Winters on coast from C North to S South America, and from W & S Europe and Africa through S Asia to Australasia and some tropical Pacific islands.



Descriptive notes. 20-21 cm; 33-110 g; wingspan 35-39 cm. Chunky, medium-sized *Calidris* with shortish, thickish bill; intensity of coloration variable, with head, upperparts and breast mostly pale buff to chestnut; dark streaks on head and breast and bold black marks and white spots on upperparts; underparts white; in flight, striking white wingbar in all plumages. Female averages slightly larger and paler, with less chestnut. Non-breeding adult very white; pale grey above with white face and underparts; lesser wing-coverts darker. Juvenile has buffy white head and breast; streaked crown and sides of breast; upperparts marked black and grey with almost black shoulder patch.
Habitat. High Arctic barren stony tundra supporting scant vegetation with well drained ridges and sparse growth of willow and saxifrage; access to shores of neighbouring waters is important requirement for young. Outside breeding season, on open sandy beaches exposed to swell of open sea, and sandy outer reaches of estuaries; also rocky or muddy shores, less frequently on mudflats. On migration, occasionally at inland waters; few birds winter at inland saline lakes.
Food and Feeding. On breeding grounds, insects, mainly adult and larval Diptera, occasionally beetles and Lepidoptera; also spiders and crustaceans and vegetable matter (seeds, saxifrage buds, moss and algae). On migration and in winter, small molluscs, crustaceans, polychaete worms, adult, larval and pupal insects (Diptera, beetles, Lepidoptera, Hemiptera, Hymenoptera); occasionally fish, medusae and larger molluscs and crustaceans taken as carrion; on outer beaches in North and South America, mostly hippid crabs (*Emerita*); on N migration up E coast of USA, primarily eggs of horseshoe crabs (*Limulus polyphemus*); observed scavenging bread from people, often in company of *Arenaria interpres*. Mostly feeds by rapid probing or pecking. Typically, close to water's edge, following retreating waves. Touch, smell and probably taste important for locating prey, and sometimes vision initially. Feeds in small flocks, or very large ones, especially on staging sites. Some birds defend winter feeding territories. Diurnal and nocturnal forager.
Breeding. Laying Jun to mid-Jul. Monogamous; occasionally polyandrous. High degree of breeding site fidelity. Solitary; density up to 13·7 pairs/km². Nest is exposed depression, frequently on bare earth or stones, often lined with dry leaves and lichens. 4 eggs, sometimes 3, with laying interval 26-29 hours; incubation 24-32 days, by both sexes; often 2 clutches, each incubated by one parent; perhaps occasionally 3rd clutch, with different male; chick cinnamon-buff to ochraceous above with fine black down tips and black bands with rows of white down tips, pale buff-yellow face and throat and white underparts; fledging 17 days; when both parents incubate, both probably care for chicks, at least initially; parents depart soon after fledging. Annual adult mortality c. 44%, 1st-years c. 62%. Age of first breeding unknown, but many return to breeding grounds as 1-year-olds. Oldest ringed bird 11 years.
Movements. Long distance migrant. Seems to be restricted to few stopover sites along flyways; highly faithful to wintering sites. Migration largely offshore and coastal, but locally frequent inland across Africa and North America; also occurs on many small oceanic islands. Birds from Greenland and Siberia (E to Taymyr) pass through British Is, some staying there, but most winter down continental coasts from Europe S to S Africa; evidently loop migration, as in spring some birds from W Africa cross Sahara to C Mediterranean. Siberian birds E of Taymyr move down E Russian coast or overland, to Indian Ocean and SW Pacific; in E Asia, common migrant through Korea, E China and Japan, and also through Vietnam and Cambodia. Birds wintering in SE Asia and Australia probably originate from New Siberian Is. Nearctic birds move along Pacific and Atlantic coasts and via prairies and Texas coast; most abundant on Pacific coast of South America, whence N migration mainly via inland and Atlantic routes; high numbers staging at Delaware Bay, probably mostly from Brazil; Pacific North American winterers migrate along Pacific coast. Many 1-year-olds apparently return to breeding grounds, but some remain S all year.
Status and Conservation. Not globally threatened. North American winter population comprises probably 100,000-200,000 birds; most numerous small shorebird on beaches of South American Pacific coast; in 1952, population on Banks I estimated at 65,000 birds; in 1958, population on Prince of Wales I at 70,000; in 1970, c. 450,000 birds claimed overwintering at Puerto Viejo, NC Chile (presumably overestimated). E Atlantic winter population estimated at c. 123,000 birds (1989), with large numbers in W & S Africa; 17,000 pairs estimated breeding in high Arctic Greenland and Ellesmere I (1985); major portion of E Atlantic flyway population stages in Wadden Sea, where numbers considered stable. E Africa and SW Asia hold c. 120,000 birds (1991); SC Asia probably 25,000-100,000 birds; E & SE Asia and Australasia c. 25,000 birds, with c. 8000 in Australia. Numbers staging in E North America declined by 80% from 1972 to 1983; in Pacific North America, winter populations have fluctuated in recent years, but no apparent overall decline. Species sensitive to disturbance on beaches, moving to other sites if disturbance becomes too intense.

64. Semipalmated Sandpiper
Calidris pusilla

French: Bécasseau semipalmé **German**: Sandstrandläufer **Spanish**: Correlimos Semipalmeado

Taxonomy. *Tringa pusilla* Linnaeus, 1766, Santo Domingo.
Formerly placed in genus *Ereunetes* with *C. mauri*. Monotypic.
Distribution. W & N Alaska and N Canada. Winters on Pacific coast from S Mexico to S Peru, and on Atlantic coast from Yucatán and West Indies to C Argentina.

Descriptive notes. 13-15 cm; 20-41 g; wingspan 34-37 cm. Breeding plumage duller than in most congeners; brownish grey upperparts with dark centres to scapulars; breast and flanks with dark streaks; toes partly webbed. Resembles *C. mauri*, but bill averages broader at base and shorter, with rounded or droplet-like tip; legs shorter. Female averages larger. Non-breeding adult plain grey-brown above; dark crown and eyestripe; face, breast and flanks white; faint lateral breast patches. Juvenile has varying amounts of rufous on scapulars and mantle.
Habitat. High and low Arctic and subarctic wet sedge or heath tundra, often near pools, rivers and lakes; river deltas in dry shrubby areas; sandy areas along rivers. Non-breeding habitat mainly coastal, on sandy beaches and intertidal mudflats, also in shallow lagoons with dead mangroves, sometimes salt-marsh; on migration, also at inland wetlands, edges of lakes, junctions of short-grass marshes and tidal flats.
Food and Feeding. During breeding season mainly chironomid larvae; also spiders, snails, larvae of other Diptera and beetles, and seeds; prey items usually 2-5 mm long. During migration, small aquatic and marine invertebrates, including small arthropods, especially amphipod *Corophium volutator*, various larvae, snails, molluscs and polychaetes, some terrestrial invertebrates such as insects (Diptera larvae) and spiders; on N migration up E USA, feeds on horseshoe crab (*Limulus polyphemus*) eggs. Pecks (visual) and probes (tactile); compared to *C. mauri*, probes less often and less deeply. Highly gregarious; occasionally, when food scarce and patchy, defends feeding territory.
Breeding. Lays Jun to early Jul. Monogamous. Territorial; density 11-100 pair/km². Low degree of natal philopatry (5%). Nest is mere depression filled with plant matter, often on top of small island or hill, under willow bush or small birch tree, or in tussock. 4 eggs, sometimes 3, with laying interval 24-32 hours; single brood; incubation 20-22 days, by both sexes; female usually leaves brood 0-11 days after hatching, occasionally (9%) male deserts family first; fledging 16-19 days. Nest success, in nests where at least 1 chick hatched, 7-100%; egg survival 25-59%; chick survival c. 50%; 0·3-1·2 young fledged per pair, 1·5-1·7 per successful pair; adult annual survival 70%. Age of first breeding 1 year. Oldest known individual 12 years.
Movements. Long distance migrant; non-stop flights of up to 4000 km; flocks of up to 350,000 birds may gather at key stopover sites. Few move to S Florida, most to West Indies and N South America, mainly Surinam and French Guiana. Alaskan birds move across Great Plains, sometimes farther E, especially on way S. C population migrates by James Bay, upper Bay of Fundy and W Atlantic; return migration across Gulf of Mexico and Great Plains. E Canadian population crosses W Atlantic to West Indies, with return migration up Atlantic coast. About two thirds of all juveniles spend summer on wintering grounds. High fidelity to staging areas and breeding grounds, but unknown for wintering grounds.
Status and Conservation. Not globally threatened. Total population estimated at 3,200,000-3,900,000 birds (1993); up to 1,000,000 breeding birds in E Canadian Arctic. Total winter population in South America estimated at 2,142,000 birds (1989), of which about 80% wintering on coast of Surinam. Flocks of up to 350,000 appear in upper Bay of Fundy and 1,122,000-2,200,000 estimated to stage there during S migration. Numbers migrating in E Canada declined significantly from 1974 to 1991, possibly in part due to cold breeding seasons in 1970's; numbers staging in Delaware Bay on N migration, have declined since 1986. Destruction and manipulation of coastal and inland wetlands, and perhaps pollution, are major threats to populations.
Bibliography. Amos (1991), Armstrong (1983), Ashkenazie & Safriel (1979a, 1979b), Ashmole (1970), Azevedo-Junior (1988), Bent (1927-1929), Biaggi (1983), Blake (1977), Blomqvist (1983a), Boates & Smith (1989), Brock (1990), Cartar (1984), Clark *et al.* (1993), Cramp & Simmons (1983), Driedzic *et al.* (1993), Dunn *et al.* (1988), Gilliland (1992), Grant, P.J. (1985), Wilson (1990).

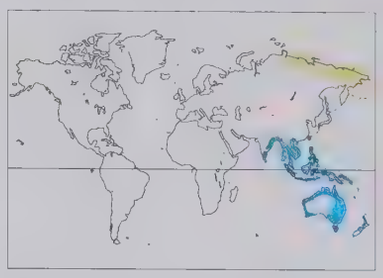
65. **Western Sandpiper**

Calidris mauri

French: Bécasseau d'Alaska **German**: Bergstrandläufer **Spanish**: Correlimos de Alaska

Taxonomy. *Ereunetes Mauri* Cabanis, 1857, South Carolina.
Formerly placed in genus *Ereunetes* with *C. pusilla*. Monotypic.
Distribution. E Chukotskiy Peninsula and W & N Alaska. Winters on Pacific coast from N California to N Peru, and locally down Atlantic coast from S New Jersey through Gulf of Mexico and West Indies to Surinam.



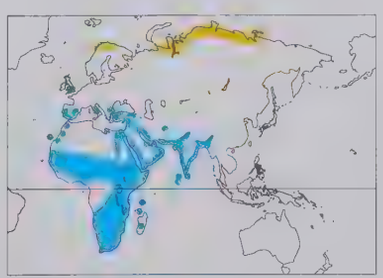
Descriptive notes. 14-17 cm; 18-42 g; wingspan 28-37 cm. Distinctive with rufous chestnut on crown and ear-coverts; chestnut and black scapulars with pale fringes; neck, breast and flanks heavily streaked dark brown; toes partly webbed. Resembles *C. pusilla*, but bill normally longer and more pointed, with drooping tip; legs longer. Female averages larger; tends to have longer bill, with more drooping tip. Non-breeding adult plain brownish grey above; head, neck and sides of breast finely streaked grey; rest of underparts white. Juvenile has rufous on upper scapulars and grey on lower scapulars; crown buff-grey and streaked; mantle blackish, fringed rufous and white; underparts white with breast washed orange-buff and finely streaked.
Habitat. For breeding, occupies tundra of low Arctic and subarctic, preferably dominated by dwarf birch, dwarf willow, crowberry and various shrubs; elevated areas required for nesting, wet areas for feeding; generally drier than breeding habitat of *C. pusilla*. In winter and on migration, preferably on estuarine mudflats and sandy beaches; also wide variety of other coastal or near-coastal wetlands, such as margins of lakes and ponds.
Food and Feeding. During breeding, mainly insects (larvae, pupae and some adults), especially Muscidae and chironomids, also craneflies and beetles; also spiders and small crustaceans; young mainly eat surface-dwelling insects, but later diet identical to adults'. On migration, amphipods, bivalves, polychaetes, fly larvae, beetles, ants, snails, spiders and occasionally seeds. Pecks or probes; feeds more in water and probes more than *C. pusilla*. Recently suggested that planktonic food may be taken, using a filtering system in bill. Highly gregarious.
Breeding. Lays late May to late Jun. Monogamous. Territorial; nests sometimes strongly clustered; density up to 490 pairs/km² (W Alaska), c. 30 pairs/km² (Siberia and N Alaska). Nest is depression in tundra, usually under dwarf birch, sometimes among grasses; filled with plant material. 4 eggs (3-5), with laying interval 23-28 hours; single-brooded, but may renest after clutch failure; incubation 21 days, by both sexes; fledging 18-21 days; in Alaska both parents tend young until fledging, although sometimes female deserts family earlier; in Siberia often female, but sometimes male, abandons mate during incubation, whereas latter may depart prior to fledging. Adult annual survival c. 70%. Age of first breeding probably 1 year. Oldest known individual 9 years, 2 months.
Movements. Unlike other small *Calidris*, migration appears as series of shorter flights; flight range c. 600 km. E Siberian birds join Nearctic population on migration. Most migrate down Pacific coast, although significant numbers move through interior North America, with Cheyenne Bottoms as most important interior stopover site, during both spring and autumn. During N migration Copper R Delta functions as a key staging site, used by more than 90% of total population; other major spring stopover sites are San Francisco Bay, Grays Harbor, Fraser Delta, Chesterman Beach, Tofino mudflats and Stikine Delta; southbound, Yukon Delta, Kuskokwim Bay and Boundary Bay. On Atlantic coast, common autumn migrant to Puerto Rico. Males winter, on average, closer to breeding grounds, and predominate at start of N migration. In autumn, departure occurs Jul to early Aug; adults precede juveniles, and females slightly precede males. Migrates in huge flocks. Many immatures stay in non-breeding range all year. Arrival on breeding grounds May to mid-Jun.
Status and Conservation. Not globally threatened. Total world population estimated at 2,000,000-3,000,000 birds (1994); other estimates have claimed 6,500,000 individuals, but unlikely; virtually entire population passes through Copper R Delta each spring, and numbers passing through British Columbia each autumn have been estimated at 2,400,000 birds. Stopover and wintering areas in need of protection, though some stopover sites are already listed as "Hemispherically Significant", including Cheyenne Bottoms, San Francisco Bay, Grays Harbor and Copper R Delta; oil spill from Exxon Valdez in Mar 1989, which just missed Copper R Delta, demonstrated vulnerability of even such a huge population.
Bibliography. Armstrong (1983), Ashmole (1970), Bardon (1991), Bent (1927-1929), Biaggi (1983), Blake (1977), Blomqvist (1983a), Brazil (1991), Brown (1962), Butler & Kaiser (1988), Butler *et al.* (1987), Cartar (1984), Colston (1975), Colwell (1993), Colwell & Landrum (1993), Cramp & Simmons (1983), Gill & Handel (1990), Harrington & Haase (1994), Haverschmidt (1968), Haverschmidt & Mees (1995), Hilty & Brown (1986), Holmes (1971a, 1972, 1973), Holmes & Pitelka (1968), Howell & Webb (1995a), Isleib (1979), Iverson *et al.* (1996), Knystautas (1993), Matthiessen (1994), Meyer de Schauensee & Phelps (1978), Monroe (1968), Morrison & Myers (1989), Mullarney (1992), Myers, Hildén & Tomkovich (1982), Myers, Morrison *et al.* (1987), Naranjo *et al.* (1994), Nisbet (1963), Norton (1972), Ouellet *et al.* (1973), Palindant *et al.* (1973), Rattner *et al.* (1995), Ridgely & Gwynne (1989), Root (1988), Scott & Carbonell (1986), Senner (1979), Senner & Martínez (1982), Senner, Norton & West (1989), Senner, West & Norton (1981), Slud (1964), Snyder (1966), Spaans (1978), Stevenson (1975), Stiles & Skutch (1989), Tomkovich (1996), Tomkovich & Morozov (1980, 1994), Tostain *et al.* (1992), Warnock & Takekawa (1996), Wetmore (1965), Wilson, W.H. (1993, 1994a, 1994b).

66. **Red-necked Stint**

Calidris ruficollis

French: Bécasseau à col roux **German**: Rotkehl-Strandläufer **Spanish**: Correlimos Cuellirrojo
Other common names: Rufous-necked Stint/Sandpiper, Eastern Little Stint

Taxonomy. *Trynga* [sic] *ruficollis* Pallas, 1776, Kulussutai, southern Transbaikalia.
Formerly placed in genus *Erolia*. May form superspecies with *C. minuta*. Monotypic.
Distribution. C & E Taymyr; Kharaulakh Mts and area around Lena Delta; R Kolyma to Chukotskiy Peninsula and S to extreme N Kamchatka; sporadically W & N Alaska. Winters in SE Asia, from E India, Myanmar, S China and Taiwan through Philippines and Indonesia to Solomon Is, Australia and New Zealand.



Descriptive notes. 13-16 cm, 18-51 g, wingspan 29-33 cm. Chestnut lower face, throat and upper breast; white around bill base and on part of supercilium; crown and upperparts have chestnut, black and white markings contrasting with grey upperwing; underparts white. Resembles *C. minuta*, but slightly larger; slightly shorter legs and rather longer wings; bill shorter and thicker. Female averages slightly larger in wing and bill. Non-breeding adult has crown streaked; grey lateral breast patches; usually indistinguishable from *C. minuta* in field. Juvenile has back buff and grey with pale edges; crown streaked buff and black, ear-coverts greyish; breast with ochre wash and faint streaks on sides of breast; very similar to *C. minuta* and *C. pusilla*.
Habitat. Low altitude montane tundra in subalpine belt, on mossy and scrubby tundra, usually in rather dry and raised areas. During non-breeding season, mostly coastal, on intertidal mudflats, sheltered inlets, bays and lagoons, but also commonly on wide variety of freshwater, brackish and saltwater wetlands; occasionally on sandy beaches and rocky shorelines.
Food and Feeding. On breeding grounds takes beetles, insect larvae, Hymenoptera and tiny seeds; may forage far from nest in wet habitat. Outside breeding season, small invertebrates, such as polychaete worms, crustaceans, insects and molluscs; also seeds. Constant pecking motion, like *C. minuta*; probes in sediment to depth of 20 mm, or jabs; also gleans. Feeds in dense flocks; birds spread out during feeding, but come together when flushed.
Breeding. Laying Jun. Monogamous. Densities 4-6 pairs/km², up to 28 pairs/km². Low degree of site fidelity. Nest is shallow depression lined with leaves and grass. 4 eggs, sometimes 3; single brood, but replacement clutches laid; incubation 20·5-22 days, by both parents; female leaves soon after hatching (especially in late breeders), and male usually tends chicks up to fledging; fledging 16-17 days. Annual survival estimated at 80%; longevity up to 10-15 years; oldest ringed bird at least 11 years, 1 month.
Movements. Migratory. Probably moves in large flocks. Uses several stopovers, mostly on coasts of Japan, Korea, SE China, Taiwan, Hong Kong, Vietnam, Malaysia, Indonesia, New Guinea, Philippines and W Micronesia; migrating flocks crossing Pacific often stage on islands. Some Siberian birds move overland and cross Krasnoyarsk, Irkutsk and Buryatskaya regions; some cross Mongolia, Manchuria and Ussuriland; others W to E Kazakhstan. Most of population breeding in Alaska appears to pass through Aleutian and Pribilof Is to migrate with Siberian population; some spend boreal winter in the Americas. Australia reached by late Aug and arrivals continue until Nov; juveniles arrive latest and may use different route; departure mainly Mar-Apr. Immatures usually remain in non-breeding range throughout 1st year, often moving inland after rains fill wetlands. Adults show high fidelity between years to non-breeding sites.
Status and Conservation. Not globally threatened. Australasian population estimated at 471,000 birds, with 353,000 wintering in Australia (1993); numbers apparently declining. In SE Asia, concentrations occur in Philippines and W Peninsular Malaysia. Locally common in breeding areas; in non-breeding areas often abundant. Populations in Tasmania have declined since mid-1980's; New Zealand populations have increased significantly since late 1950's. Most important Australian sites are Coorong and Eighty Mile Beach, but many also move to SE Australia, where human population is densest; in Victoria, birds seem not to be greatly disturbed by boating traffic and pedestrians. Hundreds died round L Forrestdale, Perth, Western Australia, after spraying with pesticides.

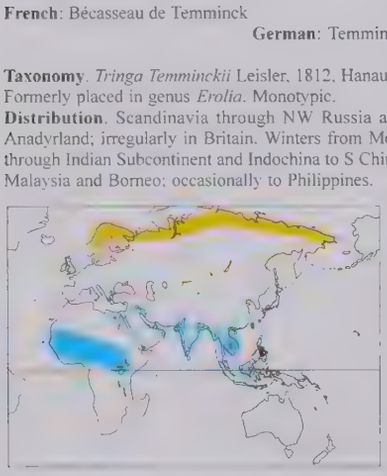
67. **Little Stint**

Calidris minuta

French: Bécasseau minute **German**: Zwergstrandläufer **Spanish**: Correlimos Menudo
Other common names: Lesser Stint

Taxonomy. *Tringa minuta* Leisler, 1812, Hanau am Main, Germany.
Formerly placed in genus *Erolia*. May form superspecies with *C. ruficollis*. Monotypic.
Distribution. N Scandinavia through S Novaya Zemlya and NW & NC Siberia to New Siberian Is and R Yana. Winters from Mediterranean and Africa through Arabian Peninsula and Persian Gulf E to Indian Subcontinent and Myanmar; small numbers in SE Britain and Madagascar.



Descriptive notes. 12-14 cm; 17-44 g; wingspan 28-31 cm. Tiny, compact stint with short bill; feathers of upperparts have dark brown centres and pale rufous fringes or tips; mantle with yellowish edges forming distinct "V"; head, neck and breast rufous buff with brown streaks; rest of underparts, throat and chin white. Differs from *C. ruficollis* by slightly longer bill and legs; white throat, dark streaks on sides of neck and breast. Female averages larger. Non-breeding adult has brownish grey upperparts mottled dark and fringed pale; crown grey, streaked dark; eyestripe and sides of breast dull grey; rest of face and underparts white. Juvenile has tertials, lower scapulars and wing-coverts with dark brown centres and rufous and white edges; white edges of mantle

form distinct "V"; head and breast suffused pale buff; pale grey crown, neck and broad eyestripe with fine streaking; whitish supercilium.
Habitat. Tundra of high Arctic, chiefly on dry ground at lower altitude, often among dwarf willows, near swampy areas or salt-marshes; avoids areas with more than 250 mm annual rainfall. On migration found at small inland waters and riverbanks, or coastal, on mudflats and seashore. In winter quarters mainly coastal, at estuarine mudflats, enclosed lagoons, tidal creeks; also at inland fresh waters, such as open pools in marshes, paddyfields, *jheels*.
Food and Feeding. Chiefly invertebrates; during breeding season primarily larval and adult Diptera and small beetles; after breeding also ants, Hymenoptera, water-bugs, annelids, small molluscs, crustaceans, freshwater mites and plant material. Feeds by rapid pecking actions, sometimes probes; detects prey by sight. Gregarious, in small to large flocks, up to several thousand birds; sometimes defends feeding territory.
Breeding. Lays late Jun to early Jul. Monogamous, polygynous or polyandrous. Loosely territorial, with no clearly defined area defended; little or no fidelity to breeding site. Density of up to 5 pairs/ha, more often c. 10 nests/km²; very variable between years. Nest on ground, exposed, but sometimes covered by vegetation, and lined with leaves and pieces of grass. 4 eggs, sometimes 3; incubation 20-21 days, by both parents, but in cases of polygamy by male or female only; polyandrous females may incubate a second clutch; chick orange to tawny, mottled above with black bands and dense rows of white or pale down tips, white underparts; chick-care by one parent; fledging period unknown; fledged young start migrating S after several days. Age of first breeding unknown, but at least some return to breeding grounds as 1-year-olds. Oldest ringed bird 8 years, 10 months.
Movements. Migratory; in broad front across much of W Palearctic; movements S-SW in Jul-Nov, birds returning mid-May to early Jun. Juveniles probably migrate farther W than adults, due to weather displacement. Finnish and Swedish population crosses C Europe, Italy, Mediterranean, France and Tunisia; also major routes between C Mediterranean and Black Sea, and via Caspian Sea and Kazakhstan lakes to and from E & S Africa, apparently following route via Rift Valley lakes; W & C Siberian breeders presumably winter in India, passing through Kazakhstan and also N through Mongolia and Tuva. In Britain, commoner in autumn than in spring, with few birds passing winter. Small numbers may migrate along E Asian coasts, including Hong Kong and Philippines. Many immatures remain S all year. Typical migrating flocks comprise 20-30 birds.
Status and Conservation. Not globally threatened. Population wintering in coastal W Africa and Europe considered to be stable and estimated at 211,000 birds (1989); of these, up to 123,000 in Guinea-Bissau, which was earlier estimated to hold 350,000 but only 60,000 in 1992/93, with numbers perhaps varying due to exchange with inland habitats; numbers inland evidently exceed those at coastal wetlands; wintering population in S Africa 23,000 birds; more than 1,000,000 birds estimated in NE & E Africa and SW Asia, with 250,000-500,000 in Sudan, some 100,000's along freshwater and soda lakes in Ethiopia and E Africa and over 100,000 in Egypt; in SC Asia at least 200,000 birds, with high numbers in India, Pakistan and Sri Lanka. In Norway, no overall change in breeding numbers since 19th century.
Bibliography. 68. Temminck's Stint
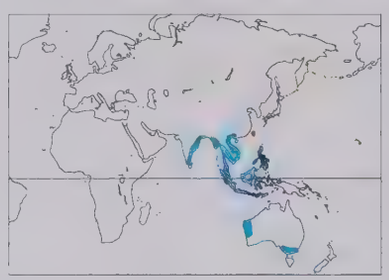
Calidris temminckii

French: Bécasseau de Temminck **Spanish**: Correlimos de Temminck
German: Temminckstrandläufer

Taxonomy. *Tringa Temminckii* Leisler, 1812, Hanau am Main, Germany.
Formerly placed in genus *Erolia*. Monotypic.
Distribution. Scandinavia through NW Russia and N Siberia E to Chukotskiy Peninsula and Anadyrland; irregularly in Britain. Winters from Mediterranean, N tropical Africa and Middle East through Indian Subcontinent and Indochina to S China, Taiwan and S Ryukyu Is, and S to Peninsular Malaysia and Borneo; occasionally to Philippines.



Descriptive notes. 13-15 cm; 15-36 g; wingspan 34-37 cm. Small, short-legged stint with broad white sides of tail and rump, unique amongst *Calidris*; upperparts range from dull grey to olive brown, with variable patches of black-brown, dull rufous and grey; head and breast grey-brown; breast heavily streaked brown; white on chin, throat and belly. Female averages slightly larger. Non-breeding adult has plain dark grey upperparts and head; breast uniform pale grey-brown; chin and throat white. Juvenile like non-breeding, but upperpart feathers brown-grey with dark subterminal band and buff fringes.
Habitat. Typical (southern) tundra, shrub tundra and along floodplains in forest tundra; on flat ground clear of vegetation, or covered with short grass interspersed with patches of shrubs; also near inlets, fjords, deltas and streams; upland and inland, at sheltered sites on shrubland fringes, around human habitation; avoids severe Arctic conditions. Outside breeding season, variety of wetland types, preferably inland freshwater sites, e.g. floodlands, irrigated fields, sewage farms and more or less densely vegetated wetlands; more rarely on tidal mudflats and coastal lagoons; avoids open coast.
Food and Feeding. At breeding grounds and inland, primarily insects and their larvae, especially beetles and Diptera, occasionally plant material; on coast, mainly annelids, crustaceans and small molluscs. Pecks prey from surface, rarely probes. Singly or in small groups of up to 30 birds.
Breeding. Lays late May to early Jul. Successive bigamy by both sexes, occasionally with third clutch. Territorial; up to 6-7 "pairs"/km², but on C Siberian tundra locally 25-40 (52) birds/km². Site fidelity c. 50% and some natal philopatry. Nest on ground, in open or low vegetation, lined with plant stems and leaves. 4 eggs (2-4); 2nd clutch started 2-9 days after 1st; each nest cared for by one parent, 1st by male; in case of 3 clutches, 2nd cared for by another male, 3rd cared for by female; incubation 21-22 days; chick obscurely mottled cinnamon-buff to ochraceous above with blackish band and white to buff down tips, buff-yellow face and throat, and white underparts; fledging 15-18 days. Nesting failure mainly caused by flooding and predation; c. 56% egg mortality; 3·5 hatchlings per succesful clutch; 1st-year mortality c. 50%; annual adult mortality 19%. Age of first breeding 1 year and older. Oldest ringed bird 11 years.
Movements. Migratory. Broad front migration spans towards N Africa and S Asia. Arrival in N Africa late Jul to mid-Sept or mid-Oct, reaching Mali Aug-Oct, Eritrea Sept to early Oct, and tropics mainly from Oct. Departs wintering grounds mainly late Mar to Apr, some as late as May. Small numbers winter in Europe, occasionally as far N as Britain. Scandinavian birds move S-SW in autumn. Usually migrates in small flocks, up to 250 individuals.
Status and Conservation. Not globally threatened. Wintering population in SW Asia unknown, but up to 10,000 have been counted in Iran; in SC Asia probably 25,000-100,000 birds, with high numbers in India and Pakistan; E & SE Asia probably up to 100,000 birds; no estimates available for populations wintering in Africa, and irregularly in Europe. Evidence for southward expansion of breeding range in Norway, and also, with irregular breeding, in Britain. Increases and decreases noted locally in Fenno-Scandia; breeding population estimated at 25,000 pairs, of which 20,000 in Sweden (1976).

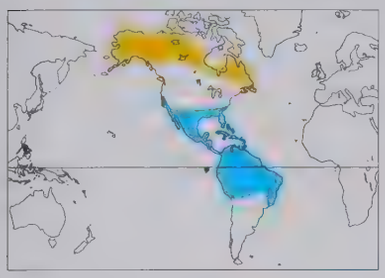
69. Long-toed Stint
Calidris subminuta

French: Bécasseau à longs doigts **Spanish**: Correlimos Dedilargo
German: Langzehen-Strandläufer

Taxonomy. *Tringa subminuta* Middendorff, 1853, Stanovoye Mountains, Russia.
Formerly placed in genus *Erolia*. Forms superspecies with *C. minutilla*, with which in past considered conspecific. Monotypic.
Distribution. Disjunct populations from forest zone of SW Siberia to S tundra of Koryak Mts; also Commander Is and N Kuril Is. Winters from E India and Indochina to Taiwan, and S through Philippines and Indonesia to W & SE Australia.

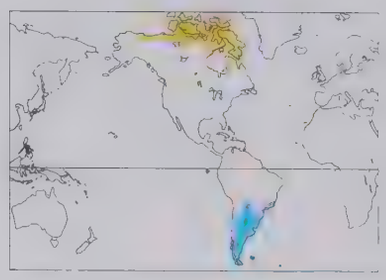


Descriptive notes. 13-16 cm, 20-37 g, wingspan 26-31 cm. Small, slim stint with relatively long neck, legs and toes; short bill; rufous crown and ear-coverts, with dark streaks; prominent whitish supercilium and narrow dark loral stripe; nape pale rufous and neck, flanks and rufous-tinged breast finely streaked dark brown; upperpart feathers have dark brown centres and rufous and pale buff fringes. Female averages slightly larger. Non-breeding adult has upperpart feathers with black-brown centres and grey edges; crown, neck and ear-coverts grey, finely streaked; breast suffused grey-brown with faint streaks on sides and flanks. Juvenile similar to breeding adult but streaking on breast finer, and more contrasting pattern on mantle and scapulars; rufous crown contrasts with white supercilium; head, neck and breast streaked.
Habitat. Breeds in wide variety of subarctic and boreal open habitats, often in open bogs or mountain tundra in taiga zone. In non-breeding season prefers inland wetlands, especially rice fields; also muddy or vegetated edges of coastal and sub-coastal shallow freshwater and brackish wetlands, sewage farms, salt-works and salt-marshes; less frequent on intertidal flats. Sometimes hides in depressions in mud.
Food and Feeding. Diet poorly known, but includes insects (carabid beetles), small gastropod molluscs, crustaceans and seeds. Usually feeds among vegetation at water's edge; often pecks prey items from mud or water surface; pecks more, probes less than *C. minutilla*. Feeds singly or in small flocks; possibly defends feeding territory in non-breeding period.
Breeding. Nests early Jun to Jul. Probably monogamous. In scattered single pairs, often very close together. High degree of site fidelity. Nest is shallow depression filled with leaves, well hidden. 4 eggs, sometimes 3; both parents incubate, only male tends brood. No further information available.
Movements. Migratory. Probably two main routes, which converge in China: down E coast of Asia, through Ussuriland, Manchuria, Japan and Korea; and overland on broad front through continental Asia, where locally abundant in Tuva; some indications of weak migration through Middle East. In Australia movements dispersive, between temporary wetlands. Most birds winter in SE Asia and Philippines; very few in Australia, though small numbers visit every year and their moult pattern suggests that they are different to SE Asian birds. S passage of adults, females first, starts early Jul and peaks Aug-Sept; N migration Apr-May. Only mildly gregarious, and seldom in large flocks.
Status and Conservation. Not globally threatened. Total wintering population probably 25,000-100,000 birds. Regular migrant to freshwater wetlands in Australia; annual maximum of 277 birds counted during austral summer shorebird counts in period 1981-1985. No specific threats identified, and species appears in no immediate danger, but poorly known.
Bibliography. Ali & Ripley (1980), Alström & Olsson (1989), Beaman (1994), Beehler *et al.* (1986), Blakers *et al.* (1984), Blomqvist (1983a), Brazil (1991), Coates (1985), Cramp & Simmons (1983), Curry (1984), Deignan (1945), Dickinson *et al.* (1991), Doherty (1991), Dunnett (1992), Étchécopar & Hüe (1978), Hirschfeld (1991), Hutton (1992), Jaensch (1988), Knystautas (1993), Lekagul & Round (1991), Leonovitch (1973), MacKinnon & Phillipps (1993), Marchant & Higgins (1996), van Marle & Voous (1988), Medway & Wells (1976), Miller *et al.* (1988), Myers *et al.* (1982), Perennou *et al.* (1994), Phillips (1978), Ripley (1982), Rogacheva (1992), Scott (1989), Short *et al.* (1990), Smythies (1981, 1986), Tomkovich (1980b, 1989, 1996), Urban *et al.* (1986), White & Bruce (1986), Williams, M.D. (1986).

70. Least Sandpiper
Calidris minutilla

French: Bécasseau minuscule **German**: Wiesenstrandläufer **Spanish**: Correlimos Menudillo
Other common names: American/Least Stint

Taxonomy. *Tringa minutilla* Vieillot, 1819, Halifax, Nova Scotia.
Formerly placed in genus *Erolia*. Forms superspecies with *C. subminuta*, with which in past considered conspecific. Monotypic.
Distribution. Alaska through NW & NC Canada to Quebec, Newfoundland and Nova Scotia. Winters from S USA through Central America and West Indies to N Chile and CE Brazil.



Descriptive notes. 13-15 cm; male 17-33 g, female 20-33 g. Smallest of all shorebirds, with needle-like bill; dark brown upperparts with chestnut and grey fringes; head dark with indistinct supercilium. Differs from *C. subminuta* by more compact build, shorter legs and slightly bill length; darker lores; breast washed brown, with dense streaking; darker, more uniform upperparts. Female averages slightly larger, especially in longer bill. Non-breeding adult has brown-grey upperparts with paler fringes; throat and breast washed and streaked grey brown. Juvenile has rufous cap and black-brown upperparts with chestnut and whitish fringes, forming thin "V" on mantle; breast suffused buff-grey with streaking at sides.
Habitat. Breeds from subarctic tundra to far N boreal forest, farther S than other Nearctic *Calidris*; on treeless vegetated bogs with nearby muddy areas, near fresh and brackish ponds, pools, lakes and brackish lagoons with vegetated sand dunes; tussock-heath ridges and valley bottoms; ditches near intertidal cobble and mudflats. During migration, on muddy margins of inland lakes, ponds, sloughs, riverbanks, ditches, bogs and marshes, and intertidal mudflats, mainly at upper edges of small creeks; also wet meadows and flooded fields; on coast, roosts in adjacent salt-marshes and wet pastures. In winter quarters, on muddy parts of similar variety of inland and coastal wetlands.
Food and Feeding. Benthic and terrestrial invertebrates smaller than 6 mm, such as small amphipods, particularly *Corophium*, gastropods, isopods, ostracods, adults, larvae and pupae of Diptera, beetles, worms and also eggs of horseshoe crabs (*Limulus polyphemus*). Probes in moist mud or pecks from surface; during brood-rearing, also in drier habitats; pecking rates very high. During non-breeding season, occurs in compact to scattered flocks; some may defend feeding territories. Diurnal and nocturnal.
Breeding. Laying mid-May to early Jun. Monogamous, for one season or longer. Territorial, with maximum reported density of 90 pairs in 111 ha; birds feed outside territory; males very faithful to sites; at least some natal philopatry. Nests in short grass or sedge on damp ground; where very wet, on drier rise or hummock; nest is depression in ground cover, sparsely lined with bits of dead vegetation. 4 eggs, laid at intervals of c. 30 hours; single brood; replacement clutches laid; incubation 19·5-23 days (starting with 4th egg), by both parents, but females briefer and mainly in evening; chick black and yellowish to golden or chocolate brown above with white-tipped down on middle of back, while hind crown and nape orange-buff mottled black, underparts whitish and face, neck and breast whitish with buff or brown tinge; both parents tend young; female deserts brood 1-2 weeks before male; fledging 14-20 days; young independent few days later. 11-40% of clutches predated, and also subject to trampling by cattle; 86-93% of eggs in successful clutches hatch; hatchling mortality 38-67%. Significant predation by falcons outside breeding season. Age of first breeding 1 year, possibly later in N. Oldest ringed bird 17 years old.
Movements. Migratory. Migrates in broad front over interior North America to S USA, Greater Antilles, Gulf of Mexico and NW South America; E population crosses Atlantic Ocean from NE North America to Lesser Antilles and NE South America, but returns N through S North America or up coast; part of W population migrates down Pacific coast to NW South America. Some fidelity to wintering and staging sites. Adults precede juveniles during S migration, departing respectively from late Jun and mid-Jul, and adult females precede males; arrives N wintering grounds late Jun to Jul, in Surinam mostly Aug but juveniles mid-Aug to Oct; in California most birds disperse S in Nov. Migrates N across USA and Canada in May, up E USA coast mid-Apr to mid-May, 1-2 weeks earlier on W coast; males arrive on breeding grounds c. 7 days earlier than females. Migrates in flocks of 10's to 100's.
Status and Conservation. Not globally threatened. Total population over 100,000 birds; Canadian breeding population estimated at 50,000-100,000 birds. Numbers apparently increased after hunting stopped in early 20th century. No significant trend in numbers staging on Atlantic coast in period 1972-1983. Numbers migrating through E Canada declined between 1974 and 1991, especially during late 1970's perhaps due to cold breeding seasons. Species is difficult to count, due to scattered distribution in wintering areas and mixing with other small *Calidris* species. Not threatened at breeding areas, but wetlands used for wintering and staging are threatened with destruction and irrigation.
Bibliography. Amos (1991), Armstrong (1983), Baker, M.C. (1977), Baker, M.C. & Baker (1973), Baldassarre & Fischer (1984), Bent (1927-1929), Biaggi (1983), Blake (1977), Blomqvist (1983a), Brooks (1967), Butler & Kaiser (1995), Colwell & Landrum (1993), Cooper, J.M. 71. White-rumped Sandpiper
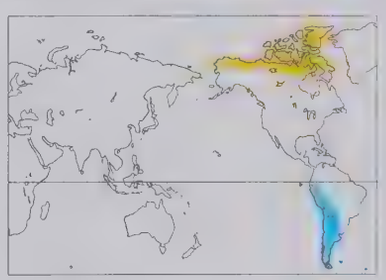
Calidris fuscicollis

French: Bécasseau à croupion blanc **Spanish**: Correlimos Culiblanco
German: Weißbürzel-Strandläufer
Other common names: Bonaparte's Sandpiper

Taxonomy. *Tringa fuscicollis* Vieillot, 1819, Paraguay.
Formerly placed in genus *Erolia*. Monotypic.
Distribution. NE Alaska and N Canada E to S Baffin I. Winters in SE South America, from CE Brazil to Tierra del Fuego.
Descriptive notes. 15-18 cm; 30-60 g; wingspan 36-38 cm. White uppertail-coverts contrast with dark rump and tail; yellow base to lower mandible; crown, cheeks, mantle and scapulars centred dark brown and edged rufous pink and grey; wing-coverts paler; sides of neck, breast and flanks spotted and streaked brown; at rest, wings project beyond tail tip. Male has inflatable throat; female averages slightly larger, with smaller white throat. Non-breeding adult has head and upperparts plain ashy brown with faint streaks and paler fringes; breast pale ashy brown with faint dark streaks. Juvenile like breeding adult, but upperparts more brightly coloured, and with more white tips; breast streaked and washed buff-grey.
Habitat. Breeds in low areas on marshy, hummocky tundra, well vegetated with mosses, grasses, sedges or shrubs. On migration in N South America, occurs on sea beaches, riverbanks, open fields and marshes. On wintering grounds, on intertidal mudflats, salt-marshes, flood fields, marshes, ponds and lagoons.



Food and Feeding. Invertebrates, including adult and larval insects, such as grasshoppers, beetles and craneflies, also spiders, small molluscs, crustaceans, leeches, polychaete worms and earthworms; some seeds. On breeding grounds, probes in moss and wet vegetation; during non-breeding season probes in muddy substrates at edge of water and picks prey from surface. May defend feeding territories on wintering grounds.
Breeding. Laying early to mid-Jun. Polygynous. Solitary; territory vigorously defended by male during egg-laying; birds often foraging outside territory; highest local density c. 1 bird/ha; nests usually widely spaced, but sometimes as close as 12 m. Male extends highly inflatable throat while performing aerial display. Nests near ponds, lakes or streams; well hidden, shallow scrape with lining of willow leaves and bits of moss and lichens. 4 eggs; females single-brooded, some males multiple-brooded; replacement clutches not reported; incubation 22 days (1 observation); male deserts female soon after egg-laying; chick mottled grey-brown or tawny and black above with white spots, face, throat and breast buffish, nape buff, grey and dusky, underparts greyish white; fledging 16-17 days. Nest predation by Arctic Skuas (*Stercorarius parasiticus*), other avian predators and Arctic foxes (*Alopex lagopus*); skuas also take young on Canadian coast in autumn. Age of first breeding presumably 1 year.
Movements. Migratory. Migrates in few, non-stop jumps of up to 4000 km; flies from NE North America over W Atlantic directly to N South America, whence continues with short hops down coast, then moving inland at mouth of R Amazon, reaching wintering grounds 1 month later; shows some degree of site fidelity. During N migration flies across Central America, Caribbean and inland North America, staging in Great Plains; little information on other staging areas. Departs from winter quarters Mar to mid-Apr, arriving N South America late Apr to mid-May, and on breeding grounds early Jun. Leaves breeding grounds up to early Aug; arrives at Canadian coast Aug to early Sept, N South America late Aug, and S Brazil and Argentina mid-Nov to Dec.
Status and Conservation. Not globally threatened. Population 50,000-100,000 birds, with 25,000 on Banks I (1959), 15,000 on Prince of Wales I and adjacent islands (1961), only rather irregularly in N Alaska; up to 30,000-40,000 birds at Decatur (Alabama) and Cheyenne Bottoms (Kansas) in spring. In past, large numbers were shot for human consumption. Preservation of wetlands in Great Plains and in Latin America is critical to secure areas of migratory fattening along migration route, but many of these areas are drying out due to irrigation for agricultural purposes.
Bibliography. Alström (1985, 1987), Alström *et al.* (1989), Armstrong (1983), Barthel (1989), Belton (1984), Beltzer (1986a, 1991), Bent (1927-1929), Biaggi (1983), Blake (1977), Blomqvist (1983a), de Bruin & Dietzen (1995), Cartar & Montgomerie (1985, 1987), Contreras *et al.* (1990), Cramp & Simmons (1983), Drury (1961), Dufourny & Lebailly (1991), Fjeldså & Krabbe (1990), Godfrey (1986), Harrington *et al.* (1991), Haverschmidt (1968), Haverschmidt & Mees (1995), Hayes (1995), Hayes & Fox (1991), Hilty & Brown (1986), Holmes & Pitelka (1962), Howell & Webb (1995a), Humphrey *et al.* (1970), Johnson (1965b), Maisonneuve *et al.* (1990), Matthiessen (1994), McCaffery (1983), Meyer de Schauensee & Phelps (1978), Miller (1983c), Miller *et al.* (1988), Monroe (1968), Myers & Myers (1979), Parmelee (1992), Parmelee, Greiner & Graul (1968), Parmelee, Schwilling & Stephens (1969), Parmelee, Stephens & Schmidt (1967), de la Peña (1992), Scott & Carbonell (1986), Sick (1985c, 1993), Skagen & Knopf (1994), Skagen *et al.* (1993), Snyder (1966), Spaans (1978), Stotz *et al.* (1992), Thomas, B.T. 72. Baird's Sandpiper
Calidris bairdii

French: Bécasseau de Baird **German**: Bairdstrandläufer **Spanish**: Correlimos de Baird

Taxonomy. *Actodromus Bairdii* Coues, 1861, Great Slave Lake, Canada.
Formerly placed in genus *Erolia* or alternatively in *Pisobia*. Monotypic.
Distribution. Wrangel I and Chukotskiy Peninsula E across N Alaska and N Canada to Ellesmere I, N Baffin I and NW Greenland. Winters in W & S South America.

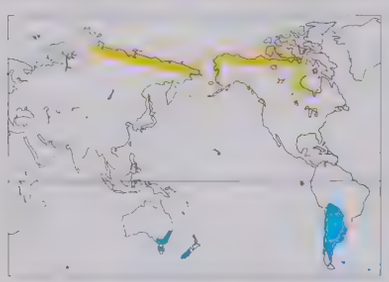
Descriptive notes. 14-17 cm; 32-63 g; wingspan 36-40 cm. Small sandpiper with long wings and short legs; black-brown crown, nape, mantle and scapulars with broad buff and brown fringes; ear-coverts and breast buff with brown streaks; lower back, rump and uppertail dark; at rest, wings project beyond tail. Very similar to *C. fuscicollis*, but complete breast band sharply cut off from white underparts; thin, pointed bill all dark; uppertail-coverts dark, with only narrow white edges. Female averages slightly larger. Non-breeding adult has more subdued coloration, becoming mainly dull greyish brown above. Juvenile like breeding adult, but with narrower, white fringes.
Habitat. Low mountain tops, river terraces and coastal barren areas and bluffs in high Arctic tundra; dry, high-lying lichen tundra and stony ridges. On migration and in winter, inland wetlands to coastal habitats, including grassland, ditches, irrigated or rain-soaked fields, pools in desert, sand dunes; occasionally in upper littoral zone of estuaries, mudflats and beaches; usually on higher parts of shore or dry fringes of wetland sites, often among vegetation. Locally abundant staging and in winter in high Andes along alpine lakes and on grasslands at altitudes of 2500-4700 m.
Food and Feeding. During breeding, mainly insects, such as chironomid and cranefly larvae and adults, and beetles; also spiders. On migration, adult and larval beetles, larval Diptera. Feeding action brisk; pecks up prey with quick bill jabs, less frequently probes. Less gregarious than most other calidrines; in winter, in flocks of 20-30 birds; some individuals defend feeding territory.
Breeding. Laying Jun. Monogamous. Density 5-8 pairs/km², up to 18 pairs/km² (Nearctic), c. 0·2 pairs/km² (Chukotskiy Peninsula). Nest is relatively exposed; simple, shallow depression in bare ground, or amid short vegetation, filled with bits of lichens or other vegetation. 4 eggs, sometimes 3, with laying interval of 1 day; incubation 19-21 days, by both parents; chick tawny above with bold black bands and clear rows of white down tips, face, throat and underparts white; both parents tend chicks, but female often leaves earlier, and females from late nest may even leave at or prior to hatching; fledging 19-20 days.
Movements. Migratory. Many migrate inland, across North American prairies, Rockies and N Andes, often staging at high altitude lakes. Funnel through Canada W of Hudson Bay, then stopover in prairies

of S Canada and N USA, especially Cheyenne Bottoms (Kansas), whereafter non-stop journey to Andes by mid-Aug, bypassing Central America off W coast. Adults depart early Jul, females slightly preceding males; juveniles migrate later from breeding grounds, from late Jul, in more leisurely fashion, and over broader front, from Pacific states to Atlantic; unlike adults, many juveniles move into SW USA; juveniles reach Patagonia mainly early Oct. N migration largely along same route.

Status and Conservation. Not globally threatened. Total population estimated at 50,000-100,000 birds, and thought to be relatively stable; remote, high latitude breeding grounds probably relatively secure at present, as is much of winter habitat. Cheyenne Bottoms is a very important staging site during northward migration.

Bibliography. Alström (1985, 1987), Alström *et al.* (1989), Andersson & Breife (1986), Armstrong (1983), Baldassarre & Fischer (1984), Bent (1927-1929), Blake (1977), Blomqvist (1983a), Brazil (1991), Contreras & Contreras (1994), Contreras *et al.* (1990), Cramp & Simmons (1983), Dixon (1917), Dott (1985), Drury (1961), Finch (1986b), Fjeldså & Krabbe (1990), Hayes (1995), Hilty & Brown (1986), Holmes & Pitelka (1968), Howell & Webb (1995a), Jehl (1979), Johnson (1965b), Knystautas (1993), Matthiessen (1994), Meyer de Schauensee & Phelps (1978), Miller *et al.* (1988), Murphy (1991), Myers *et al.* (1982), Norton (1972), Page (1978), Parmelee *et al.* (1967), Paulson (1983), de la Peña (1992), Prainsson (1995), Reid & Montgomerie (1985), Schiefer & Hodges (1987), Scott & Carbonell (1986), Sick (1985c, 1993), Slud (1964), Smith, F.T.H. (1987), Snell (1988), Stiles & Skutch (1989), Tomkovich (1985b, 1996), Urban *et al.* (1986), Wetmore (1965).

73. Pectoral Sandpiper



Calidris melanotos

French: Bécasseau à poitrine cendrée **Spanish**: Correlimos Pectoral
German: Graubrust-Strandläufer

Taxonomy. *Tringa melanotos* Vieillot, 1819, Paraguay.

Formerly placed in genus *Erolia*. Recently discovered Cox's Sandpiper "*C. paramelanotos*" shown to be hybrid between *C. ferruginea* and, most probably, present species (see page 446). Monotypic.

Distribution. Taymyr E through Chukotskiy Peninsula to W & N Alaska, NC Canada and W Hudson Bay; recent records from Yamal Peninsula, NW Siberia. Winters from S Bolivia, Paraguay and N Argentina to S Argentina; much smaller population in SE Australia, Tasmania and New Zealand.

Descriptive notes. 19-23 cm; male 45-126 g, female 31-97 g; wingspan 37-45 cm. Medium-sized sandpiper with heavily streaked buff breast sharply demarcated from white belly; black-brown mantle and scapulars with buff and chestnut fringes and whitish tips, wing-coverts paler; crown black-brown; crown, neck, face, breast and upper flanks streaked; legs yellow to greenish or brownish. Female smaller, with paler breast. Non-breeding adult duller. Juvenile like breeding adult, but upperparts have paler, narrower fringes, producing clear "V" across mantle and scapulars; finer streaking on breast.

Habitat. Breeds on Arctic tundra, usually in wet and well vegetated habitats, such as bog and tundra complexes with vegetation of moss or *Eriophorum*, bogs of *Polygonum*, and moss-lichen tundra lining water bodies. Outside breeding season, in variety of freshwater and brackish wetlands, both coastal and inland, including upland plateaux and *puna* zone at 3500-4500 m, in salt-marshes, swamps, lakes, floodplains, wet grasslands, sewage farms, commercial salt-works, coastal lagoons and bays. Usually feeds on drier, vegetated patches away from water's edge.

Food and Feeding. In breeding area, variety of insects, especially larvae and adults of craneflies, chironomids and Diptera; also beetles; spiders. On migration, often grasshoppers and crickets; diet outside breeding range includes annelids, molluscs, crustaceans, spiders, insects, algae and seeds. Feeding action leisurely, with steady walking; very similar to that of *C. acuminata*, combined pecking with rapid shallow probing. Often feeds in pairs or small flocks; some defend feeding territory.

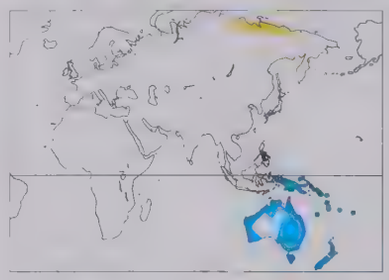
Breeding. Lays Jun-Jul. Monogamous, sometimes polygamous; males mate several times within territory, while females may visit territories of other males. Densities 0·5-6 birds/km² (Siberia) and over 10 nests/km² (Alaska), but numbers may vary considerably between years. Nest-site well drained and covered by sedges and grasses. Male guards mate, does not incubate, and often leaves area before hatching, to gather in pre-migratory flocks, although some males participate in brood defence. 4 eggs; incubation 21-23 days; fledging c. 3 weeks.

Movements. Siberian and North American birds migrate to South America, down Atlantic and Pacific coasts and through highlands of Colombia and Ecuador, and lakes in W Amazonia. Small fraction of Siberian population winters in Australasia and passes through Magadan, Commander Is, Kuril Is, Sakhalin, Ussuriland, Japan and Korea; on SE Asian coast, not recorded farther S than China, Taiwan and Hong Kong. Males start S migration late Jun; females to early Aug; juveniles migrate over broader range of North America early Aug and Oct. N migration Mar to early Jun, farther W via interior North America, but avoiding W USA; high numbers stage at Cheyenne Bottoms (Kansas). Regular on passage on Hawaiian, Phoenix and Line Is. Many 1st-years probably migrate N to breeding grounds in boreal spring.

Status and Conservation. Not globally threatened. Population spending boreal winter in South America estimated at 25,000-100,000 birds; no estimate available for Australasian wintering population. Extensive range and moderately high breeding densities attained in favorable habitats suggest that total population must be substantial. Possible westward expansion of breeding range recently noted, with birds recorded breeding on Yamal Peninsula.

Bibliography. Amos (1991), Armstrong (1983), Beehler *et al.* (1986), Beel (1991), Belton (1984), Bent (1927-1929), Biaggi (1983), Blake (1977), Blomqvist (1983a), Brazil (1991), Brooks (1967), Chambers (1989), Coates (1985), Contreras *et al.* (1990), Cramp & Simmons (1983), Eckert (1967), Fjeldså & Krabbe (1990), Flint & Tomkovich (1982), Garrod (1991), Hamilton (1959), Haverschmidt (1968), Haverschmidt & Mees (1995), Hayes (1995), Hilty & Brown (1986), Holmes & Pitelka (1968), Howell & Webb (1995a), Jaensch (1988), Johnson (1965b), Kaufman (1987), Kieser & Smith (1982), Kistchinski (1974), Knystautas (1993), Marchant & Higgins (1996), Matthiessen (1994), Meyer de Schauensee & Phelps (1978), Miller *et al.* (1988), Monroe (1968), Myers (1982), Norton (1972), de la Peña (1992), Pitelka (1959), Ridgely & Gwynne (1989), Rogacheva (1992), Scott (1989), Scott & Carbonell (1986), Shirihai (1996), Sick (1985c, 1993), Slud (1964), Snyder (1966), Stiles & Skutch (1989), Stotz *et al.* (1992), Taylor, P.B. (1980b), Tostain *et al.* (1992), Urban *et al.* (1986), Veling (1977), Wetmore (1965).

74. Sharp-tailed Sandpiper



Calidris acuminata

French: Bécasseau à queue pointue **Spanish**: Correlimos Acuminado
German: Spitzschwanz-Strandläufer
Other common names: Siberian Pectoral Sandpiper

Taxonomy. *Totanus acuminatus* Horsfield, 1821, Java.

Formerly placed in genus *Erolia*. Cooper's Sandpiper "*C. (Pisobia) cooperi*" was probably hybrid between *C. ferruginea* and present species (see page 446). Monotypic.

Distribution. NC & NE Siberia from Lena Delta to R Kolyma. Winters from New Guinea through Melanesia to New Caledonia and Tonga, and S to Australia and New Zealand.

Descriptive notes. 17-22 cm; male 53-114 g, female 39-105 g; wingspan 36-43 cm. Medium-sized sandpiper with rufous cap; dark brown upperparts with chestnut and whitish buff fringes; neck and breast heavily streaked; lower breast, upper belly and flanks have heavy blackish chevrons; legs yellowish to greenish or brownish. Differs from *C. melanotos* by lack of sharp demarcation of breast from belly; more distinct ginger cap; bolder white supercilium and prominent eye-ring. Female smaller, especially with shorter wing. Non-breeding adult lacks warm coloration; breast greyish with faint streaks, indistinctly demarcated from white belly. Juvenile has bright buff, chestnut and whitish fringes on upperparts, rufous crown and conspicuous white supercilium; breast bright buff, sometimes with faint streaks forming narrow gorget; flanks washed buff.

Habitat. Tundra of low Arctic and subarctic, especially damp hillock tundra and moss-sedge bogs with drier, shrub-covered hummocks; more specialized in habitat than *C. melanotos*. During non-breeding season, wide variety of coastal and inland wetlands (many ephemeral), including coastal salt-marshes, intertidal mudflats, shallow brackish lagoons, flooded grassland, river mouths; often feeds amongst vegetation, on drier margins.

Food and Feeding. Diet highly variable, including insects and their larvae, bivalves, snails, crustaceans, polychaete worms and seeds. Feeds at water's edge; uses combined pecking and jabbing with rapid, shallow probing. Often in large flocks of 100's to 1000's, fragmented into scattered groups for feeding.

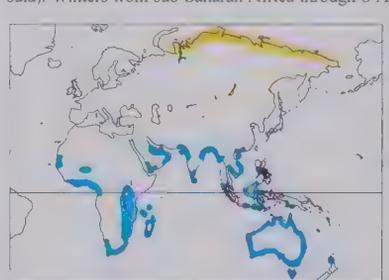
Breeding. Laying early Jun. Polygynous or promiscuous. Up to 20 birds/km². Large breast sac important in flight display, producing dry, crackling warble unlike any other calidrine vocalization. Nest well hidden, shallow depression filled with grass and leaves. 4 eggs, sometimes 3; single brood; only female incubates and cares for young; males leave during incubation period. Oldest ringed bird at least 5 years, 9 months.

Movements. Migratory. Leaves breeding grounds Jul-Sept. Main flyway via Transbaikalia, E of L Baikal, with smaller numbers in broad front from E Kazakhstan to Sea of Okhotsk; continues over E Mongolia and China, including Manchuria, to Japan, Korea, Philippines and New Guinea; probably overflies New Guinea during N migration. Juveniles on passage also occur regularly down Pacific coast and even into Alaska. Arrival in Australia Aug-Nov, and 25,000 birds arrived in single night, mid-Sept 1984; birds leave S Australia early, mid-Feb to early Mar, undertaking rather prolonged N migration to breeding grounds, with series of short flights. Movements within Australia seem to be dispersive, with birds leaving when wetlands dry. Most of population migrates to Australia, mainly SE; few 1st-year birds spend N summer in winter quarters.

Status and Conservation. Not globally threatened. Total population numbers c. 166,000 birds. Although using a variety of wetlands, and therefore probably relatively able to adapt to changes in wetlands brought about by human activities, most of world population winters in SE Australia, where human population density is high; therefore, suitable management of coastal and inland wetlands in this region is essential for survival of species. Most important wintering sites are Coorong (South Australia), and area of Port Hedland Saltworks, Eighty Mile Beach and Anna Plains wetlands (Western Australia).

Bibliography. (1980), Catley (1984), Chambers (1989), Coates (1985), Contreras (1988), Cramp & Simmons (1983), Dann (1983), Dementiev & Gladkov (1951b), Dennison (1979), Dickinson *et al.* (1991), Étchécopar & Hüe (1978), Flint & Kistchinski (1973), Flint & Tomkovich (1982), Fröbel (1982), Granberg (1978), Holyoak & Thibault (1984), Kaufman (1987), Kent (1991), Knystautas (1993), Kozlova (1966), Lane & Davies (1987), Lowe (1976), MacKinnon & Phillipps (1993), Mantlik (1986), Marchant & Higgins (1996), Myers *et al.* (1982), Perennou *et al.* (1994), Petersen (1989), Rogacheva (1992), Rosenband (1982), Scott (1989), Starks & Lane (1987), Tomkovich (1982c), Veling (1977), Watkins (1993), Webb & Conry (1979), White & Bruce (1986), Willi (1983), Williams, M.D. (1986), Wren (1988).

75. Curlew Sandpiper



Calidris ferruginea

French: Bécasseau cocorli **German**: Sichelstrandläufer **Spanish**: Correlimos Zarapitín

Taxonomy. *Tringa Ferrugineus* Pontoppidan, 1763, Christiansø Islands, Denmark.

Formerly placed in genus *Erolia*. Species name *testacea* formerly used, but pre-dated by *ferruginea*. Recently discovered Cox's Sandpiper "*C. paramelanotos*" shown to be hybrid between present species and, most probably, *C. melanotos*; Cooper's Sandpiper "*C. (Pisobia) cooperi*" was probably hybrid between present species and *C. acuminata* (see page 446). Monotypic.

Distribution. Arctic Siberia from Yamal Peninsula to Kolyuchinskaya Gulf (N Chukotskiy Peninsula). Winters from sub-Saharan Africa through S Asia to Australasia.

Descriptive notes. 18-23 cm; 44-117 g; wingspan 38-41 cm. Medium-sized sandpiper with longish neck and legs and long, decurved bill; head, neck and all underparts rusty rufous to deep chestnut-red, with dark streaks on crown; mantle and scapulars dark brown with chestnut and whitish fringes; wing-coverts greyer. Female normally has longer bill; somewhat paler, with greater tendency to have white barring on underparts. Non-breeding adult plain grey above, white below; contrasting white supercilium; sides of breast washed grey. Juvenile like non-breeding adult, but upperparts brownish with whitish fringes; breast washed buff with little streaking.

Habitat. Breeds on lowlands of high Arctic, along coast and on islands in Arctic Ocean, on open tundra with marshy depressions and pools. In winter, chiefly on coast, on muddy or sandy surface of tidal flats, coastal lagoons, estuaries and salt-marshes; also inland, at muddy edges of marshes, large rivers, lakes, salt-pans, irrigation schemes and flooded areas.

Food and Feeding. On breeding grounds, mainly insects, including adults, pupae and larvae, especially of Diptera and beetles; also bugs and leeches. Feeds by pecking and probing in wet marsh and peat. Outside breeding season, mainly polychaete worms, molluscs, crustaceans, such as amphipods, shrimps and copepods, and sometimes insects; occasionally seeds. Picks prey from mud or sand surface or probes in mud, regularly wading in shallow water; worms usually washed before being eaten. Diurnal and nocturnal. Gregarious outside breeding season, in flocks of up to several thousand.
Breeding. Nests Jun-Jul. Density 2·3 nests/km², but may exceed 50 birds/km²; nests sometimes 200-300 m apart. Nest on margins of marshes and pools, on slopes of hummocky tundra or dry patches in *Polygonum* tundra. Average clutch size 3·8, with laying interval of 1 day; incubation 19-20 days, by female only; chick-care by female; fledging 14-16 days. Breeding success highly dependent on lemming (*Lemmus sibiricus*, *Dicrostonyx torquatus*) abundance, with considerable predation by Arctic foxes (*Alopex lagopus*) during low lemming years, which occur once every 3-4 years. Age of first breeding 1 year or older. Oldest ringed bird at least 11 years.
Movements. Migratory. In W Palearctic three major routes: to White Sea, down W European coasts to W Africa; across E Europe via Black Sea and Tunisia to W Africa, following N African coast or flying via Mali; and via Black and Caspian Seas and across Middle East and Rift Valley lakes to E & S Africa. Route through W Europe little used during N migration; instead, many fly via Tunisia and Sivash (N Crimea); birds passing S through Sivash winter in E , C & S Africa and probably migrate N via Caspian Sea. Other routes are across Siberia to India, where some continue through SE Asia to Australia, but many winter in S India and Sri Lanka; also overland to E Asia and via Chinese coast to Australia, a route used more on N migration. Migrates long distances non-stop. Males show high degree of site faithfulness. During autumn migration adults precede juveniles and adult males depart early Jul, 3-4 weeks before females; more males than females migrate farther S. On S migration, crosses Europe in Jul, reaching Africa from mid-Jul in N and mainly Sept in S; arrives Australia late Aug to early Sept; juveniles follow 4-6 weeks later. N migration late Apr to May; arrives on breeding grounds from early Jun. Many 1st-year birds remain on wintering grounds while other non-breeding birds apparently remain just S of breeding grounds, in C Siberia.
Status and Conservation. Not globally threatened. Population wintering in W Africa and SW Europe estimated at 436,000 birds, of which 340,000 in Guinea-Bissau, but possibly up to 50,000 more in Guinea; E Africa and SW Asia 310,000, and species is typically most abundant wader on E African coast, with 90,000-120,000 in Tanzania; SC Asia at least 100,000 birds, with high numbers in SE India and Sri Lanka; E & SE Asia 60,000; and Australia 188,000. Australasian population possibly declining. Species has bred in N Alaska, apparently only irregularly, between 1962 and 1972.
Bibliography. 76. **Purple Sandpiper**

Calidris maritima

French: Bécasseau violet **German**: Meerstrandläufer **Spanish**: Correlimos Oscuro

Taxonomy. *Tringa Maritima* Brünnich, 1764, Christiansø Islands, off Bornholm, Denmark.
Formerly placed in genus *Erolia*. Forms superspecies with *C. ptilocnemis*, with which sometimes considered conspecific. Considerable geographical variation in size may warrant recognition of at least two subspecies. Monotypic.
Distribution. Arctic and subarctic, from NE Canada through Greenland, Iceland, Svalbard and Franz Josef Land to NW Siberia; also N temperate regions of Fenno-Scandia. Winters on coasts of E North America and NW Europe.

Descriptive notes. 20-22 cm; male 52-94 g, female 60-105 g; wingspan 42-26 cm. Medium-sized sandpiper with yellow legs and yellow base to bill; black-brown crown, mantle and scapulars with chestnut, pale buff and whitish fringes; whitish supercilium; neck, breast and flanks heavy streaked brown. Very similar to all but nominate race of *C. ptilocnemis*; normally has finer streaks on underparts, although some birds can have similar dark smudges; white wingbar normally fainter. Female averages slightly larger, especially with longer bill. Non-breeding adult has black-brown head and upperparts with pink or buff tips to crown, mantle and scapulars, and white spots and streaks on face, neck and breast; wing-coverts with whitish fringes; purplish gloss over back. Juvenile like adult breeding, but mantle and scapulars with pale chestnut fringes, wing-coverts and tertials with pale fringes; breast washed brown-grey and distinctly spotted.
Habitat. In high Arctic breeds from sea-level up to c. 300 m, in low Arctic and subarctic also on inland uplands, close to fringes of snow and ice; also on rocky islands and islets; on wet tundra with cover of mosses, and on barren, rocky upland tundra with patches of lichens and vegetation; shingle beaches, among boulders near streams; on Svalbard, before and after breeding, mainly on mudflats, shingle beaches and coastal lagoons. Outside breeding season, on wave-beaten tidal rocky shores with nearby high tide rocky roosting place; also on breakwaters, jetties and piers.
Food and Feeding. During breeding season, invertebrates, including insects such as springtails, adults, pupae and larvae of dipteran flies, ichneumons and aphids, spiders, gastropods and annelid worms; also plant material, such as leaves, buds, berries and seeds. During migration and winter, many gastropods, especially *Littorina* and bivalves, e.g. mussels (*Mytilus edulus*); also insects, including beetles and dipteran flies, small crustaceans (e.g. amphipods), annelid worms and some algae (e.g. *Enteromorpha*). Runs over seaweed and rocks in littoral zone, sometimes almost into waves, picking prey from between rocks, mussels or barnacles or turning over seaweed or debris; also picks from tundra surface and rarely probes in soil; swims well. Probably mainly diurnal feeder, although nocturnal feeding observed. Gregarious, often also during breeding season, usually in small flocks but sometimes up to 250 birds; in Scotland, 40-100 birds/km of rocky shore.
Breeding. Laying from mid-May in Faeroes and Iceland, late Jun in Svalbard, mid-Jun to mid-Jul in Russia. Monogamous. Solitary and territorial; also feeds outside territory. Densities low, 0·04-11 nests/km²; high degree of site faithfulness. Nests in tundra moss, in the open; nest is small scrape, lined with plant material. 4 eggs, sometimes 3, laid at 24-48 hour intervals; single brood; incubation 21-22 days, starting with last egg, by both parents equally, though during first 2 weeks males less during day; chick extensively black above, mottled with cinnamon and with white specks, much black on face, underparts pale greyish or off-white; young tended by male, female deserting just before or after hatching; fledging 21-24 days. On Svalbard, 35% of hatchlings survived to 35 days old. Breeds first at 2 years old, sometimes 1 year old; oldest ringed bird 8 years, 1 month.
Movements. Migratory and sometimes partially migratory, but movements in various low Arctic and N temperate regions unclear. Non-breeding range extends further N than in other *Calidris*, to just below ice, e.g. SW Greenland, Finnmark and Murmansk, and S to Maryland (USA) and W France. Northernmost breeders fully migratory. Easternmost breeders migrate W to Murmansk or beyond. Unclear whether breeders at S of range are replaced by N breeders or N breeders show leap-frog migration, wintering S of S breeders. E Greenland breeders believed to winter in Iceland. Birds breeding in W Greenland winter in W & S Greenland. Ringing recoveries indicate migration between W Europe and Iceland, Greenland, Newfoundland and Baffin I, and between Norway and E Britain. Post-breeding migration later than in other *Calidris* species; females depart breeding grounds in advance of males and young, from Iceland in late Jun; males in Iceland until late Aug, and on Arctic islands from late Aug to mid-Sept. Arrival in North Sea and Iceland Oct-Nov. N movement Apr-May, and arrival in N breeding grounds mid-May to mid-Jun.
Status and Conservation. Not globally threatened. Altogether c. 66,000 breeding pairs in NW Europe, with some 50,000 pairs in Iceland (1985), 10,500 pairs in Norway (1981), 2000-4000 in Svalbard (1981) and 2000 in Sweden (1984). Eurasian population, wintering on E Atlantic coasts, estimated at 50,000 birds (1989) and considered to be stable; in winter 10,000's on Icelandic and Norwegian coasts, and c. 20,000 in Britain. Nearctic population comprises c. 10,000 birds.

77. **Rock Sandpiper**

Calidris ptilocnemis

French: Bécasseau des Aléoutiennes **German**: Beringstrandläufer **Spanish**: Correlimos Roquero
Other common names: Aleutian/Pribilof Sandpiper

Taxonomy. *Tringa ptilocnemis* Coues, 1873, St George Island, Pribilof Islands.
Formerly placed in genus *Erolia*. Forms superspecies with *C. maritima*, with which sometimes considered conspecific. Birds from Kuril Is have on occasion been awarded separate race *kurilensis*. Four subspecies normally recognized.
Subspecies and Distribution.
C. p. quarta (Hartert, 1920) - Kuril Is, S Kamchatka and Commander Is.
C. p. tschuktschorum Portenko, 1937 - E Chukotskiy Peninsula, St Lawrence I, Nunivak I and W Alaska; winters in NW North America and locally in E Japan.
C. p. ptilocnemis (Coues, 1873) - St Matthew and Hall Is and Pribilof Is; winters on Alaska Peninsula.
C. p. couesi (Ridgway, 1880) - Aleutian Is and Alaska Peninsula.

Descriptive notes. 20-23 cm; male 80-132, female 118-135 g. Chunky, medium-sized sandpiper. Adult nominate (and many *tschuktschorum*) very pale on head, neck and breast with dark patches on lores, ear-coverts and lower breast; rich buff fringes to upperparts; underwing extensively white; recalls *C. alpina*, but different shape and face pattern. Other races virtually identical to *C. maritima*, but generally darker chestnut fringes above; broader streaks below create variable blackish patch on breast and sometimes belly; white wingbar typically bolder. Female averages larger, especially with longer bill. Non-breeding adult of nominate has grey upperparts and pale grey breast, with rest of underparts mainly white; all other races like *C. maritima*. Juvenile nominate similar to that of *C. maritima*, but scapulars fringed pale chestnut and buff, and breast washed buff; other races very similar to *C. maritima*. In addition to plumage, races differ in size, with nominate largest, *couesi* smallest.
Habitat. Nests in upland tundra in coastal regions, probably at lower altitudes than *C. maritima*, in areas with cover of lichens, mosses and sometimes dwarf willows on rolling plains and in low mountains; also on exposed hills, along stream beds and on grassy wet tundra. Outside breeding season, occurs on rocky shores and stony beaches; on large boulders and rocky shelves covered with seaweed; also tidal mudflats. Often with *Aphriza virgata*. Roosts on rocks near feeding grounds just above high tide spray.
Food and Feeding. Molluscs (including snails), marine worms, crustaceans, icebound sea lice, sandfleas, flies, beetles and gammarids; some algae. Picks prey from mussel and barnacle beds, and especially from mats of foliose algae, while walking slowly; often feeds up to breast in water, and swims readily; on Pribilof Is, often probes in muddy and sandy areas. Can form rather large flocks in winter.
Breeding. Laying early May to late Jun, mainly early Jun. Monogamous, often for several years. Up to 12 breeding pairs/km²; high degree of site fidelity. Nests often among dense cover of reindeer moss, or among *Hyphnum* mosses and dwarf willow; also in debris on beach gravel. 4 eggs, laid at intervals of 1-3 days; replacement clutches can be laid; incubation probably c. 20 days, by both parents; chicks tended by male; immediately after fledging, young move to beach, later joined by adults, forming

flocks of over 100 birds. Breeding success may be strongly affected by Arctic foxes (*Alopex lagopus*) and other predators.

Movements. Partly migratory; leap-frog migration, with northernmost breeders winter S of more S breeding populations. Race *quarta* possibly only moves short distance to C Kuril Is; *tschuktschorum* migrates to Alaska and farther S, regularly to Tokyo region in Japan, and Oregon and N California; nominate moves to Alaska Peninsula; *couesi* thought to be resident, possibly moving as far as Kodiak I in winter. Late autumn migrant. Returns to breeding grounds early, from mid-Apr, and adults start autumn migration early Jul, followed by juveniles in late Jul to early Aug. Occurs on N Vancouver I from mid-Sept and in Oregon from mid-Oct, remaining till early May.

Status and Conservation. Not globally threatened. No population estimates available; numbers thought to be low; 4000 counted on Nelson Lagoon, Alaska Peninsula, in 1979, of which maximum of several hundred were breeding pairs. Winter counts from periphery of wintering distribution, in NW America, show numbers decreasing since 1970's; although the actual numbers counted were very low, this might suggest overall decreasing numbers or contraction of wintering range in S.

Bibliography. Armstrong (1983), Beaman (1994), Bent (1927-1929), Blomqvist (1983a), Boland (1990), Brazil (1991), Conover, B. (1944), Gabrielson & Lincoln (1959), Gill & Handel (1981, 1990), Hanna (1921), Matthiessen (1994), Miller *et al.* (1988), Murie (1959), Myers *et al.* (1982), Paulson & Erckmann (1993), Portenko (1972), Root (1988), Tomkovich (1982a, 1982b, 1994b, 1996).

78. Dunlin

Calidris alpina

French: Bécasseau variable **German**: Alpenstrandläufer **Spanish**: Correlimos Común
Other common names: Red-backed Sandpiper

Taxonomy. *Tringa alpina* Linnaeus, 1758, Lappland.

Formerly placed in genus *Erolia*. During recent years 5-13 races have been recognized, but validity of some obscure; suggested race *centralis* included in *alpina*; race *hudsonia* sometimes included in *pacifica*, and *pacifica* sometimes included in either *sakhalina* or *arcticola*. Nine subspecies recognized.

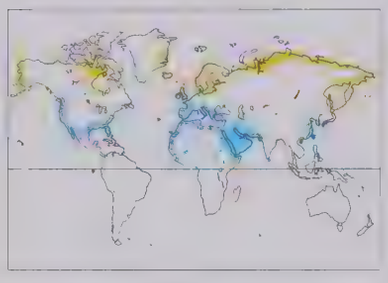
Subspecies and Distribution.

C. a. arctica (Schioler, 1922) - NE Greenland; winters mainly in NW Africa.

C. a. schinzii (C. L. Brehm, 1822) - SE Greenland and Iceland through Faeroes and British Is to Baltic and S Scandinavia; winters in S Europe and NW Africa.

C. a. alpina (Linnaeus, 1758) - N Scandinavia and N Russia E to R Kolyma; winters from W Europe and Mediterranean to NW India, and sparsely to Bangladesh.

C. a. sakhalina (Vieillot, 1816) - R Kolyma to Chukotskiy Peninsula and Anadyrland; winters in E China, Korea, Japan and Taiwan, and perhaps in small numbers in W North America.



C. a. actites Nechaev & Tomkovich, 1988 - N Sakhalin; wintering grounds unknown.

C. a. kistchinskii Tomkovich, 1986 - N Sea of Okhotsk and Koryak Mts through Kamchatka to Kuril Is; wintering grounds unknown.

C. a. arcticola (Todd, 1953) - NW Alaska N of Seward Peninsula, and NW Canada; winters in E China, Korea and Japan.

C. a. pacifica (Coues, 1861) - SW Alaska S of Seward Peninsula; winters in W USA and W Mexico.

C. a. hudsonia (Todd, 1953) - C Canada; winters in SE USA and probably E Mexico.

Descriptive notes. 16-22 cm; 33-85 g; wingspan 33-40 cm. Smallish, short-necked sandpiper with hunched posture; rufous upperparts, black belly; longish bill noticeably decurved, especially towards tip. Female averages larger and longer-billed; often has browner, less contrasting hindneck. Non-breeding adult has plain grey head, breast and upperparts; white chin, throat and lower underparts. Juvenile has pale buff, streaked breast; flanks and sides of white belly with lines of bold brownish spots. Races differ mainly in size, bill length, coloration of upperparts and extent of black on belly: *pacifica* and *hudsonia* largest and brightest, with longest bills; *arctica* smallest and dullest, with shortest bill; fringes of upperparts rusty-red in *alpina*, yellower in *schinzii*, reddish yellow in *arctica*.

Habitat. Utilizes wide variety of breeding habitats, primarily on moist, boggy ground, interspersed with surface water, including tussock tundra and peat-hummock tundra in Arctic, and wet coastal grassland, salt-marshes and wet upland moorland. Outside breeding season, mainly at estuarine mudflats, but also at wide variety of freshwater and brackish wetlands, both coastal and inland, including lagoons, muddy freshwater shores, tidal rivers, flooded fields, sewage farms, salt-works; sometimes on sandy coasts.

Food and Feeding. During breeding, diet includes insects, primarily adults and larvae of Diptera, craneflies, beetles, caddisflies, wasps, sawflies and mayflies; also spiders, mites, earthworms, snails, slugs and plant material. Non-breeding diet chiefly polychaete worms and small gastropods; also insects, crustaceans, bivalves, occasionally small fish and plant matter. Feeds mainly by probing, in quick manner, often interspersed with short runs; also by "sewing", lunging and pecking. Most prey swallowed as bill extracted from mud; worms often washed before swallowed; when ingesting molluses, ejects shell fragments by regurgitation. Diurnal and nocturnal forager. In non-breeding range highly gregarious.

Breeding. Lays Jun to early Jul in Arctic, late Apr to May in S. Monogamous. Solitary; locally up to 100 pairs/km², more often 3-30 birds/km²; parents feed within territory. Nest concealed in vegetation, usually on top of tussock; nest cup filled with grass and leaves. 4 eggs, sometimes 3, with laying interval 24-36 hours; single brood, rarely second is started; often starts replacement clutch after failure; incubation 20-24 days; both sexes incubate and tend brood, female usually leaving first; chick ochraceous tawny to orange-cinnamon above mottled with black bands and dense rows of white down tips, ochraceous face and dirty white underparts; fledging 18-24 days. Number of hatchlings per nest 0·83-1·72, but 0·3-0·4 in a declining *schinzii* population. 1st-year mortality 62-75%; adult annual mortality 25-39% (Europe). Age of first breeding 1 year or older. Oldest recorded bird 24 years.

Movements. Migratory. Variety of migration strategies, from short coastal flights to long, non-stop flights overland on broad front. Race *arctica* moves from Greenland through Iceland, Britain and W France to Morocco and W Africa, primarily to Banc d'Arguin, Mauritania; arrives in Africa from late Jul and departs mainly Mar to early Apr; return migration farther W up W Britain, probably overflying Iceland. Race *schinzii* passes through Britain, France and Portugal to NW Africa; few may winter in SW England; continental birds move N up continental coasts, when fewer reach Britain than after breeding. Race *alpina* winters in Europe and NW Africa; easternmost birds migrate farthest; many moult in Wadden Sea or Wash, arriving from Jul, followed by W movements in Oct-Nov to British Is; birds wintering in E Mediterranean make long distance, flights overland across E Europe. At least 3 races move down E Asian coast, where passage recorded through Ussuriland, Korea, Japan, Hong Kong and coastal China. Race *arcticola* stages in W Alaska, and crosses Bering Strait to E Asian winter quarters. Almost entire population of *pacifica* uses Copper R Delta, SE Alaska, as spring staging site. Some 1-year-old birds remain in non-breeding range all year.

Status and Conservation. Not globally threatened. Total population of *arctica* estimated at 15,000 birds (1989); *schinzii* 821,000 birds (1989), virtually all breeding in Iceland, with c. 10,000 pairs in temperate Europe (1986); *alpina* 1,373,000 birds (1989), possibly few 100,000's more, with 55,000 pairs breeding in Scandinavia (1986); *sakhalina* probably c. 100,000 birds; *pacifica* 450,000-600,000 birds (1992); *hudsonia* more than 100,000 birds. Total European wintering population c. 1,000,000 birds, of which up to 566,000 in British Is; this European population has declined considerably since 1970, especially in Britain, France, Belgium and Portugal, but seems to have stabilized now or even recovering somewhat; on migration, c. 900,000 pass NW Europe and up to 1,200,000 birds have been counted in Wadden Sea; up to 800,000 on Banc d'Arguin; over 100,000 in Egypt; c. 150,000 birds winter in E Africa and SW Asia, where very common in Oman, Saudi Arabia and Iran; 25,000-100,000 birds in SC Asia. Populations of races *arctica* and *schinzii* considered stable. In winter, species restricted to small number of estuaries, making it vulnerable to changes in this restricted habitat; such sites under pressure from land reclamation, pollution incidents, and in Britain from spread of *Spartina anglica* on mudflats resulting in decreased feeding area. Palearctic breeding populations at N latitudes stable; at temperate latitudes declining (*schinzii* in Britain, Finland, Denmark and Estonia), chiefly due to changes in land use; Scottish breeding population has declined by 17% due to afforestation of moorland. Race *hudsonia* shows (non-significant) declining trend over last decades. Rarer and poorly known races should be monitored.

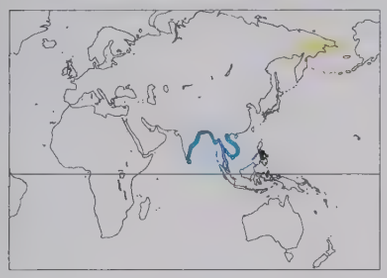
PLATE 45 ➤

PLATE 45

inches 4
cm 10



Genus *EURYNORHYNCHUS* Nilsson, 1821

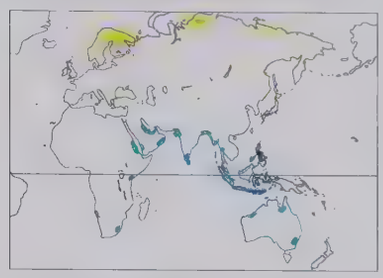
79. Spoon-billed Sandpiper

Eurynorhynchus pygmeus

French: Bécasseau spatule **German**: Löffelstrandläufer **Spanish**: Correlimos Cuchareta
Other common names: Spoonbill Sandpiper

Taxonomy. *Platalea pygmea* Linnaeus, 1758, Surinam = eastern Asia.
Often placed in genus *Calidris*. Monotypic.
Distribution. Chukotskiy Peninsula S to N Kamchatka. Winters locally from SE India and Sri Lanka to Indochina and S China, and S to Singapore.

Descriptive notes. 14-16 cm; male averages 29·5 g, one female 34 g. Small wader closely resembling *Calidris*, but with spatulate bill; red-brown head, neck and breast with dark brown streaks; upperparts blackish with buff and pale rufous fringes. Resembles *Calidris ruficollis*, but very different bill. Female averages slightly larger. Non-breeding adult lacks reddish coloration, but has pale brownish grey upperparts with whitish fringes on wing-coverts; supercilium and underparts white. Juvenile has blackish upperparts with white and buff fringes; wing-coverts paler; underparts white with buff on breast; crown and broad eyestripe brown, supercilium white.
Habitat. Nests on sea coasts with sparsely vegetated sandy ridges near lakes and marshes, often near a river mouth, lagoon or sandy spit; also stream-deposited gravel strips alternating with marshy sections on dry and gravelly tundra. During non-breeding season, apparently on muddy coasts and mudflats in coastal lagoons.
Food and Feeding. Terrestrial insects, including beetles, Hymenoptera and Diptera, small seeds, larvae of beetles and small aquatic amphipods; possibly larval crustaceans, juvenile polychaetes and juvenile molluscs. On breeding grounds usually feeds around freshwater pools. Feeds in shallow water and soft, wet mud by sweeping bill from side to side, while moving forward slowly, much like Eurasian Spoonbills (*Platalea leucorodia*); also picks at food items from water and mud surface; drill-like action with bill tip in mud, bill held slightly open; also observed foot-trembling. Feeds alone or in small flocks and often associates with small calidrines.
Breeding. Nests Jun-Jul. Monogamous, usually for more than one season; parents feed in territory, but also in communal feeding areas. Site faithful, with c. 65% of adults returning each year, and males establishing territories in same places. Two nests found in area of mosses, sedges and creeping osiers; one lined with dwarf willow leaves. 4 eggs, usually 3 in replacement clutches; incubation probably 18-20 days, by both parents; chicks initially tended by both parents, but female abandons when they are 4·5-6 days old, or immediately after hatching in late broods; males leave when chicks are 15-20 days old. Adults aggressive towards conspecifics. Breeds successfully only when lemmings (*Dicrostonyx groenlandicus*) present in moderate or high numbers, as predators alternatively feed on eggs and chicks when lemmings not available. Males do not breed before 2 years of age. Oldest ringed bird more than 10 years.
Movements. Migratory. Migrates along coasts of E Asia. During non-breeding season occurs at scattered localities on coasts of E, SE & SC Asia. Migrates N through E Russia from late May to early Jun; after breeding season, adults migrate Jul to late Aug, females first, and juveniles early Aug to mid-Oct. Most frequented stopover areas are S Sakhalin and W Kamchatka. Occurs on passage in North and South Korea, Japan, Taiwan, Hong Kong and E China, chiefly in late Apr to May and Sept; small numbers recorded wintering in Vietnam, Thailand, Peninsular Malaysia, Singapore, Myanmar, Bangladesh, E India and Sri Lanka; large numbers observed only in Bangladesh; vagrant to Alaska and Canada. Main wintering area or areas still undiscovered.
Status and Conservation. VULNERABLE. Total population estimated at 2000-2800 pairs. Stopover sites holding 10's to 100's of birds are mouth of R Moroshechnaya (WC Kamchatka) and Lososey Harbour (S Sakhalin); in addition, Terpeniya Bay (SC Sakhalin), coasts of Tatarski Strait and S Primorskiy area may prove important, as may other sites. In winter quarters, highest number counted is 257 birds on islands in Bay of Bengal in Bangladesh (1989); also regularly found in Maulavir Char (50 birds), Dhal Char and Urir Char in SE Bangladesh (1987-1991); 48 birds in Orissa, EC India, in 1992. In 1993, only 3 birds encountered during Asian Waterfowl Census. Wintering sites of rest of population remain unknown. Breeding habitat is limited to suitable patches distributed along narrow coastal zone. Combination of small population, specialized breeding habitat requirements and high risk of nest predation makes species vulnerable.
Bibliography. Ali & Ripley (1980), Bent (1927-1929), Burton (1971), Cha Meiwah & Young (1990), Collar & Andrew (1988), Collar *et al.* (1994), Dixon (1918), Étchécopar & Hüe (1978), Fujimaki & Haneda (1976), Gerasimov (1988), Howes & Parish (1989), Inskipp & Collins (1993), Knystautas (1993), Lim Kimseng (1994), MacKinnon & Phillipps (1993), McWhirter (1987), Medway & Wells (1976), Perennou *et al.* (1994), Piersma (1986d), Portenko (1957, 1972), Rosair (1995c), Sauppe *et al.* (1978), Scott (1989), Smythies (1986), Sugathan (1985), Swennen & Marteijn (1988), Thompson *et al.* (1993), Tomkovich (1991a, 1991b, 1991c, 1992c, 1992d, 1994a, 1996), Voronov (1980).



Genus *LIMICOLA* Koch, 1816

80. Broad-billed Sandpiper

Limicola falcinellus

French: Bécasseau falcinelle **German**: Sumpfläufer **Spanish**: Correlimos Falcinelo

Taxonomy. *Scolopax Falcinellus* Pontoppidan, 1763, Denmark.
Occasionally included in *Calidris*. Two subspecies recognized.
Subspecies and Distribution.
L. f. falcinellus (Pontoppidan, 1763) - Scandinavia and NW Russia; winters from E & S Africa through Arabia to W & S India and Sri Lanka.
L. f. sibirica Dresser, 1876 - Taymyr, and R Lena E to R Kolyma; winters from NE India through SE Asia, Philippines and Indonesia to Australia.

Descriptive notes. 16-18 cm; 28-68 g; wingspan 34-37 cm. Small sandpiper with long, broad bill decurved at tip; distinctive split supercilium; short legs; black mantle and scapulars with whitish fringes in fresh plumage, and whitish lines down edges; wing-coverts grey-brown with whitish fringes. Female averages larger. Non-breeding adult has grey-brown upperparts with dark streaks or feather centres and white fringes; underparts white, but breast with faint grey-brown streaks; resembles *Calidris alpina*, but supercilium remains apparent. Juvenile like breeding adult, but with chestnut and whitish fringes on upperparts; wing-coverts pale brown with pale buff fringes; breast washed buff-brown with faint brown streaks. Race *sibirica* has brighter rufous fringes to feathers of upperparts; also distinguished by broader "lower" supercilium and narrower "upper" supercilium.
Habitat. Race *falcinellus* breeds in subarctic montane and lowland zone, usually at altitudes of above 200 m, possibly up to northernmost taiga, in wet bogs and on open peatland; race *sibirica* breeds in wet Arctic tundra. During migration, species occurs in soft muddy areas on shores of ponds and lakes; also found on windflats, shallow freshwater to saline, occasionally hypersaline, lagoons, overgrazed meadows, temporary small swampy patches, inlets of fjords, harbours, flooded rice fields, and farther S also riverine sandbanks. Winters mainly on large, soft intertidal mudflats, in brackish lagoons and also saltpans.
Food and Feeding. Mainly marine worms, including nereids; also small bivalves and snails, crustaceans (e.g. amphipods), adult and larval insects, including beetles, flies, grasshoppers and ants; also seeds. While feeding, walks slowly, picking from side to side and occasionally drilling and probing, often with head at typical sideways angle; may make short runs; feeds on soft mud or wet sand and occasionally wades in shallow water. Singly or in small flocks, sometimes mingling with other waders. In Namibia, recorded holding a feeding territory along a beach.
Breeding. Laying early to late Jun in Fenno-Scandia, mid-Jun to early Jul in Russia. Monogamous. Breeds in loose colonies, of 2-10 pairs, 80-100 m apart, minimum 9 m; densities of up to 20 pairs/km² locally in Finland; males aggressively territorial. Nest is cup lined with vegetation, often on top of tussock. 4 eggs, sometimes 3; single brood; no evidence of replacement clutches; incubation 21-22 days (2 records); chick has chestnut or hazel brown upperparts, with bold black bands and lines of powder-puff, contrasting white underparts and buff tinged breast; young initially tended by both parents, but female deserts before fledging; fledging period unknown. Oldest ringed bird at least 10 years.
Movements. Adults depart breeding grounds in Fenno-Scandia Jul, juveniles Aug; migrates in broad front SE across Europe; substantial numbers stage in Sivash, S Ukraine, in late May; also Middle East coasts, Caspian Sea and Sivash in Jul (adults) and Aug (juveniles), and Bulgarian seaboard in Sept; evidently some cross Sahara from Mediterranean and some pass E Mediterranean, from late Apr to late May and in early Oct. Present in Africa mainly from Sept to early Apr, early adults from Aug; in Sind, Pakistan, adults arrive late Jul to early Aug, juveniles late Aug to early Sept. In E, probably flies across taiga in broad front, concentrating in S to cross the mountains; at least some birds apparently migrate via Minusinsk depression and Tuva (SC Siberia) and Transaltai Gobi (Mongolia) in autumn; migrates through Hong Kong, along E Chinese coast, Taiwan and Japan in Apr-May and Sept-Oct, taking a more westerly route northward; large numbers pass Jiangsu, NE China, in Aug. Present in NW Australia mainly from late Oct. Return migration mid-Apr to early Jun, reaching breeding grounds in Fenno-Scandia mid-May to mid-Jun. A few remain at wintering sites. Migrates singly or in small parties, but on spring migration flocks of up to several hundred.
Status and Conservation. Not globally threatened. Total population of nominate 13,000-22,000 pairs, with 200-1000 pairs in Norway (1990), 3000-5000 pairs in Sweden (1987), 10,000-15,000 pairs in Finland (1992), and 100-1000 pairs in NW Russia, but all numbers uncertain, especially those in Russia; 25,000 estimated to winter in E Africa and SW Asia, with possibly up to 6000 on Saudi Arabian Gulf coast. Race *sibirica* has population estimated at c. 16,000 birds. Breeding range poorly known, due to inaccessibility of habitat and skulking habits; Swedish population decreasing since 1970's, and range has probably contracted, especially towards E. Local extinctions in Norway, partly due to habitat changes, but also some new breeding areas dicovered in S Norway in 1970's; now probably stable. Reported common on coast of Pakistan. Much of breeding habitat probably too wet for afforestation, perhaps safeguarding it for future. In Finland some peatland areas have been flooded to create artificial lakes. Most important site for European population during migration is Sivash, S Ukraine, with 6000-8000 birds estimated staging in spring; up to 600 birds stage in Bulgaria in Sept. Important wintering sites are Bahrein with 1500-2000 winterers, Barr al Hikman in Oman, As-Sayhat Bay and lagoons in Tarout Bay in Saudi Arabia, and Khor Dubai in Dubai, with up to 1000 wintering birds each (in Barr al Hikman 1648 birds in 1989/90). 7 sites in SE Asia hold more than 100 birds each, with up to 400 in Samut Sakhon in Gulf of Thailand; c. 8000 birds winter in Australia, with Port Hedland Saltworks holding up to 6000 birds and SE Gulf of Carpentaria up to 1740 birds.

Genus *MICROPALAMA* Baird, 1858

81. Stilt Sandpiper

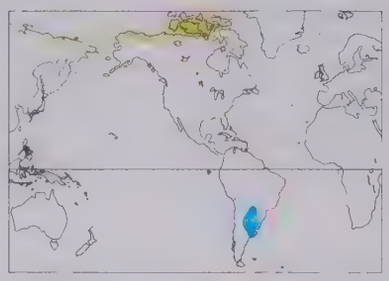
Micropalama himantopus

French: Bécasseau à échasses **German**: Bindenstrandläufer **Spanish**: Correlimos Zancolín

Taxonomy. *Tringa himantopus* Bonaparte, 1826, Long Branch, New Jersey.
Should perhaps be included in genus *Calidris*, but more research required. Monotypic.
Distribution. N Alaska E to S Victoria I; W & S Hudson Bay. Winters from N Chile, Bolivia and SC Brazil to N Argentina and Uruguay; small numbers locally in S USA.

Descriptive notes. 18-23 cm; 40-68 g; wingspan 38-41 cm. Medium-sized wader resembling *Calidris*, but with long, slightly decurved bill and long legs; chestnut stripe across side of head, broad white supercilium; dark upperparts fringed with rufous and whitish; neck and upper breast with dark brown streaks; rest of underparts barred. Female averages slightly larger in wing and bill. Non-breeding adult has brown-grey upperparts with white-fringed wing-coverts; distinct white supercilium; underparts white with grey streaking on lower neck, breast and flanks. Juvenile has dark brown upperparts fringed rufous or whitish buff; wing-coverts greyer with buff fringes; foreneck and breast washed buff and streaked; belly white.
Habitat. Breeds mainly in subarctic, on sedge tundra near water, moist tundra with willow growth and high, dry slopes; often near wooded borders of taiga. During non-breeding season, in freshwater wetlands: flooded fields, shallow ponds and pools, sewage lagoons and freshwater or brackish marshes; rarely along coast, on intertidal mudflats and beaches.
Food and Feeding. Adults and larvae of aquatic and terrestrial beetles, adult Diptera, other larval insects, snails and also seeds; young birds often eat larval midges. Diet similar throughout year. Feeds by probing, often with rapid "stitching" action, moving forward slowly; in open water, often belly-deep with head frequently submerged; rarely in soft, wet mud or sand. Occasionally picks up insects from water's surface. Usually feeds singly or in small groups, regularly associating with *Tringa flavipes* and dowitchers (*Limnodromus*).
Breeding. Laying early Jun in Victoria. Monogamous, often for several years. High degree of site fidelity; 15% of birds reuse nest cup from previous year. Territorial, but feeding outside territory. In Alaska breeds at low densities; in Manitoba 5-25 pairs/km². Nest on relatively open dry tundra, especially on top of sedge hummock or on low, well drained gravel ridge that crosses sedge meadow, but sometimes in wet tundra habitat; nest is unlined scrape. 4 eggs, laid at average interval of 36 hours; incubation 19·5-21 days, starting with final egg, by male during day and female at night; parents accompany hatchlings to wetter areas; fledging 17-18 days; both parents desert brood before fledging, female after 1 week and male 1 week later; fledglings congregate near inland waters. Hatching success c. 80% in Alaska. Age of first breeding unknown.
Movements. Migrates through interior North and Central America to C South America, but during autumn also down Atlantic coast to N South America, where fairly large numbers occur in Surinam Aug-Sept; small numbers winter locally in S USA. Females migrate S from 2nd week of Jul, males 1 week later, and juveniles from mid-Aug; in Manitoba young and adults move at same time. On return, overflies West Indies and Gulf of Mexico from coast of Colombia and Venezuela, reaching USA mainly Apr; migrates N along rivers to Arctic coast; arrives at breeding grounds from late May, males c. 2 days earlier than females. Some remain in winter quarters during breeding season. Migrating flocks can total up to hundreds of birds.
Status and Conservation. Not globally threatened. Total population estimated at 50,000-100,000 birds; few precise data available, but no major threats identified, and numbers seem to be stable. May also breed locally farther S in Canada, at border of taiga.

(1977), Baldassarre & Fischer (1984), Belton (1984), Bent (1927-1929), Biaggi (1983), Blake (1977), Bolster & Robinson (1990), Brazil (1991), Burton (1972b), Contreras *et al.* (1990), Cramp & Simmons (1983), Fjeldså & Krabbe (1990), Haverschmidt (1968), Haverschmidt & Mees (1995), Hayes (1995), Hayes & Fox (1991), Hilty & Brown (1986), Howell & Webb (1995a), Jehl (1970, 1973a), Johnson (1965b), Matthiessen (1994), Meyer de Schauensee & Phelps (1978), Miller (1983c), Miller *et al.* (1988), Monroe (1968), Parmelee *et al.* (1967), de la Peña (1992), Ricklefs (1987), Root (1988), Scott & Carbonell (1986), Sick (1985c, 1993), Smith, F.T.H. (1992), Stiles & Skutch (1989), Tejedor (1986), Tostain *et al.* (1992), Wetmore (1965).



Genus *TRYNGITES* Cabanis, 1857

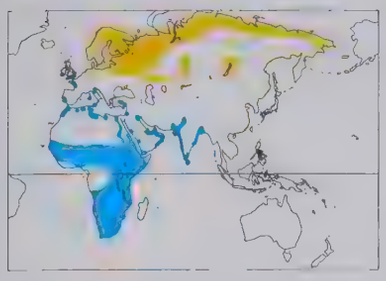
82. Buff-breasted Sandpiper

Tryngites subruficollis

French: Bécasseau roussâtre **German**: Grasläufer **Spanish**: Correlimos Canelo

Taxonomy. *Tringa subruficollis* Vieillot, 1819, Paraguay.
Genetically close to *Calidris*; also suggested to be intermediate between *Calidris* and *Philomachus*. Monotypic.
Distribution. Wrangel I and Ayon I E to R Ekvyvatan and N coast of Chukotskiy Peninsula; Barrow area (N Alaska) E to Boothia Peninsula, and irregularly N to Devon I. Winters from SE Bolivia, Paraguay and S Brazil to Uruguay and NE Argentina.

Descriptive notes. 18-20 cm; male 53-117 g; female 46-81 g; wingspan 43-47 cm. Medium-sized wader with small, round head, fairly long neck and warm buff face and underparts; dark brown centres to feathers of upperparts and blackish spots on crown, hindneck and mantle; belly white towards rear; underwing mostly silvery white with black band on coverts. Resembles juvenile *Philomachus pugnax*, but smaller and more compact, with noticeably shorter legs. Female smaller than male. Non-breeding adult has broader, browner fringes to feathers of upperparts. Juvenile like adult, but paler below, especially towards vent, and with narrower fringes and dark subterminal line to feathers of upperparts.
Habitat. Breeds in high Arctic on well drained sandy tundra with tussocks and scant vegetation, or with vegetation of mosses, willows and grass, or on moist meadows with sedges and grass; not often near sea, and avoids marshes; favoured sites for leks, though not for nests, are well vegetated hummocky ground around marshy ponds; during brood-rearing, does not move to wet lowland areas. During migration, on short-grass prairies, meadows, golf courses, airfields, pastures, burnt grassland, stubble, ploughed fields, inundated barren land and margins of freshwater wetlands; in Venezuela, also recorded on rain forest riverbanks, marshes and seashores. Winters primarily on flooded *pampas* and grazed grasslands; also in short vegetation near wetlands.
Food and Feeding. During migration, takes terrestrial invertebrates, especially adults, larvae and pupae of beetles and Diptera, and craneflies; spiders, copepods and gammarid crustaceans; also seeds. Forages while walking steadily; occasionally runs and stops like a plover. On migration, often forages in short, sparse grass or dry stubble, close to water's edge. Gregarious outside breeding season, in flocks of 5-6 birds, although frequently defends small territories on staging and wintering grounds. Often associates with *Pluvialis dominica*.
Breeding. Laying early to late Jun. Polygynous; uses lekking system, where 2-10 males in relatively large territories attract females with typical "Wing-flash" display; males also perform solitary displays away from lek. Copulation may take place before reaching breeding grounds; males do not participate in nesting activities; 8 of 32 broods had multiple-paternity. Densities vary considerably between years, 0-14 and 1-19 birds/km² at some sites; 0·3·3 nests/km² in Alaska. Little or no site fidelity and no natal philopatry. Nest on moist, grassy or "black" lichen tundra, usually close to stream; shallow scrape lined with lichens and plant material. 4 eggs; single brood; no records of replacement clutches; incubation 23-25 days, starting fully with 3-4 eggs; chick brownish grey above with blackish brown mottling and white down tips, dark crown patch and whitish below; fledging 18-20 days. 50-65% of nests lost in N Alaska due to predation; of remaining eggs 42-43% hatch; minimum 7-18% fledge; another Alaskan study reports hatching success of 80%. Presumably breeds first at 1 year old.
Movements. Migrates, probably non-stop, through interior North America, mainly Canadian prairies and C USA, across Gulf of Mexico to N South America; on S migration, some pass W Hudson Bay and Great Lakes, probably crossing W Atlantic to N South America; flies through interior South America to wintering grounds. Migrates S in broad front, and reverse route N on much narrower front. Stages at traditional stopover sites. Departs from breeding grounds late Jul to early Sept, adults before juveniles; males and non-breeding or failed-breeding females leave mid-Jun to early Jul, crossing USA Aug-Sept to arrive at wintering grounds from late Aug, but mainly mid-Sept to mid-Oct. Departure from wintering grounds from late Jan, mainly early Feb, to late Mar (mainly females); arrives S North America mid-Apr to early May, S edge of breeding grounds late May, and farther N until mid-Jun. Probably nocturnal migrant. Extremely tame during migration.
Status and Conservation. Not globally threatened. Total population estimated at maximum of 25,000 birds; 5000 to over 10,000 birds in Canada, with c. 2000 breeding birds on Banks I; not more than several 10's of birds on Wrangel I, and sporadic distributional pattern on Chukotskiy Peninsula. Close to extinction by early 1920's due to excessive hunting, especially around turn of century, when population may have numbered millions. Numbers declined by 65-100% at small staging site in NC Texas during 1980's; similar decline in numbers of birds staging in Canada; population decline, thus indicated, possibly caused by degeneration of staging areas, especially Cheyenne Bottoms, and South American wintering grounds. Surveys in Argentina no longer indicate declining numbers. Flocks of 100's to 1000's found near Houston (Texas), York County (Nebraska), Beaverhills L (Alberta) and Saskatoon (Saskatchewan). Considering distances involved, a staging area in N South America is to be expected, but none known. Estimated 2000 birds wintering on 11,000 ha ranch of Estancia Medaland in Buenos Aires Province, Argentina (1973).
Bibliography. Abbott (1982), Alberghetti *et al.* (1992), Ali & Ripley (1980), Antas (1983), Armstrong (1983), Arthur (1987), Beehler & Forster (1988), Belton (1984), Bent (1927-1929), Beser (1986), Blake (1977), Blanco & Canevari (1992), Bolster & Robinson (1990), Brazil (1991), Campbell & Gregory (1976), Cartar & Lyon (1988), Castan (1964), Contreras *et al.* (1990), Cramp & Simmons (1983), Dorogoy (1983), Driessens & van Rossum (1988), Fjeldså & Krabbe (1990), Haverschmidt (1968, 1972b), Haverschmidt & Mees (1995), Hayes (1995), Hayes & Fox (1991), Hayes *et al.* (1990), Hilty & Brown (1986), Hobcroft (1987), Hopson & Hopson (1974), Howell & Webb (1995a), Hubaut (1984), Knolle & Balten (1993), Knystautas (1993), Lanctot (1994, 1995), Lanctot & Laredo (1994), Matthiessen (1994), Meyer de Schauensee & Phelps (1978), Miller *et al.* (1988), Monroe (1968), Myers (1979, 1980b, 1981b), Myers & Myers (1979), Oring (1964), Palmer (1967), Parmelee *et al.* (1967), Paulson & Erckmann (1985, 1993), de la Peña (1992), Pitelka *et al.* (1974), Prevett & Barr (1976), Pruett-Jones (1988), Ridgely & Gwynne (1989), Scott & Carbonell (1986), Sick (1985c, 1993), Slud (1964), Sorensen (1990), Stiles & Skutch (1989), Stishov (1989, 1994), Strauss (1991), Sutton (1967), Trawoger & Kurz (1986), Urban *et al.* (1986), Wetmore (1965).



Genus *PHILOMACHUS* Merrem, 1804

83. Ruff

Philomachus pugnax

French: Combattant varié **German**: Kampfläufer **Spanish**: Combatiente
Other common names: Reeve (female)

Taxonomy. *Tringa Pugnax* Linnaeus, 1758, Sweden.
Has been proposed for inclusion in *Calidris*. Monotypic.
Distribution. NW Europe through Siberia to Chukotskiy Peninsula and Sea of Okhotsk. Winters from Mediterranean and sub-Saharan Africa through Middle East to Indian Subcontinent.

Descriptive notes. Male 26-32 cm, 130-254 g, wingspan 54-58 cm; female 20-25 cm, 70-170 g, wingspan 48-52 cm. Extreme sexual dimorphism. Male has head-tufts and ruff variably coloured buff, chestnut, dark purple, black or white, often barred or flecked; white coloration of tufts and ruff associated with satellite behavioural role (see page 472); mantle and scapulars vary from black to brown, buff, chestnut, ochre or white; yellow to brown facial warts; underparts usually dark, lower belly and undertail white; bill brown to dull orange and legs yellow-green to dark orange. Female considerably smaller than male, with overall colour rather variable; lacks specialized head plumage of male; dark upperparts with buff to rufous fringes and black blotches on breast and flanks; bill black, legs pinkish orange to green or grey. Non-breeding adult like breeding female, but paler grey-brown above with whiter lower face and dusky buff on breast; bill dark, legs duller; some males retain much white on head and neck. Juvenile has buff-fringed dark brown upperparts and rufous buff foreneck, breast and belly; face mainly buff with pale throat; bill and legs as in breeding female.

Habitat. Breeds in Arctic and subarctic, and S to temperate zones in Europe; requires habitat with adjacent feeding, lekking and nesting areas; coastal tundra to forest tundra, near small lakes, in marshes and deltas with shallow water margins, variably covered with vegetation, and with dry mounds and slopes with some low scrub for leks; in W Europe, damp to swampy meadows, often with shallow pools or ditches, and patches of birch, willow scrub and short grass or bare ground. Outside breeding season, prefers muddy margins of lakes, pools, ponds, rivers, marshes and flooded areas, including brackish, saline or alkaline waters; in India, large numbers on tidal mudflats and lagoons, but not commonly on seashore elsewhere; W African wintering sites include flooded or dry plains, marshes and grass, wheat or rice fields, not always close to water; observed picking up spilled grains from road. During migration commoner along shores and in freshly mown or short-grazed grasslands in W Europe. Uses night-time roosts on shallow water along lake edges.

Food and Feeding. During breeding season, mainly terrestrial and aquatic insects, including adults and larvae particularly of beetles and dipteran flies; outside breeding season diet more varied, including caddisflies, water-bugs, mayflies and grasshoppers, small crustaceans, spiders, small molluscs, annelid worms, frogs and small fish; birds wintering in Sahel zone often feed on rice seeds and other cereals, sedges, grasses and aquatic plants. Probes in mud or soil and picks up prey from surface or plants; sometimes follows ploughs; sometimes wades in shallow water. Nocturnal and diurnal feeder.

Breeding. Laying from early May in NW Europe, mid-May in Sweden and early Jun in Finnmark. Polygynous, with no true pair-bond; mating primarily takes place at traditional leks where males gather to display and females visit. Three types of males appear on arena: (1) residents, possesing small territories ("courts"); (2) marginals, without territory; and (3) satellites, occurring on periphery of arena and mating opportunistically; satellites are generally white tufted and ruffed. Many females may copulate during migration. No site fidelity and natal philopatry. Nests solitary or semi-colonial, in densities of 0·1-2·5 nests/ha, occasionally only several metres apart and sometimes near lek; non-territorial. Nest concealed in marsh plants or meadow grass; shallow scrape lined with grass, leaves and stems. 4 eggs, sometimes 3, laid at 24-36 hour intervals; incubation 20-23 days, starting with last egg; incubation and brood rearing by female only; chick ochre-orange above, with black and brown streaks and lines of "powder-puffs", of which two along crown, underparts entirely buff; fledging 25-28 days; female leaves chicks at or some days before fledging. Hatching success 93% (only one study). Age of first breeding 2 years, probably later in males; annual mortality 48%; oldest ringed bird 10 years, 11 months.

Movements. Migratory. Chief winter quarters in Africa; huge concentrations in Sahel zone, e.g. Senegal Delta, Niger inundation zone in Mali, Sokoto region in Nigeria, Yobe Delta in Niger and Nigeria, Nile system in Sudan. In autumn, flies in broad front SW across Europe, following route farther E in spring; Scandinavian breeders probably virtually all stage in Wadden Sea region from late Apr to mid-May; W movement of E breeders in autumn towards Europe; E & S African winterers come from Siberia, migrating via Caspian and Black Seas; smaller numbers fly across easternmost Asia. Autumn migration starts late Jun to early Jul (males), mid-Jul (females) and late Jul to Aug (juveniles), crossing temperate Europe mainly late Jul to mid-Sept, and S Asia Sept; at least in Britain juvenile females precede juvenile males; important staging and moulting areas lie around North Sea, W Germany and N Caspian Sea; arrives Senegal from mid-Jul (earliest males) and tropics mainly late Aug to Sept. Females winter farther S than males and juveniles move S gradually. Spring migration starts Mar, but mainly Mar to mid-May, males starting a month earlier than females; some non-breeders remain in winter quarters; breeding grounds reoccupied from mid-Apr in W Europe, but progressively later to N & E, mid-May to Jun in Siberia. Migrates in large groups, of hundreds or thousands.

Status and Conservation. Not globally threatened. Total population possibly over 2,000,000 birds, of which over 1,000,000 winter in W Africa, up to 1,000,000 in E Africa and SW Asia; up to 1,000,000 birds counted within a 25 km radius of Senegal Delta in 1972, 180,000-200,000 in 1991 and 1992; less than 10,000 birds in Atlantic Europe and Mediterranean; c. 100,000 in SC Asia, with 113,000 in India in 1992. In Norway and Sweden, 60,000-95,000 breeding "pairs" and 30,000-50,000 in Finland, where earlier estimated at 196,000 in 1973-1976 and 150,000 in 1986. Numbers declining at W African wintering sites. W breeding range has contracted considerably during last 200 years, especially in S, as result of drainage of wetlands; in Netherlands decline of 90% since 1950's. In Norway and Finland, has expanded range S since 1940's. In recent years breeding range and numbers have increased in E Russia; small British population has increased since late 1960's.

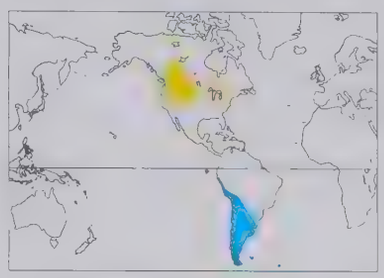
Subfamily PHALAROPODINAE

Genus *STEGANOPUS* Vieillot, 1818



84. Wilson's Phalarope

Steganopus tricolor

French: Phalarope de Wilson **German**: Wilsonwassertreter **Spanish**: Falaropo Tricolor

Taxonomy. *Steganopus tricolor* Vieillot, 1819, Paraguay.
Commonly placed in genus *Phalaropus*, but genetically distinct; apparently quite close to *Tringa*. Monotypic.

Distribution. N Alberta and EC California E to Great Lakes area, with scattered small outlying populations. Winters from N Peru to Uruguay and S to Tierra del Fuego.

Descriptive notes. 22-24 cm; male 30-110 g, female 52-128 g; wingspan 35-38 cm. Largest phalarope, with longest legs and bill; legs grey to black; toes lobed, but less so than in *Phalaropus*. Reversed sexual dimorphism. Female has greyish white cap and nape, black band from bill through eye to side of breast; blue-grey mantle and wing-coverts, reddish chestnut edge to mantle and scapulars; foreneck and upper breast rich orange. Male much darker and generally duller above. Non-breeding adult uniform pale grey above and white below; white forehead and supercilium; white uppertail-coverts conspicuous in flight; legs yellow. Juvenile has dark brown upperparts with buff fringes, producing somewhat scaled aspect; sides of breast washed buff; legs yellow.

Habitat. Breeds mostly in wetlands in prairie region, up to taiga region, on grassy plains, often grazed or cultivated, peppered with small potholes; hay meadows and pastures, in vicinity of water; near marshy grassland and marshes with open grassy fringes; only occasionally near lakes. After breeding, all adults stage at large, shallow, hypersaline lakes in W North America; not common at coast, although sometimes in sheltered tidal pools, lagoons and estuaries. Unlike other phalaropes, not pelagic in winter; chief wintering habitats are mudflats and shallow, open water of saline lakes in highlands of Andes in Peru, Chile, W Bolivia and NW Argentina; sparsely at freshwater wetlands in *pampas* and on alkaline ponds.

Food and Feeding. Small, mostly aquatic, invertebrates, especially dipteran flies, bugs, beetles and their larvae, crustaceans, spiders and some seeds. At breeding areas feeds on open water and flooded meadows; females more aquatic than males. At staging sites, females feed on brine-shrimps (*Artemia*) and brine-flies (*Aphydra*) from water's surface, while males and juveniles feed more terrestrially on brine-flies, later becoming fully aquatic too. At salt-lakes in wintering sites, recorded taking brine-shrimps, copepods, chironomid midges and brine-flies. When swimming, spins less than other phalaropes; usually pecks prey from water or mud surface, also upends, lunges at prey, probes in soft mud, and in shallows scythes with bill through water.

Breeding. Laying early May to late Jun. Usually monogamous; 0-11% of females polyandrous when males in excess, or in extended breeding season. Sex roles reversed. Densities up to 1·1 nests/ha; nests average 60 m apart, sometimes less than 5 m; not territorial; low degree of natal philopatry and site fidelity. Nest in fairly tall, dense vegetation, within 100 m of water; scrape lined, during egg-laying, with plant material. 4 eggs, laid at 24-27 hour intervals; single or double brood; up to 3 replacement clutches laid; incubation 18-27 days, starting regularly with 3rd egg, by male; female deserts male 0-18 days after clutch completed, and courts other males, which may still be incubating; chick has tawny and fulvous breast band and upperparts, latter with some black spots and black line on back, pale buff or greyish white underparts; young tended by male; fledging period and timing of independence unknown. Many clutches may be lost due to predation by birds, mammals or reptiles, and incubating males occasionally taken; also disturbance by cattle and humans. Hatching success 12-50%; in some years, local fledging success close to 0%. Age of first breeding 1 year.

Movements. Migratory. After breeding, adults migrate to large hypersaline lakes in W North America to moult and to fatten up, attracted to abundance of food; up to 600,000 recorded on Great Salt L. Females depart from breeding areas and arrive at staging sites by mid-Jun, followed by males and finally juveniles. Adults migrate across Pacific to coastal W South America and thence S through Andes; females depart late Jul to late Aug, males 2 weeks later; juveniles migrate after males, overland on broad front to N South America; adults arrive in South America from early Aug, juveniles late Aug, and at wintering sites late Sept to early Nov, occurring on lakes in concentrations of up to 500,000. Main wintering areas in Bolivia, Chile and Argentina. On spring migration crosses highlands of South America in mid-Mar, then Central America or Gulf of Mexico and interior USA; arrives at breeding areas from late Apr to early May. Migrates nocturnally in large flocks. A dead specimen found at Alexander I (71° S) is most southerly wader record.

Status and Conservation. Not globally threatened. Total population estimated at 1,500,000 during autumn 1988, but not over 1,000,000 in 1994. Numbers likely to have decreased as consequence of substantial habitat loss of prairie wetlands until middle of present century. During last few decades breeding range has expanded enormously in all directions. Population may have declined since mid-1980's, probably as result of drought, but now considered stable. Movements indicate eastward shift since 1920's, possibly due to drought in breeding areas. Recreational use of water and reclamation projects in W North American staging areas present threats.

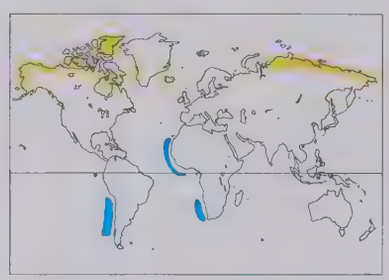
Genus *PHALAROPUS* Brisson, 1760

85. Red-necked Phalarope

Phalaropus lobatus

French: Phalarope à bec étroit **German**: Odinshühnchen **Spanish**: Falaropo Picofino
Other common names: Northern Phalarope

Taxonomy. *Tringa tobata* [sic] Linnaeus, 1758, Hudson Bay.
Sometimes placed in monospecific genus *Lobipes*. Monotypic.
Distribution. Circumpolar, in coastal regions of Arctic Ocean, S to Aleutians and NW Britain. Winters pelagically off CW South America, in Arabian Sea and from C Indonesia to W Melanesia.



Descriptive notes. 18-19 cm; 20-48 g; wingspan 31-34 cm. Smallest phalarope, with needle-like bill and slender neck; toes lobed. Reversed sexual dimorphism. Female has slate-grey head, neck and sides of breast with bright orange-red horseshoe collar and white throat; golden buff fringes on upperparts form lines on sides of mantle. Male much duller, with browner head, neck and upperparts; white above eye often spreads out to form narrow supercilium. Non-breeding adult has dull blue-grey upperparts with white fringes; head mainly white with black patch through and behind eye; underparts white with faint streaks on lower flanks. Juvenile has brown crown, hindneck and eye-patch; upperparts black-brown with bright buff fringes; breast washed buff, rest of underparts white.
Habitat. Breeds from coast to interior of Arctic, to lower latitudes than *P. fulicaria*; on tundra, forest tundra and Scandinavian alpine tundra, at or near lakes and pools with marshy margins, often overgrown with grass, sedges and moss; sparsely vegetated lava deserts in Iceland; coastal moorland; often in floodplains of large rivers or on islets; also *Polygonum* bogs. During migration, uses inland saline and hypersaline lakes. Winters at sea, in upwelling zones and ocean slicks with high availability of plankton.
Food and Feeding. During breeding season, chiefly insects, especially dipteran flies and their larvae, as well as beetles, caddisflies, ants and bugs; also other small invertebrates, including snails, crustaceans and annelid worms; some seeds. On saline lakes brine-flies (*Ephydra*), mostly larval. During pelagic non-breeding period, mainly euphausiids and calanoid copepods, and small amounts of various other floating particles. Forages by swimming, wading and walking; pecks at prey at water surface, from vegetation or mud, rapidly lunges at prey just below water surface, upends, seizes flying insects, and often spins around in water, anti-clockwise, slightly faster than *P. fulicaria*. Makes use of surface tension to transport prey from bill to mouth. Associates with other feeding birds, probably to benefit from the higher prey availability brought about by disturbance; at sea, reported to be found near whales and shoals of fish, where profits from high local plankton densities; also at floating seaweed; in flocks of 20-100.
Breeding. Laying Jun in Fenno-Scandia. Monogamous, but sometimes polyandrous when males in excess; sex roles reversed. Solitary or loosely colonial where habitat restricted, with up to 50 nests at 1 site; densities in N Siberia 0·3-6 pairs/ha, and 0·6-32 birds/km² in S, varying greatly between years; not territorial. Low degree of site fidelity and natal philopatry. Nest on bare ground or among sparse vegetation, close to water; scrape, lined with leaves and stems. 4 eggs, occasionally 3, laid at intervals of 24-30 hours; usually single-brooded, but in case of polyandry double-brooded; replacement clutches may be laid; incubation 17-21 days, by male only, starting fully with 4th egg; chick cinnamon-buff to whitish with black bands, crown and eyestripe black and three black bands down back, underparts white, greyish and buff; chicks tended by male; fledging 18-21 days; young independent at c. 14 days. Females depart soon after hatching of 1st clutches and males c. 2 weeks later, before young fledge. Breeding success can be high: 80% of nests reported to hatch at least 1 egg. Breeds first as 1-year-old. Oldest ringed bird at least 5 years old.
Movements. Migrates over land more than *P. fulicaria* and spends non-breeding season pelagically. Nearctic population winters mainly at edges of Humboldt Current off W South America; large numbers off Peru in Oct-Mar and few off Chile indicate more N distribution than *P. fulicaria*; migrates S across N Canada and W USA, where occurs on saline lakes, with 10,000's on Mono L, Great Salt L and L Albert; thence S over sea. In NW Atlantic, birds migrating S possibly include some from Nearctic, Greenland and Iceland; huge numbers, up to 2,000,000 (Aug 1977) aggregate at Bay of Fundy in May and Aug, but winter quarters of these birds unknown; it seems unlikely that they fly farther S crossing Caribbean and Central America towards Pacific, since rarely observed in these zones, but no wintering sites known in Atlantic Ocean. W Eurasian population winters in Arabian Sea; migrates on broad front, but many via Caspian Sea and lakes in Kazakhstan, Aug-Sept and Apr-May, with 600,000 at L Tengiz in May 1959; enter and leave Arabian Sea via Gulf of Oman. Arrive at breeding grounds late-May to mid-Jun, 3-4 weeks earlier at temperate latitudes, and females often earlier than males; females depart from end Jun, followed by adult males late Jul, and juveniles in Aug. E Siberian population winters among East Indies, migrating across land and sea. Gregarious in winter and on spring migration.
Status and Conservation. Not globally threatened. Total breeding population in Eurasia estimated at 500,000-1,000,000+ birds; Nearctic population exceeds 2,000,000 birds; Iceland 50,000-100,000 breeding pairs (1985), Norway 9500 pairs (1981), Sweden 50,000 pairs (1984) and Finland 15,000 pairs (1986). Numbers in Bay of Fundy have decreased dramatically during recent years, but cause unknown. Numbers may be decreasing at S of range; those in Britain and Ireland decreased in 19th century probably due to egg-collection; 28-32 pairs in 1985; still breeds irregularly in Ireland. More than 1,000,000 birds winter in Arabian Sea.

86. Red Phalarope

Phalaropus fulicaria

French: Phalarope à bec large **German**: Thorshühnchen **Spanish**: Falaropo Picogrueso
Other common names: Grey Phalarope

Taxonomy. *Tringa Fulicaria* Linnaeus, 1758, Hudson Bay.
Genus sometimes broadened to include *Steganopus tricolor*, or conversely narrowed to exclude *P. lobatus*. Species name often erroneously spelt *fulicarius*. Monotypic.
Distribution. Circumpolar, on coasts of Arctic Ocean. Winters pelagically mainly off W South America and W & SW Africa.

Descriptive notes. 20-22 cm; 37-77 g; wingspan 37-40 cm. Larger and chunkier than *P. lobatus*, with broader, heavier mainly yellow bill. Reversed sexual dimorphism. Female mainly chestnut-red with blackish brown crown and front of face; grey centre of nape, white at side of face; upperparts blackish brown with cinnamon and buff fringes. Male duller, with streaked crown and mantle; white on face less pure; duller underparts often mixed with white. Non-breeding adult pale blue-grey above, white below; dark crown-patch, black eye-patch. Juvenile has upperparts like breeding male and head pattern as non-breeding adult, but browner; face, neck and sides of breast pink-buff; belly white.
Habitat. Most pelagic of phalaropes. Breeds near coast, on marshy tundra with small pools, boggy meadows with moss and grass, marshy river valleys or islets in fjords. Outside breeding season pelagic, in tropical and subtropical upwelling zones where plankton occurs at high concentrations of over 50,000 organisms/litre. Regularly seen ashore during gales.
Food and Feeding. During breeding season takes invertebrates, including insects and their larvae, such as dipteran flies, caddisflies, beetles and bugs, also molluscs, crustaceans, annelids, spiders and mites, and occasionally plant material, mainly seeds, especially when food is limited; feeds in or around small pools or lagoons or on *Fucus* seaweed washed ashore; also often at sea; forages by swimming, wading and walking, and typically spins around fast pecking at or just below water surface; also quickly lunges forward at prey, or upends, tilting body forward and immersing bill only or part of head, or seizing flying insects. Outside breeding season feeds at sea on plankton, including amphipods less than 2 mm long, Hydrozoa and small fish, from water surface or just below, using exceptionally broad bill; reported to be found near whales or schools of fish that bring plankton to surface and even recorded picking parasites from whale's back; formerly used by whalers to locate their prey; recorded feeding and resting on floating mats of seaweed. Large quantities of floating plastic particles may be ingested. Outside breeding season in small flocks of c. 20, occasionally several thousand together.
Breeding. Laying mid-Jun to mid-Jul in Iceland, early Jun to early Jul in Russia. Usually monogamous, but, when excess of males, polyandrous, with females starting 2nd clutch several hundred metres from 1st; female usually leaves male after clutch completed. Sex roles reversed. Breeds in loose groups when habitat is limited; 0·02-2 pairs/ha, up to 7-10 in patchy habitat, but very variable between years; no territorial behaviour; breeding males have their own feeding flocks and females, failed breeders and non-breeders also feed together in small parties; low degree of site faithfulness; may nest in colony of aggressive seabirds, e.g. Arctic Terns (*Sterna paradisaea*), thus reducing risk of predation. Nest in short vegetation, usually close to or surrounded by water; shallow scrape, which male lines with plant material. 4 eggs, sometimes 3, laid at 24-26 hour intervals; sometimes double-brooded and 1 replacement clutch can be laid; incubation 18-20 days, by male, starting once clutch complete; chick has cinnamon-buff upperparts with white patches and black streaks, 3 black streaks on back, underparts pale violet-grey with some buff on flanks and white on breast; tended by male; fledging 16-20 days; independent at or just before fledging; soon after fledging young move to larger lakes in large flocks. Fledging success almost 2 young/pair in Iceland, 0·1-0·2 young/pair in poor year in E Siberia. Many non-breeders present over summer in coastal waters near breeding grounds. Age of first breeding 1 year.
Movements. Migrates almost exclusively via sea routes; observed migrating 80-160 km offshore. Non-breeding birds disperse from late Jun, adult females leave early Jun and adult males and juveniles late Jul to Aug, adult males on average earlier; few birds S of equator before late Aug, but most present at non-breeding quarters by end Nov. Chief non-breeding areas off coast of W & SW Africa, in upwellings of Guinea and Canary Currents, especially off Mauritania, and also Benguela Current off Namibia and South Africa, and W South America, especially Humboldt Current off Chile; suggested wintering areas in SW Atlantic and Arabian Sea uncertain. Nearctic breeders do not move down W Atlantic coast but winter off Africa, uncertain how many Nearctic breeders winter in Pacific; sightings in C Pacific and lack of them in SE Asia suggest that Siberian breeders winter in Humboldt Current. Evidently departs South African and Chilean seas in Mar, and W & SW African seas in Apr. Migrates along Arctic coasts and reoccupies breeding grounds late May to mid-Jun, C Siberia from early Jun; females on average first, often after waiting at sea for 2-3 weeks for ground to thaw.
Status and Conservation. Not globally threatened. Population size 100,000-1,000,000 birds. On Svalbard 150-300 pairs (1981), Iceland probably 50-60 pairs and low numbers in Greenland and on Ellesmere I. Few precise data available; as with *P. lobatus*, pelagic wintering habit makes counts of non-breeding birds rather difficult.

Class AVES

Order CHARADRIIFORMES

Suborder CHARADRII

Family PEDIONOMIDAE (PLAINS-WANDERER)

- Small, quail-like terrestrial birds, with slim bill and very short tail; unlike Turnicidae, hind toe present.
- 15-19 cm.

- Australia.
- Sparse native grasslands.
- 1 genus, 1 species, 1 taxon.
- 1 species threatened; none extinct since 1600.

Systematics

The Plains-wanderer (*Pedionomus torquatus*) is of great scientific interest, as the sole representative of a family of birds found only in eastern Australia. The fact that the female is both larger and more colourful than the male led John Gould to describe them as two separate species in the early 1840's.

Through the years, this singular species has almost invariably been classified alongside the buttonquails (Turnicidae), these two groups usually sharing a suborder, Turnices, in the order Gruiformes. The main taxonomic issue was whether *Pedionomus* merited a family of its own or only subfamily status within the Turnicidae. However, osteological studies published by S. L. Olson and D. W. Steadman in 1981 switched the focus elsewhere, as their results strongly suggested that this species belonged in the Charadriiformes. Further studies of the anatomy and behaviour of the Plains-wanderer, together with those based on DNA-DNA hybridization, support the conclusion that Pedionomidae is probably more aptly placed in the Charadriiformes, and that it is related to the seedsnipes (Thinocoridae) of South America. In this case, it may be that the Plains-wanderer is an ancient member of Australia's avifauna, with origins dating back to when Australia was part of the Gondwanan supercontinent and connected to South America via the Antarctic land bridge. This ancient link remains hypothetical because the fossil records of both Pedionomidae and Thinocoridae consist entirely of Quaternary specimens of genera that are still extant.

A detailed analysis of the anatomy and osteology of the Plains-wanderer has revealed that the formula of the thigh muscles, the configuration of the carotid arteries, the morphology of the liver, the nature of the brachial nerve plexus, the presence of the hind toe, the diastataxic condition of the secondaries, and 22 osteological characters all combine to support its removal from the Gruiformes and its placement in the Charadriiformes. In common with some waders, but not the buttonquails, the Plains-wanderer has pointed, rather than oval, eggs; spotted, rather than striped, downy young; two long brood patches, rather than one; and a noticeable wingbar in flight. The gait of the Plains-wanderer is free, and typical of a wader. When alarmed, the bird will often run a short distance, stop and stand tall, with its head bobbing, and then repeat this behaviour several times, again as some waders do. Unlike buttonquails, Plains-wanderers never occur in coveys, but are solitary, except when breeding; at that time only, the members of a pair or a male with its dependent young may be seen together.

Morphological Aspects

The Plains-wanderer is a small ground-dwelling bird, similar in size and shape to the *Coturnix* quails, but it has a finer bill, longer legs and neck, and a lankier appearance. With its slim bill, it takes both seeds and insects, while its walks about and stretches up to its full height from time to time (see General Habits). In flight, it is more ponderous than a quail, and the tips of its feet trail beyond the end of its short tail. It has a fluttering descent and will land in an open area, this behaviour contrasting with the characteristic dive of quails into cover. It is reluctant to fly, but its longer, high-stepping legs carry it much more quickly than quails enable it to run.

The adult male Plains-wanderer is pale brown with dark brown and white scallops on the sides of the neck, upper breast and flanks. The bare parts are cream to pale yellow and the sides of the head, chin and throat are pale buff. Although the adult female has a similarly coloured body, unlike the male she sports a distinctive broad black collar, spotted white, and a rufous gorget on the upper breast, while the bare parts are a brighter yellow than those of the male. This reversal of sexual dimorphism in plumage ties in with the different roles taken by the sexes in the reproductive cycle (see Breeding).

Prior to moult, the juvenile is similar to the adult male, but shows dark brown spotting, rather than scallops, on the breast and flanks. The species' well camouflaged plumage and cryptic behaviour mean that, though diurnal, it is seldom seen, even in the few remaining areas where it is common.

Adults undergo one complete (pre-basic) moult a year, probably in the post-breeding season, as most individuals are in body moult from February to May, although there are records as early as October and as late as June. Primary moult is gradual, interruption is not uncommon, and the sequence of moult may be similar to that of seedsnipes, in which the outer three primaries are moulted before a complex moult sequence of the inner primaries takes place. The post-juvenile body moult begins between the fifth and thirteenth weeks, and is complete by 22 weeks of age.

Habitat

The lowland native grasslands of eastern Australia form the natural habitat of the Plains-wanderer. The species is more or less restricted to those areas with only a very sparse covering of vegetation. Permanent water does not seem to be a requirement, as the bird gleans droplets of dew and rain from blades of grass.

The Plains-wanderer has traditionally been linked with the buttonquails (Turnicidae), but recent work suggests that it may belong close to the seedsnipes (Thinocoridae) in the shorebird order Charadriiformes. Like the buttonquails, it shows reversed sexual dimorphism, the female wearing the brighter plumage, but it differs from them in possessing a hind toe. This splendid female illustrates an upright stance rather typical of the species.

[*Pedionomus torquatus*. Photo: Christo Baars/ Foto Natura]

The Plains-wanderer is not present in dense pastures formed of introduced species, nor is it found in treed areas, even when the ground layer is similar to that of its favoured habitat. Similarly, large expanses of bare ground are avoided, whilst areas preferred seem to be where the topsoil has been eroded to expose a red clay subsoil, which does not support dense vegetation under any seasonal conditions, but rather low-growing herbs, such as salt-bushes (chenopods). Such areas contain about 50% bare ground, where fallen litter covers a further 10%. The more robust plants in the flora are generally spaced 10-20 cm apart and rarely exceed 30 cm in height. The bulk (94%) of the vegetation is less than 5 cm tall, but the small proportion that is over this height is important for the bird's concealment. As the Plains-wanderer stands about 15 cm tall when on tiptoe, in areas with thinnish grass cover it can see over the vegetation, move freely when foraging and running away from terrestrial predators, and at the same time avoid detection from the air.

Breeding, foraging and roosting all take place in sparse native grasslands which may be grazed by flocks of domestic animals. Changes to the preferred habitat brought about by cultivation, pasture improvement and weed invasions can cause populations of Plains-wanderers to become locally extinct. Overgrazing during droughts and burning can lead to widespread displacements of the birds, but, in contrast, light to moderate grazing pressure from domestic stock during droughts can change the structure of grasslands and enable birds to occupy areas that are normally too dense for them.

The Plains-wanderer is occasionally found in cereal stubble and some low crop fields. These are similar in structure to the sparse grasslands, but offer the bird only a temporary refuge until they are cultivated again. Areas of habitat suitable for the species can be indicated by the presence of more conspicuous species, such as the Banded Lapwing (*Vanellus tricolor*) in the Riverina region of New South Wales, and Inland Dotterels (*Peltohyas australis*) in south-west Queensland. However, when overgrazing temporarily eliminates Plains-wanderers from an area, these two other species sometimes remain.

General Habits

The Plains-wanderer is typically seen walking between tussocks in the sparse open grasslands that it frequents, periodically standing on tiptoe to keep a look-out for potential predators.

If threatened by a terrestrial predator, Plains-wanderers will run through the thin grass in a crouching posture. Birds sometimes lie flat on the ground, relying on their cryptic plumage to conceal them from any predators that may be in the vicinity. When such threats are present, Plains-wanderers do not seek dense cover, as quails do, nor do they usually "explode" into flight when discovered. On the contrary, birds that are hiding can sometimes be picked up by a human or a dog, or they will run when flushed, and only fly when hard pressed. They are probably vulnerable to raptors when in the air, particularly on their fluttering descent flights. Like waders, such as coursers (Glareolidae), alert or disturbed Plains-wanderers may stand on tiptoe with the head bobbing, as they scan the surrounding open country for intruders.

Because the birds are so seldom seen, they were once assumed to be nocturnal, but studies of both captive and wild radio-tracked birds prove that they are diurnal and crepuscular. Captive birds spend over a third of their day walking and foraging, a similar amount standing on tiptoe scanning their surroundings, and most of the rest in comfort behaviour, such as preening, stretching, standing hunched, sitting and dust-bathing. They have rarely been seen drinking but they avidly peck up droplets of water that accumulate at the tips of blades of grass after rain has fallen. The dominant, more colourful females spend significantly more time than males standing on tiptoe, on tufts of grass, with the head bobbing conspicuously. This behaviour, which is typical of the bird in the wild when alarmed, could attract predators and may in part account for the ratio of two to one in favour of males that has been recorded in field studies.

At night, Plains-wanderers roost solitarily on the ground in sparse grass, and accumulations of faeces indicate that the same site may be used for many nights. If disturbed with a spotlight, roosting birds seem reluctant to fly away, although some birds may walk away from the danger.

The species is usually solitary, especially outside the breeding season. At times during the breeding season, members of a pair may be 1-3 m apart, or a breeding male may be found in sole charge of two to four young. During droughts, up to ten birds may be found in an area normally occupied by one or two pairs in wetter years, but they never form flocks. Home ranges of breeding birds may cover 7-21 ha, but they average 12 ha in extent. There tends to be a considerable overlap between birds of the opposite sex, but there is none with birds of the same sex, unless the female takes a second mate.

Voice

Outside the breeding season Plains-wanderers are usually silent. When the birds are vocal, the most obvious call is a repeated low-pitched resonant "oo", which sometimes sounds dove-like, though at other times it appears bovine. It is associated with the establishment and maintenance of the pair-bond, and may be given only by the female. The male makes a quiet "irr-irr" call in response to the chicks' staccato "chip-chip-chip" distress calls. He also utters a piping drawn out "pie-pie-pie" to summon to him lost chicks which are giving a weak "peep" call.

Food and Feeding

The Plains-wanderer is omnivorous, and a wide variety of seeds and insects have been recorded in its diet. In all seasons insects comprise about 40% of the diet, except in spring, when their proportion is slightly higher. Ants, and beetles up to 15 mm long, constitute the major portion of the insect foods that are eaten throughout the year. Sucking bugs and caterpillars, the next most important insect foods, are taken mainly in summer and autumn. Grass, chenopods and other plants provide seeds that comprise about 58% of the remainder of the annual diet. Whereas in summer grass seeds make up the main part of the seed intake, in autumn the predominance shifts to seeds of chenopods and other plants. Native plants provide the majority of the seeds while introduced plant species make only a minor contribution to the Plains-wanderer's diet. It is rare for the Plains-wanderer to eat plant parts other than seeds.

Foraging takes place during the day and also at dusk. Birds feed by pecking up seeds and insects from the ground, and rarely by gleaning seeds off standing inflorescences. They will also hammer compacted soil with the bill in order to expose arthropods.

Breeding

The Plains-wanderer probably practises serial polyandry, a strategy also known in the charadriiform families Rostratulidae, Jacanidae and Scolopacidae (Phalaropodinae). In Pedionomidae, both sexes may incubate, but the male takes the dominant role and he assumes the sole responsibility of rearing the chicks, leaving the female free to pair with another male.

Though eggs have been found in all months except March and April, the main breeding season in the south-east of the continent commences with pairing and the females calling during winter, in June and July. Prior to copulation, the female walks about, calling, with her wings drooped. First clutches are laid in late winter and spring, from late August to November. If summer rains fall, second clutches may be laid in the summer months of January and February. North of the Tropic of Capricorn Plains-wanderers tend to breed in autumn and early winter, from March to June.

Most nests are in sparse native grassland rather than crops, often with a sheltering plant alongside or above them. Sometimes grasses are pulled together to form a concealing cone above the nest. The nest hollow is 6-8 cm wide and 2-4 cm deep. It is scratched in the ground by the female and lined with grass. Anything from two to five pyriform eggs may be laid, though clutch size is normally four. The eggs are ground-coloured and well covered with brown specks and splotches, measuring 32·8 x 23·6 mm on average. Incubation lasts 23 days, and is undertaken mostly by the male, even though the female remains on the territory.

Chicks are mustard-coloured with dark brown spots. They are precocial and nidifugous, attaining full independence about two months after hatching. The male feeds in the company of the chicks, but has not been seen to provide food for them. When danger threatens, the male is a stout defender of the young and may place himself with wings outstretched between a human intruder and the chicks; he may also call the chicks until they are all gathered out of sight beneath him.

Neighbouring pairs are usually 250-400 m apart. After the first clutch has hatched the female may pair with a second male and lay a second clutch, generally about 40 m from the first nest-site.

Virtually nothing is known about breeding success, but recently independent young captured and ringed during surveys were found to outnumber adults by a ratio of three to two. Torrential rains can flood nests and cause widespread breeding failure. Nevertheless, the species has the ability to recover quickly from population slumps following droughts, and birds can breed when they are only one year old. It is not known how long birds may survive in the wild, but in captivity they have been known to live for at least eight years.

Movements

Plains-wanderers are sedentary unless displaced by changes to their habitat, such as overgrazing during droughts, cultivation or burning. Birds that have been forced to disperse may move long distances, as evidenced by sporadic records in unusual localities, but whether most of them successfully settle elsewhere or die is not known. While overgrazing can force birds away, after rain and the regrowth of the grass and herbs suitable habitat may be reoccupied by newly arrived birds. Conversely, when unusually heavy rains promote dense growth of introduced grasses and weeds in the native pastures, Plains-wanderers can be forced to move to other areas in search of better feeding opportunities.

Most recaptures of ringed birds have been within 200 m of the ringing site, even though in some cases many months had elapsed. Radio-tracked birds also remain close to their release site, so in normal circumstances the birds would appear to carry out all of their foraging, breeding and roosting activities in the same area.

Relationship with Man

Being small, cryptic both in plumage and behaviour, and uncommon into the bargain, it is hardly surprising that the Plains-wanderer has made little impact on man. The fact that the sexes were originally described as two distinct species is proof enough of how poorly known the bird was, at least in the early years of the nineteenth century, when Australia was even more sparsely populated than it is today, and the native grasslands survived intact.

Although Plains-wanderers have suffered to some extent from the activities of hunters (see Status and Conservation), at the same time it would seem that it has partly been through hunters that the Plains-wanderer's presence and habits have been brought to the public notice, as this typical report of Plains-wanderer escape behaviour from an early shooter testifies: "Whilst quail shooting in 1892 our dog which was a remarkably good worker made a decided set, but before either of us got within shot he started off for about 20 yards, and again set. This was repeated again and again until we had traversed the greater part of a 50 acre paddock in a zig-zag fashion. At last we saw a Plains-wanderer running like a rat through the grass. During the time occupied in following the dog we must have walked nearly half a mile. The same tactics were followed for about an hour, during which three more birds were shot. On several other occasions I have known them to lie motionless when set by the dog, and continue in that position until caught".

Status and Conservation

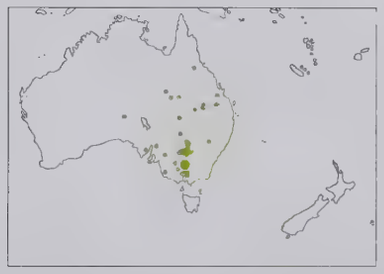
Lowland native grasslands are among the most depleted ecosystems in eastern Australia, and threatened grassland fauna have undergone a marked decline. There are now possibly fewer than 11,000 Plains-wanderers left in the wild, and in drought years, when overgrazing of habitat occurs, the population may be halved. These threats to the habitat remain constant, and the species is currently listed as globally Vulnerable.

The Plains-wanderer has been unable to adapt to the many changes that have taken place in these grasslands, changes brought about by the gradual influx of European settlers and the spread of their agricultural and pastoral activities. The species can not survive where sparse native grasslands are converted to crops or dense pastures formed of introduced plants, nor where the grasslands are dominated by weeds. Incapable of modifying its dietary requirements, it has become extinct in many areas where before it was not uncommon, and its numbers overall have dwindled alarmingly.

Conservation work for the Plains-wanderer and its threatened habitat took a major step forward with a study of the biology and management requirements of the species during the period 1984-1987. This study showed that on large inland grazing properties, the relatively small areas that are to be managed for Plains-wanderers need to be fenced off, in order to enable the intermittent removal of domestic animals. Grazing animals should be removed for the duration of the Plains-wanderer's breeding season, and reintroduced after this only if sufficient rain has fallen to prevent overgrazing.

The study identified the need for surveys to locate and rank areas with Plains-wanderers in order of priority, and for further work with landowners. These surveys have now commenced and have confirmed the threatened status of the species and the lack of large populations in any reserve. However, funds have been allocated for the reservation of the one remaining highly significant property, located during surveys of north Victoria. This 1400 ha property contains at least 150 Plains-wanderers and ten species of threatened plant, including one, *Leptorhynchos medius*, which was previously thought to be extinct. Also of importance is Willandra National Park in New South Wales, which contains perhaps some 50 Plains-wanderers, and a new reserve in south-west Queensland supports at least 150 Plains-wanderers, as well as threatened marsupials, such as the greater bilby (*Macrotis lagotis*). Despite this progress in the conservation of the species' habitat, much has still to be done with landowners, because it is on private land that the future of the Plains-wanderer rests. The fact that the species can readily be bred in captivity may yet prove significant.

The extent of the pressure that shooting may have had on the species is not clear. In the past, quail shooters killed many Plains-wanderers, and a few of these legally protected birds are still shot by mistake. In addition, introduced predators, such as the red fox (*Vulpes vulpes*), and pesticide spraying against locusts are further causes of some mortality amongst Plains-wanderers. However, there is no evidence that any of these three factors may be limiting populations to a degree remotely comparable with the dire effects of habitat alteration.



Genus *PEDIONOMUS* Gould, 1841

Plains-wanderer

Pedionomus torquatus

French: Pédionome errant **German**: Steppenläufer **Spanish**: Llanero
Other common names: Plain Wanderer, Collared Plains-wanderer/Hemipode, Turkey Quail

Taxonomy. *Pedionomus torquatus* Gould, 1841, plains near Adelaide, South Australia.
Traditionally placed in Gruiformes, in close association with Turnicidae, but evidence currently available suggests link with Thinocoridae (see page 538). Populations in New South Wales were proposed as separate race, *goulburni*, but no genuine geographical variation detectable. Monotypic.
Distribution. E Australia.
Descriptive notes. 15-19 cm; male 40-80 g, female 55-95 g. Resembles *Coturnix* quails, but bill finer, neck and legs longer, and overall appearance lankier. Male has throat grey-white, breast buff, with pattern of dark brown or black crescents on side of neck, upper breast and flanks. Female larger and more brightly coloured than male; distinctive broad collar, black with white spots; yellow-buff or rufous breast band. Juvenile similar to male, but with dark brown spots, rather than crescents, on underparts.
Habitat. Sparse lowland native grasslands with low-growing herbs; rarely in cereal stubble. Avoids trees, woodland, scrub, dense pasture of introduced plants, and large bare areas. Breeding, feeding and roosting all occur in sparse native grasslands, usually without permanent water.
Food and Feeding. Omnivorous. Insects comprise nearly half annual diet; seeds of grass, chenopods and other plants make up remainder. Insects and seeds taken from ground; water droplets pecked from leaf tips after rain. Roughly one third of day is spent foraging.
Breeding. In SE, first clutches from late Aug to Nov, second clutches in Jan-Feb if summer rains fall; further north breeding occurs Mar-Jun. Solitary and probably serially polyandrous. Nest is shallow scrape in ground, lined with grass. Usually 4 eggs (2-5). Incubation 23 days, mainly by male; chicks

mustard-coloured with dark brown spots; chick-care solely by male, lasting c. 2 months. Sexual maturity at 1 year. After breeding season, independent young outnumber adults 3:2.
Movements. Sedentary, unless displaced by changes to habitat, e.g. cultivation, burning, overgrazing during droughts.
Status and Conservation. VULNERABLE CITES II. Fewer than 11,000 birds and in drought years this number may be halved. Massive conversion of native grasslands to crops and dense pastures of introduced plants with weeds has brought about marked decline in total numbers. Regional extinctions across very large tracts of coastal and sub-coastal E Australia in all four states where species occurs. Recent surveys of Victoria, where species perhaps once most numerous, indicate possibly as few as 1000 birds; these birds mainly confined to small remnant islands of native grassland in a sea of cropland and introduced pastureland; future of many of these populations is not assured. Further inland, cultivation is not widespread, but overgrazing during droughts causes displacement, and decline in local populations. Key inland region is C New South Wales, with as many as 5500 birds. Other important areas are SW Queensland and NE South Australia, with combined population of c. 4500 birds. Recent conservation work has led to establishment of three widely separated reserves supporting c. 350 birds. Vast majority of overall population found on privately owned land, and much more joint work required with landowners. Alteration of habitat constitutes by far the major threat; additional dangers include hunting, introduced predators and pesticide spraying against locusts.

Class AVES

Order CHARADRIIFORMES

Suborder CHARADRII

Family THINOCORIDAE (SEEDSNIPES)

- Small to medium-sized birds with short legs and bills, resembling quails or partridges, but with snipe-like flight.
- 16-30 cm.

- Neotropical Region.
- Alpine vegetation, steppe and semi-desert, from sea-level up to 5500 m.
- 2 genera, 4 species, 10 taxa.
- No species threatened; none extinct since 1600.

Systematics

The seedsnipes are endemic to the Neotropical Region, where they inhabit Patagonia and the Andean zone. There is no paleontological record of them, apart from Pleistocene subfossils within the current range. However, their distinctive appearance and the DNA divergence data available indicate that the lineage dates well back into the Tertiary.

The seedsnipes differ strongly in overall impression and shape from the majority of charadriiform birds, but not more so than the sandgrouse (Pteroclidae), which are frequently considered to be close to Charadriiformes, and indeed are even sometimes included in this order. Although early systematists recognized that seedsnipes resembled the shorebirds, or waders, in a number of anatomical characters, they also noted that they showed some similarities with passerine birds, sandgrouse and gamebirds. All this resulted in confusing statements about their relationships with other birds. The cranial anatomy is superficially similar to that of passerine birds, with the aegithognathous palate, and seedsnipes differ from most other shorebirds by having a crop, a gizzard and long intestinal caeca; also, the legs are short, and a hind toe is present. However, with only two exceptions, all classifications of birds proposed over the last 100 years have included the seedsnipes in the order Charadriiformes, which was previously known as Limicolae. Their aberrant characters have thus been accepted as a result of their vegetarian diet.

A detailed analysis of skeletal characters by J. G. Strauch, published in 1978, placed the seedsnipes on the same main charadriiform branch as the snipes. However, in 1981 S. L. Olson and D. W. Steadman provided strong evidence that the nearest relative of the seedsnipes may be the Plains-wanderer (*Pedionomus torquatus*), an enigmatic Australian bird which had previously been regarded as an aberrant buttonquail (see page 534). The Plains-wanderer and the seedsnipes could be relicts of an ancient group of grassland charadriiforms which might have dispersed across the Antarctic continent before it was covered by ice in the Upper Miocene period, 10-15 million years ago.

Several earlier anatomical studies had shown that *Pedionomus* differed notably from the buttonquails. Its placement alongside them might be considered an historical accident which can be traced back to the influence of H. von Gadow in the 1890's, and which remained unchallenged because later students simply did not compare *Pedionomus* skeletons with those of other bird groups. Thus, Olson and Steadman were the first taxonomists to put forward the view that the *Pedionomus* skeleton was quite typical for charadriiform birds, and particularly close to that of the small *Thinocorus* seedsnipes. The most striking similarities are the broad, two-notched sternum and the broad pelvis. A close relationship between the seedsnipes and the Plains-wanderer, as well as a more distant relationship of these two groups with the Scolopacidae, has subsequently been supported by the DNA-DNA hybridization data collected by C. G. Sibley and J. E. Ahlquist.

It may be added here that the Magellanic Plover (*Pluvianellus socialis*), a species of controversial taxonomy that is traditionally placed in the plover family, Charadriidae (see page 386), resembles *Thinocorus* seedsnipes not only in shape, but also by having a crop and in fine details of the juvenile and natal plumages. However, the anatomical characters provide conflicting evidence, and DNA data are lacking.

Morphological Aspects

The external appearance of seedsnipes resembles that of quails or grouse, except for the wings, which are long and pointed. The tail is fairly short and wedge-shaped. When the birds are flushed, their erratic, zig-zagging flight recalls that of snipes or calidrine sandpipers, and the small *Thinocorus* species may at first glance be confused with Pectoral Sandpipers (*Calidris melanotos*), which commonly winter within their range.

The *Thinocorus* species range in size roughly from that of a sparrow to that of a snipe, and they are shaped much like the Old World sandgrouse. The two *Attagis* species are much larger, resembling ptarmigans (*Lagopus*) in size, shape and, to some extent, coloration; however, in flight they differ clearly from these gallinaceous birds by having longer, pointed wings.

The seedsnipe's head is small, while the bill is short and thick, with the nostrils protected by a large shield-like cornaceous flap. The legs are short, but the toes are relatively long and strong; indeed, the middle toe is as long or longer than the tarsus, while the hind toe too is well developed.

Studies of the jaw muscles of *Thinocorus* indicate that the bill is primarily adapted for high-precision browsing, as the birds bite off leaf tips, buds and other tiny plant parts (see Food and Feeding). A strong tendon, originating from the postorbital and zygomatic processes, and connecting the lower mandible with the postorbital region of the skull, is ossified along much of its

length, restricting the mobility of the lower mandible. Apparently, then, the birds bite mainly by using the muscles of the palate, protracting the upper mandible and depressing its tip. Small plant parts are torn off by moving the bill towards the breast with a quick movement. Kinetic movements of the upper mandible are also of fundamental importance in many sandpipers, although the precise feeding mechanism varies somewhat. The *Attagis* skull differs from that of *Thinocorus* in many respects, but the functional implications of this are unknown.

Seedsnipes are cryptically coloured, the upperparts being intricately mottled and scalloped with black, brown, rufous, buff and whitish, the breast scalloped or speckled. The nominate southern race of the Rufous-bellied Seedsnipe (*Attagis gayi*) is adapted to Arctic-style desert, and has a finely vermiculated and stippled pattern, giving a "frost-bitten" appearance, as is also seen in some races of the Rock Ptarmigan (*Lagopus mutus*).

Males, but not females, of the two small seedsnipes have the face, neck and breast dove grey, but apart from this sexual dimorphism is very minor. Juveniles resemble adults, but the dorsal feathers are usually more finely vermiculated or obscurely spotted, and the primaries often pale-tipped. Juvenile Least Seedsnipes (*Thinocorus rumicivorus*) have much weaker breast stripes than those exhibited by the adult females.

Newly-hatched young are covered with dense down. However, *Attagis* and *Thinocorus* chicks look quite different. Those of *Attagis* are rich buff with a complicated pattern of black speckles. A second generation of uniform plumbeous grey down emerges, pushing out the initial down, just before the appearance of the contour feathers. This sequence is remarkably similar to that found in sheathbill (Chionidae) chicks. The chicks of *Thinocorus* are drab grey to hazel brown, with a more simple pattern of blackish spots and bands on the back, and a dense stippling of white tips to the down. Unlike the white "powder-puffs" which dot the natal plumage in many snipes, these are composed of dense brushes of barbules on just one side of each barb. However, similar brushes are also found in chicks of a few other aberrant shorebirds, such as the Magellanic Plover.

Examination of Least Seedsnipes collected in late February, towards the end of the austral summer, indicates that the juvenile plumage which replaces the natal down may, in turn, be replaced rapidly, through a partial moult, by feathers rather similar to those of adults. The pattern of replacement may be complex, or perhaps just quite variable between individuals. Primary moult in adult seedsnipes progresses with the outer three primaries moulted first, after which the inner primaries follow in a complicated sequence.

Habitat

Within their exclusively South American range, seedsnipes inhabit grassland, semi-desert and alpine habitats in Patagonia, in the Andes and along the coast of Peru. They are found in some of the most inhospitable parts of the continent.

The White-bellied Seedsnipe (*Attagis malouinus*) inhabits the windswept top ridges of the crowberry (*Empetrum*) moorlands of Tierra del Fuego and the islands south to Cape Horn. The Rufous-bellied Seedsnipe occurs in almost barren Arctic-style desert near the snow-line in the Andes, locally ranging up to 5500 m, but at altitudes as low as 2000 m in southern Chile. Both species seem to feed mainly in places with spongy cushion-plants (*Azorella*, *Pycnophyllum*, *Plantago rigida*) and a very sparse covering of grass. They are sympatric in the Andes of southern Chile and Argentina, and are apparently segregated ecologically, with the White-bellied mainly occurring on desolate moorland plateaux and the Rufous-bellied associated with well watered places fed by melting snow. The White-bellied Seedsnipe leaves its upper ridge habitat in February or March to appear on adjacent foothills and lowland flats, where it seems to favour areas with boulders and gravel in dry riverbeds. In contrast, the Rufous-bellied Seedsnipe remains at high altitudes, descending only a few hundred metres during the worst winter storms.

The Grey-breasted Seedsnipe (*Thinocorus orbignyianus*) is associated with Andean grass steppes, from Patagonia to Peru. Within this ecoregion, its most typical habitats are rather open vegetation with low cushion-plants, scattered *Tetraglochin* scrub, a matted vegetation of very short grass and herbs, or boggy habitat near the snow-line.

The Least Seedsnipe is associated much more with sandy areas in the southern lowlands and on the upland plateaux just east of the Patagonian Cordillera. It is common in areas which are heavily overgrazed by sheep. This habitat is characterized by widely scattered tussocks of bunch-grass, as well as small cushion-plants and low scrub. Another important habitat for this species comprises clay-pans, which are filled with water from

With its plump body, short legs and short, thick bill, a seedsnipe bears a superficial resemblance to the gallinaceous birds, but it has long, pointed wings and flies in a fast, erratic fashion, often zig-zagging, like the true snipes of the family Scolopacidae. Among the most peculiar physical features of the Thinocoridae are the shield-like cornaceous flaps that cover the nostrils, as can be seen on this Rufous-bellied Seedsnipe. These flaps may provide protection during the dust storms that frequently occur in arid seedsnipe habitats.

[*Attagis gayi simonsi*, Salar de Surire, Chile. Photo: A. de Sostoa & X. Ferrer]

melting snow in spring, but which dry up during the summer. Rather dry, sandy grassland is also favoured on the major wintering grounds in the Argentinian *pampas*. The Peruvian population of this species inhabits areas with short, scattered "mist vegetation" of tiny annuals in the coastal desert.

Seedsnipes spend most of their time on the ground, feeding mainly in places with a prostrate vegetation. However, singing males often use elevated posts such as rocks. In the sheep-ranching districts of Patagonia, the Least Seedsnipe sings mainly from fence posts; large heaps of their droppings can be found below some such posts, demonstrating that territorial males may use the same favourite post for long periods of time.

General Habits

The *Attagis* species are extremely poorly known. Most Andean ornithologists know them only from brief encounters, when a group of birds is suddenly flushed from a small bog, and flies away rapidly, accompanied by loud calls. However, birds actually tend to be quite approachable and can sometimes be watched at close range while feeding; at other times they are shy.

The smaller (*Thinocorus*) species are generally easier to observe, but there is very little information published on their habits. They usually feed quietly in a low, crouched attitude, looking quite flat-backed. When alerted, they often freeze in a low crouching attitude, relying on their perfect camouflage to enable them to escape detection. However, they may also walk away with the head raised, sometimes showing distinctive bobbing movements, like plovers. When flushed, they dash off with zig-zagging flight, sometimes dropping to the ground again rather quickly.

Seedsnipes roost on the ground, making shallow scrapes in which they lie. The birds are most often found in pairs or in small groups, which may be family parties. Territorial males spend long periods of time on or near their look-out posts, which are ascended promptly when the song of a conspecific, or a human imitation of it, is heard. Song activity is highest at night. In the early part of the breeding season males make aerial song flights almost throughout the night, but are quiet for much of the day.

Small flocks are often seen outside the breeding season. Up to 80 Rufous-bellied Seedsnipes have been observed in one flock, which is noteworthy considering the low density of birds generally in the Arctic-like environment frequented by this species. White-bellied Seedsnipes sometimes pack together in large numbers when the snow is deep. In Patagonia, Least Seedsnipes aggregate in large numbers in February, towards the end of the austral summer. Hundreds of individuals may forage in loose flocks on lake shores, where they feed on the low herbaceous vegetation which develops as the shallow lakes dry up around that time of the year.

Voice

The calls of seedsnipes are distinctive. In fact, the easiest way for an observer to locate the two smaller species is by imitating their territorial songs and listening for a reply. Often, a territorial male will quickly mount his traditional song post and begin to sing.

During the day, most songs are given from a rock, although the Least Seedsnipe often sings from a thick bush, a tall weed or a fence post. Song can also be given while birds are flying in wide circles. In such cases, variations in the relative direction of the flight give the impression of variations in the strength and pitch of the song, due to the Doppler effect. Aerial songs are mainly given at night. On the windy Patagonian plains, singing activity is often fairly intense during calm periods around midnight.

The song of the Grey-breasted Seedsnipe is an easily imitated soft cooing, which can be repeated monotonously for several minutes, "pooko-pooko-pooko-pooko..." (see Relationship with Man); up to 850 "pookos" have been recorded in one song. Individual birds may differ slightly in song quality, some individuals giving a more grating version, "pooráak pooráak pooráak pooráak..."

The Least Seedsnipe has a similar but less melodic and much more variable song, as illustrated by some of the different versions transcribed during fieldwork as "krii-oko", "kroo", "krro...pucui pucui-pucui" from song posts, and "vut-vut-vut-vut...", "puc-curr puc-curr puc-curr...", "pehooy pehooy pehooy...", or accelerating "tjupo-cooo tjupo-cooo..." during song flight. Aerial songs may also be more snipe-like "djek-djek-djuk-djuk" or alternate with series of low "puc-puckepuck", and may fade out during the "parachuting" final part of the display, as "phu-phrr, phu-phrr..."

When at ease, the members of a group of *Thinocorus* seedsnipes may call to one another continually, using a two note call, and feeding birds may also give low "dyurr" or "dyuc" calls. When flushed, Grey-breasted Seedsnipes make a grating snipe-like "chrp" or "bzzep", while the Least Seedsnipe gives a short snipe-like "djuc" or "djiric", or low grunts. In both species, this is often followed by a rapid series of deeper and more melodic calls, "tuc-tucketuck..."

Rufous-bellied Seedsnipes give a characteristic loud melodic "gly-gly-gly-gly..." or "cul-cul-cul-cul..." (see Relationship with Man). This can be heard, as a song, throughout the morning, and is also given continously in flight. Alerted birds may start calling before they fly, while running on the ground, and this rises to a bewildered chorus as all birds call together in flight, their calls being echoed back from the surrounding hills. The voice of this species has also been described as a rasping "tchaa", similar to the call of a Fuegian Snipe (*Gallinago stricklandii*) but even

The grey breast with a black anchor-shaped pattern identifies the male Least Seedsnipe. This species differs from other seedsnipes by its stronger preference for sandy areas, where many seeds are to be found, and it appears to live up to the name "seedsnipe" better than the rest of the family, as it may take a higher proportion of seeds.

[*Thinocorus rumicivorus rumicivorus*, Cabo Dos Bahías, Chubut, Argentina. Photo: A. de Sostoa & X. Ferrer]

Boggy areas near the snow-line constitute one of the preferred habitats of the Grey-breasted Seedsnipe, a characteristic bird of the puna. The short grass and cushion-plants that abound in this zone provide major sources of food for the birds to browse on. The heavily scalloped pattern of the upperparts that is present in all seedsnipes affords them excellent camouflage, as this photo clearly shows.

[*Thinocorus orbignyianus ingae*, above Arequipa, Peru. Photo: A. Greensmith/ Ardea]

louder; this description certainly differs from the impression of the present author.

The flight call of the White-bellied Seedsnipe has been described as an excited "tu-whít tu-whít..." recalling the flight call of the Grey Plover (*Pluvialis squatarola*); this voice is given as long as the bird is on the wing.

Food and Feeding

The name seedsnipe is rather misleading, as careful field observations reveal that the members of this family usually feed by browsing, biting off tiny bits of plants, such as buds, leaf tips and small green leaves. This is done while a bird is walking slowly in a low, crouching attitude, by means of rapid snapping movements. The plant fragments are swallowed whole. Most often the birds feed in areas with short, prostrate vegetation, such as cushion-plants or low succulent plants. They may also stretch up a little to bite off the tops of grasses, or to browse on taller herbs (*Polygonum*, *Trifolium*) or dwarf shrubs (*Margarocarpus*, *Tetraglochin*). However, aside from these generalizations, it should be noted that detailed studies of stomach contents identified to species level are still lacking, and consequently the more precise feeding habits of this family remain largely unknown.

The Least Seedsnipe, which often feeds in sandy places, may possibly take more seeds than the other species. In the Peruvian Desert it is often encountered in habitats influenced by seasonal fog, where tiny green herbs exist for only a short period each year. Because of the climatic oscillations related to El Niño (see Volume 1, page 341), a lush cover of herbs develops in certain years, indicating that large numbers of seeds must usually lie "dormant" in the desert sand. However, scattered observations indicate that even the Least Seedsnipe browses in most situations, and succulent leaves may make up a considerable part of its diet. Indeed, in its arid habitat, such leaves may represent the only source of water. No seedsnipes are known to drink in natural conditions, although they may do so in captivity.

Breeding

As with most other aspects of their biology, the breeding habits of seedsnipes remain very poorly known, and offer considerable scope for intensive study. Judging from rather unsystematic observations and anecdotal evidence, seedsnipes appear to be monogamous and territorial; for instance, males often fight and chase each other, and spend much time on or near traditional watch posts. For much of the year seedsnipes are to be seen in pairs or in small parties which may represent family groups.

Males of the two *Thinocorus* species often sing for long periods from their vantage posts, standing with the swollen neck upright or sloping slightly forwards. In suitable habitat, territory centres can be as little as 50 m apart. During the night, aerial song flights may last for several hours with only short interruptions. Song flights are also often seen by day, as a bird will fly around in wide circles while singing, and on windy days singing birds often sing from a "hanging hover", using updraught winds. Song flights terminate with a parachute-like descent with the wings downcurved or partly folded, the bird often landing on its usual vantage post; during the final horizontal glide, the Least Seedsnipe keeps the tail raised vertically.

In southern Patagonia, eggs of Least Seedsnipes can be found from August to February, suggesting that females may lay several clutches per season. The Grey-breasted Seedsnipe nests in November and again in January and February. Some Least Seedsnipes collected in Patagonia in February, at the end of the austral summer, had enlarged gonads and plumages which would seem to contain a mixture of juvenile and adult-type feathers. Although most birds were aggregating in post-breeding flocks at this time, others were displaying, and nests with eggs were also found. This could indicate a very rapid sexual maturation, as is known to occur in *Coturnix* quails, where young birds may nest towards the end of the season in which they have hatched. However, such observations need to be followed up by more thorough studies, both in Patagonia and in the Peruvian Desert. Adaptations for opportunistic breeding and for maximizing population growth could be expected especially in the latter area, where the climatic oscillations related to El Niño cause marked vegetational changes in certain years (see Food and Feeding).

In the Andean *puna* zone, the principal nesting season may be at the beginning of the rainy season, in November. However, seedsnipe nests may also be found at other times, even in the dry "winter" season.

The nests of seedsnipes are crude scrapes in the ground, often lined with some mosses and plant debris, and placed close to a stone, a bunch-grass tussock or a dense dwarf shrub. Many nests are placed in dry horse dung. All seedsnipes generally lay four eggs, or sometimes three, and these resemble those of snipes in being strongly pear-shaped, with a polished surface and cryptic spotting. *Thinocorus* eggs are usually creamy to pink or greenish white, profusely spotted with dark brown, often as a halo or cluster around the larger pole. Eggs of the Rufous-bellied

There are no published records of seedsnipes drinking in the wild, and, despite the highly suggestive photo, this Grey-breasted Seedsnipe male was not definitely recorded as doing so. As is often the case with birds inhabiting rather arid areas, the grasses and succulent plants which make up the diet apparently provide all the water that the birds need. Nevertheless, seedsnipes are known to drink once in a while in captivity, and further observations might yet show that they can do so in the wild too, at least occasionally.

[*Thinocorus orbignyianus ingae*, Ayacucho, Peru. Photo: Günter Ziesler]

Seedsnipe are normally olive-buff with spots in various shades of brown and purplish grey, while the eggs of the White-bellied Seedsnipe have been described as olive-citrine with brown spots.

In the *Thinocorus* species, at least, only the females incubate, and the same may possibly apply in *Attagis* too. The male spends much time on a perch near the nest, where he acts as a look-out, giving a warning call and running away, together with the female, as soon as danger is sighted. The female invariably covers the eggs completely with plant debris or soil whenever the nest is left, whether this be to feed or because of disturbance. This egg-covering is performed rapidly, using sideways kicks of the feet and can result in the nest resembling a completely random accumulation of plant debris. In the case of the Rufous-bellied Seedsnipe, the supply of nest material may be too scarce to allow egg-covering. An incubating female will leave the nest to feed for about an hour in the morning, and again in the late afternoon.

If the female is disturbed suddenly on the nest, and especially if there was not time to cover the eggs, she performs an elaborate injury-feigning distraction display, running with drooping and partly spread wings and tail, or fluttering away low over the ground.

The incubation period of the Least Seedsnipe is about 26 days, but no precise data exist for the other species. The young are highly precocial, and are led away from the nest by both parents as soon as they are dry after hatching. However, it is the female alone that broods them. From the start the young chicks feed by themselves and do not need to be shown food by their parents. If disturbed with young, both parents may perform distraction displays, but those of the male usually consist only of the "rodent-run" typical of shorebirds. The young may fly at about seven weeks of age.

Movements

Southern populations of the Least Seedsnipe are partially migratory, wintering on sandy grassland as far north as Buenos Aires and Uruguay. The species may vacate the Magellanic zone and Patagonian uplands in winter, but this is poorly documented in the literature and remains to be demonstrated. White-bellied Seedsnipes probably leave their inhospitable upland habitats in late February and March, at the first snowfall. They turn up at this time in the foothills and are found on lowland flats during periods of heavy snowfall. Similarly, Grey-breasted Seedsnipes vacate Tierra del Fuego and the high parts of the Patagonian Andes, and appear in winter in low mountain ranges east of the Cordillera and also in the coastal hills of Chile. There are several records of Least Seedsnipes and two of White-bellied Seedsnipe on the Falkland Islands.

In the *puna* zone of Bolivia and Peru, Grey-breasted Seedsnipes are often found in low parts of the terrain in the dry season, including *Tetraglochin* heaths, cultivated areas, river plains and shore meadows. In the rainy season they usually disappear from these parts and are instead found on high hills, in places with low cushion-plants or densely matted short vegetation, and along the edges of highland bogs, sometimes as high as 5000 m. The race *bolivianus* of the Least Seedsnipe, which breeds in the arid *puna* of western Bolivia and adjacent parts of Chile, has been found in high densities in the non-breeding season, from May to September, on gravelly moraine plains up to 4500 m in the Eastern Cordillera of La Paz.

The Peruvian population of the Least Seedsnipe may show seasonal or nomadic movements, judging from observations of flocks in some places where the species was unrecorded during other visits. There is no documentation of local or altitudinal movements in connection with the climatic oscillations related to El Niño.

To date there are no published observations which indicate significant migrations in the Rufous-bellied Seedsnipe. Observations in the Peruvian part of the range seem to indicate that the species is present near the glaciers at all seasons, in flocks in the dry season and mainly in pairs during the rainy season. However, many birds can sometimes assemble in boggy valley bottoms or in the corrals near shepherds' huts. In Chile, birds are said to withdraw briefly a few hundred metres downhill during the severest storms.

Relationship with Man

The vocalizations of seedsnipes are well known by local peasants in the Peruvian and Bolivian highlands, as reflected by the

Quechua names "Puco-puco", "Pucu-pucu", "Tuco-tuco" or "Pucpush" for the *Thinocorus* species, and "Kulle-kulle" or "Kuli" for the Rufous-bellied Seedsnipe. Despite this familiarity, nothing appears to have been recorded about the role of seedsnipes in legends or folklore.

Similarly, little is known about their economic use. Since most peasants and pastoralists kill highland tinamous (*Nothoprocta*, *Nothura*) with sling-shots or by throwing stones, one would imagine that seedsnipes are also likely to be killed in this way sometimes. The *Thinocorus* species may be too small to represent attractive prey, but they are sometimes hunted in Chile and Argentina on their wintering grounds, where they appear in large flocks. The larger Rufous-bellied Seedsnipe is regarded as excellent game. It is easy to shoot and its populations have been devastated in some mining districts in Peru, but fortunately in most parts of its range the local people lack guns. Furthermore, most Rufous-bellied Seedsnipe habitats are very sparsely inhabited and utilized by man, so the impact of hunting is presumably slight.

Status and Conservation

Over a long time perspective, human activities have probably led to an increase of seedsnipe habitat. There is growing evidence that most of the Andean highlands, up to the level of true alpine vegetation, were once dominated by dispersed woodland vegetation (*Polylepis*) and shrub-steppe (*Lepidophyllum*), with tall grasses and rushes on the floodplains. After the last glacial period, however, early human hunters and gatherers colonized the highlands as soon as the ice retreated. There was probably some use of firewood, but the main human impact in the period about 10,000-7500 years ago may have been in the form of the use of fire during hunting. Even occasional fires may have had a severe impact on the fragile high Andean ecosystems. After the establishment of permanent centres of settlement 7500-4500 years ago, fire was also used to clear pasture areas for the domesticated camelids, the llama and the alpaca. However, burning was probably kept under some control, since camelids do not like the grasses favoured by frequent burning. At the same time, many flat-bottomed mountain valleys were dammed to increase the areas of bogs favoured by camelids. All these changes would increase the habitat available for seedsnipes.

There is some debate about the relative importance of climatic changes, cutting of firewood and introduction of ecologically unsound agricultural methods after the arrival of the Spanish 500 years ago. However, there is little doubt that the sheep-grazing and the incessant burning practised today, either to stimulate the development of bunch-grass or for no clear purpose, have caused a change now which is less favourable for seedsnipes. Nevertheless, the Least Seedsnipe is still extremely abundant on those parts of the Patagonian steppes which are most strongly overgrazed by sheep. It can also be found on cultivated land in the Peruvian Desert, and may be positively affected by the irrigation schemes here. Both *Thinocorus* species may feed on cultivated areas, as long as the crop plants remain low.

With the current knowledge about seedsnipes, no realistic population estimates can be made. The *Thinocorus* species are generally common, with huge populations in certain parts of their ranges, and the Least Seedsnipe is one of the commonest birds on the windy plains of southern Patagonia. Although the population levels may change locally or in time, in response to changing land use, there is no reason for concern about the future survival of either of these species.

There are very few published records of the Least Seedsnipe on the Altiplano, where it is represented by the subspecies *bolivianus*. However, it has been found to be abundant in certain places in north-eastern Chile, and it is known to winter at considerable density on the moraine plains of the Eastern Cordillera of La Paz, in Bolivia.

The *Attagis* species undoubtedly have populations that amount to more modest numbers, which is quite natural in view of their inhospitable and unproductive environments, and the restricted extension of this high altitude habitat. As a simple consequence of the very small area available, the population of the Ecuadorian race *latreilli* of the Rufous-bellied Seedsnipe is unlikely to number more than a few hundred pairs; the total area above 4000 m in Ecuador is less than 5000 km², and only a small fraction of this is suitable habitat for the species. According to N. Krabbe, the species occurs only on the volcanoes Pichincha, Iliniza, Chimborazo, Cayambe, Antisana, Cotopaxi and Tungurahua, with an estimated total for Ecuador of 200 pairs. A careful study of the status of the Rufous-bellied Seedsnipe in Ecuador would be highly relevant and opportune.

Fortunately for the Rufous-bellied Seedsnipe, the habitats it frequents are generally little used by man. In most areas the only human activity is some pastoralism, mainly with llamas and alpacas. It is even more fortunate that many of the areas of mountain wilderness inhabited by this species have received formal protection. Thus, four of the seven Ecuadorian populations are to be found in protected areas, the Cotopaxi National Park, the Cayambe-Coca Ecological Reserve, the Chimborazo Production Reserve and the Pichincha Protection Forest Reserve. The species is protected in Peru in the large Huascarán Biosphere Reserve and in the Salinas y Aguada Blanca National Reserve. Some of the best habitats along the border between Bolivia and Chile are included in Lauca and Volcán Isluga National Parks and Las Vicuñas National Reserve in Chile, and Sajama National Park and the Eduardo Avaroa National Reserve in Bolivia. A number of protected areas are also found in the jagged Andean Cordillera along the border between Argentina and Chile. Finally, a substantial portion of the distribution range of the White-bellied Seedsnipe lies within areas where resource conservation is required by law.

Clearly, these two larger species have an advantage in inhabiting landscapes which modern man regards as beautiful and awe-inspiring. Very locally this may lead to some disturbance because of the increasing popularity and promotion of ski-ing, hiking and mountain climbing, but the only serious threat to the *Attagis* species at present seems to be from mining activities. Large areas in the Western Cordillera in Peru and Bolivia have been severely scarred and polluted by mining, and the existence of mining communities may also lead to severe hunting pressure. With this in mind, some attention should certainly be given to the conservation status of seedsnipes in mining areas.

Seedsnipes are apparently monogamous and territorial and, especially during the breeding season, are mostly found in pairs. Their overall resemblance to gallinaceous birds, and to ptarmigans (Lagopus) *in particular, is especially evident in the case of the White-bellied Seedsnipe, the similarity being reinforced by the desolate moorland habitats this species occupies.*

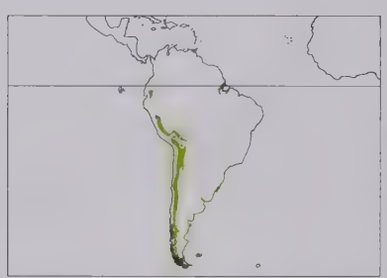
Genus *ATTAGIS*



I. Geoffroy Saint-Hilaire & Lesson, 1831

1. **Rufous-bellied Seedsnipe**

Attagis gayi

French: Attagis de Gay **German**: Rotbauch-Höhenläufer **Spanish**: Agachona Grande
Other common names: Gay's Seedsnipe

Taxonomy. *Attagis Gayi* I. Geoffroy Saint-Hilaire and Lesson, 1831, Santiago, Chile.
Three subspecies recognized.
Subspecies and Distribution.
A. g. latreillii Lesson, 1831 - N Ecuador.
A. g. simonsi Chubb, 1918 - C Peru (Lima) through N Chile and W Bolivia to NW Argentina (Jujuy).
A. g. gayi I. Geoffroy Saint-Hilaire & Lesson, 1831 - Andes of Chile and Argentina, from Antofagasta and Salta S to Tierra del Fuego.
Descriptive notes. 27-30 cm; 300-400 g. Cryptically coloured, intricately mottled rufous brown, dorsal feathers with concentric dusky lines giving scalloped effect, underparts pale pinkish cinnamon. In flight, appears uniform cinnamon brown, with no pattern on wings or tail; wing linings coloured like underside of body. Juvenile similar to adult, but with more finely mottled pattern above. Races differ mainly in general tone of coloration, with underparts deep cinnamon rufous in *latreillii*, pinkish cinnamon in *simonsi*.

Habitat. Rocky slopes, scree, and other bleak alpine terrain in Andean Cordilleras. Often stays close to snow-line, but when feeding usually descends to nearest bog or other areas with cushion-plants or low matted vegetation. In Ecuador, occurs in highest *páramos*. Typically found at 4000-5500 m in N half of range; further S occurs above 2000 m, and in extreme S of range above 1000 m.
Food and Feeding. Fragments of thorny and succulent plants recorded. No further information available.
Breeding. Egg-laying in Sept-Oct in Chile; young found in Oct in Ecuador. Monogamous and solitary. Nest is a shallow scrape. Clutch 4 eggs; chicks buff densely streaked and spotted black, but this coat soon replaced by grey down, then by feathers. No further information available.
Movements. Apparently moves only on a very local scale.
Status and Conservation. Not globally threatened. Status of species poorly known because of its harsh and inaccessible habitat. Generally fairly common within its narrow altitudinal zone near the snow-line, but strongly persecuted in some mining areas. Race *latreilli*, inhabiting seven Ecuadorian volcanoes, may not number more than c. 200 pairs; four of these populations occur in protected areas, in Cotopaxi National Park, Cayambe-Coca Ecological Reserve, Chimborazo Production Reserve and Pichincha Protection Forest Reserve. Species also occurs in protected areas elsewhere in range (see page 543).
Bibliography. Blake (1977), Butler (1979), Canevari *et al.* (1991), Dunning (1982), Fjeldså & Krabbe (1990), Humphrey *et al.* (1970), Johnson (1965b, 1972), Koepcke, H.W. & Koepcke (1971), Koepcke, M. (1970), Meyer de Schauensee (1982), Olrog (1984), Ortiz & Carrión (1991), Parker *et al.* (1982), de la Peña (1992), Remsen & Traylor (1989).

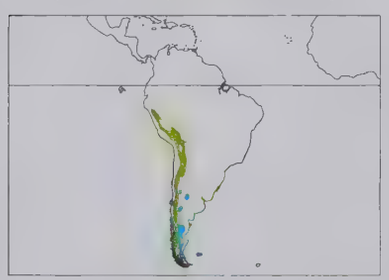
2. White-bellied Seedsnipe

Attagis malouinus

French: Attagis de Magellan **German**: Weißbauch-Höhenläufer **Spanish**: Agachona Patagona

Taxonomy. *Tetrao Malouinus* Boddaert, 1783, Falkland Islands.
Northern birds have on occasion been separated as subspecies *cheeputi*, recognized by darker rump, but doubtfully valid. Monotypic.
Distribution. S Chile and Argentina, from Magellanes and Río Negro to islands off Cape Horn.

Descriptive notes. 26·5-29 cm. Cryptically coloured, resembling Northern Hemisphere ptarmigan (*Lagopus*) in general appearance. Above and on most of foreparts densely speckled and scalloped black, buff and cinnamon; this contrasts with white chin and belly. In flight, shows white greater and median underwing-coverts and axillaries. Female tends to have demarcation between scalloped breast and white lower underparts somewhat less sharp; little or no sexual size dimorphism. Juvenile similar to adult, but appears slightly paler and more heavily scalloped.
Habitat. Occurs mainly on windswept ridges with scree or in moorland, especially in places with crowberry heath (*Empetrum*) and *Azorella* cushion-plants; breeds from 650 m up to 2000 m. Outside breeding season, found mainly on stony parts of Patagonian steppe, e.g. along dry riverbeds or wide shores of partly dry lakes.
Food and Feeding. Crowberry and other plant material recorded. No further information available.
Breeding. Eggs known from Jan. Nest is depression lined with plant matter, e.g. short stems, moss and lichen. Lays 4 eggs; downy chicks slightly warmer buff and less densely spotted than those of *A. gayi*. No further information available.
Movements. Descends in winter to adjacent lowland plains. Two records from Falkland Is.
Status and Conservation. Not globally threatened. Generally occurs at low densities, but largely protected from human interference by occupation of harsh and inaccessible habitat. Large portions of range in Chile are within areas which have received some form of legal protection.
Bibliography. Blake (1977), Canevari *et al.* (1991), Clark (1986), Dunning (1982), Fjeldså & Krabbe (1990), Humphrey *et al.* (1970), Johnson (1965b), Meyer de Schauensee (1982), Olrog (1984), de la Peña (1992), Williams (1995b), Woods (1988).



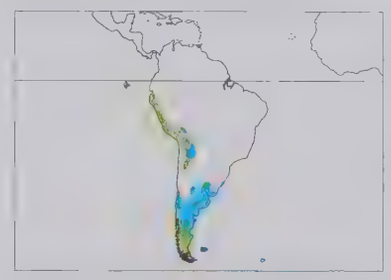
Genus *THINOCORUS* Eschscholtz, 1829

3. Grey-breasted Seedsnipe

Thinocorus orbignyianus

French: Thinocore d'Orbigny **German**: Graubrust-Höhenläufer **Spanish**: Agachona Mediana
Other common names: D'Orbigny's Seedsnipe

Taxonomy. *Tinochorus* [sic] *Orbignyianus* I. Geoffroy Saint-Hilaire and Lesson, 1831, Santiago, Chile.
Racial differentiation appears to be rather weak. Two subspecies normally recognized.
Subspecies and Distribution.
T. o. ingae Tschudi, 1843 - Andes from N Peru through W Bolivia to N Chile (Tarapacá) and NW Argentina (Catamarca).
T. o. orbignyianus I. Geoffroy Saint-Hilaire & Lesson, 1831 - Andes from NC Chile (Antofagasta) and NC Argentina (La Rioja) S to Tierra del Fuego.



Descriptive notes. 19-24 cm; 110-140 g. Cryptically coloured, with the upperparts scalloped and vermiculated with cinnamon-buff. In flight, shows narrow white wingbar above, broad white wingbar below, and contrasting black or dark brown wing linings. Male has uniform grey neck and breast with black border to white throat; also tends to have narrow black border to white lower breast and belly. Female has head and breast pale buff with heavy dark streaking. Juvenile similar to female, but more obscurely patterned. Race *ingae* has smaller wings and tarsi on average.
Habitat. *Puna* grassland, sometimes on bunchgrass steppe, but most frequent in areas with low and matted vegetation of cushion-plants and tiny herbs, or on short grass bordering highland bogs. Common at 3400-5000 m in Peru; in S of range, breeds above 1000 m, but normally much lower down during winter.
Food and Feeding. Mainly buds and leaf tips of herbs and succulent plants. No further information available.
Breeding. Eggs in Oct-Nov, but also at other times of year, e.g. Jan-Feb. Breeds in solitary pairs. Nest is placed in grass or clump of vegetation, usually near water. Clutch usually 4 eggs; chick has pale vinaceous to cinnamon drab grey down, marked with complex pattern of black bands and dense white tips to down feathers. No further information available.
Movements. Poorly known. Most populations may show seasonal altitudinal shifts. Tierra del Fuego is vacated in winter.
Status and Conservation. Not globally threatened. Generally common throughout range, even in quite heavily overgrazed highlands. Much of habitat is at high altitude where, being remote or inhospitable, seems relatively secure; species appears reasonably well adapted to limited human impact in these zones.
Bibliography. Blake (1977), Canevari *et al.* (1991), Clark (1986), Dunning (1982), Fjeldsa & Krabbe (1990), Humphrey *et al.* (1970), Johnson (1965b, 1972), Koepcke, H.W. & Koepcke (1971), Koepcke, M. (1970), Maclean (1969, 1970a), Meyer de Schauensee (1982), Olrog (1984), Parker *et al.* (1982), de la Peña (1992), Remsen & Traylor (1989), Rocha & Peñaranda (1995).

4. Least Seedsnipe

Thinocorus rumicivorus

French: Thinocore de Patagonie **German**: Zwerghöhenläufer **Spanish**: Agachona Chica
Other common names: Patagonian/Pygmy Seedsnipe

Taxonomy. *Thinocorus rumicivorus* Eschscholtz, 1829, Concepción, Chile.
Southernmost populations formerly awarded separate race, *patagonicus*, but not normally accepted nowadays. Four subspecies currently recognized.
Subspecies and Distribution.
T. r. pallidus Salvadori & Festa, 1910 - lowlands of SW Ecuador and extreme NW Peru.
T. r. cuneicauda (Peale, 1848) - Peruvian Desert.
T. r. bolivianus Lowe, 1921 - Altiplano from extreme S Peru through N Chile and W Bolivia to NW Argentina (Jujuy).
T. r. rumicivorus Eschscholtz, 1829 - Patagonian steppe S to N Tierra del Fuego; migrates to C Chile and plains of NE Argentina and Uruguay.

Descriptive notes. 16-19 cm; 50-60 g. Cryptically coloured, with upperparts more distinctly spotted and finely scalloped than in *T. orbignyianus*, to which shows similar wing pattern in flight, but tail more distinctly wedge-shaped. Male has uniform grey face, neck and breast with the black borders of white throat and lower underparts connected by black line down centre. Female has grey of head, neck and breast replaced by pale buff with diffuse darker markings; dark border to white throat. Juvenile similar to female but lacks distinct dark border to white throat. Races differ in size and overall tone of coloration, with smallest, palest birds in N; race *bolivianus* largest and, with upperparts distinctly scalloped warm buff, female recalls that of *T. orbignyianus*.
Habitat. Mainly semi-desert with rather scattered grass, low herbs or succulent plants. Race *bolivianus* inhabits Altiplano at 3700-4600 m; other races occur in lowlands, with *cuneicauda* found up to over 1000 m, and nominate below 1200 m. In Bolivia, inhabits highland semi-desert to desert *puna*; in Peru, occurs in sparse fog vegetation in the coastal desert. On Patagonian steppe frequents roads, wide gravelly shores and areas with tiny annual herbs around partly dry clay-pan lakes. Often found on cultivated land.
Food and Feeding. Mainly buds and leaf tips of succulent herbs and some seeds; may take more seeds than other species (see page 541).
Breeding. Eggs recorded Aug-Feb in Patagonia, probably with several successive broods. Breeds in solitary pairs. Nest is scrape in sandy soil, sometimes lined with animal dung. Clutch 4 eggs; incubation c. 26 days; chick has pale vinaceous to cinnamon drab grey down, marked with some black bands and speckles, and dense white tips to down feathers forming two bands down back; fledging 7 weeks. Young birds may possibly start breeding towards the end of their first summer.
Movements. Most Patagonian birds migrate in winter, possibly vacating S part of range. Observations of large flocks in other parts of the range may suggest seasonal or opportunistic movements, or long daily feeding excursions. Race *bolivianus*, which breeds in desert *puna*, winters on moraine plains in Eastern Cordillera of La Paz, Bolivia.
Status and Conservation. Not globally threatened. Generally common throughout extensive range, even in parts of Patagonia which are strongly degraded by sheep-grazing. Much of habitat is remote or inhospitable and seems to be relatively secure; species appears reasonably well adapted to limited human impact in these zones, e.g. possibly favoured by irrigation schemes enabling cultivation in Peruvian Desert. Status in Falkland Is uncertain: may be very rare breeder, but few records.
Bibliography. Class AVES

Order CHARADRIIFORMES

Suborder CHARADRII

Family CHIONIDAE (SHEATHBILLS)

- Chunky, pigeon-like shorebirds with stout legs and distinctive bill sheaths.
- 34-41 cm.

- Antarctic Peninsula and subantarctic islands of Atlantic and Indian Oceans.
- Terrestrial and intertidal.
- 1 genus, 2 species, 5 taxa.
- No species threatened; none extinct since 1600.

Systematics

Sheathbills constitute the only bird family with a breeding range that falls entirely within the Antarctic and subantarctic. In this harsh environment, with an avifauna dominated by seabirds, they are the only common and widespread land-based birds. Sheathbills probably evolved from plover-like birds, in the subantarctic tip of South America. Today, as predators and scavengers, they are strongly dependent for food on colonial seabirds, particularly penguins, and they almost certainly evolved in association with penguins.

Their inclusion in the Charadriiformes is not in doubt, but their affinities within this order have been subject to much speculation. Various morphological, behavioural and biochemical studies have produced conflicting results, showing links with seedsnipes (Thinocoridae), the Magellanic Plover (*Pluvianellus socialis*), the plover family (Charadriidae) and even skuas (Stercorariidae). Results of DNA-DNA hybridization suggest that sheathbills are offshoots of a lineage which includes seedsnipes, the Crab Plover (Dromadidae), coursers and pratincoles (Glareolidae) and oystercatchers (Haematopodidae), but that they also have affinities with gulls and their allies.

The family has commonly been called Chionididae, but current policy on nomenclature urges the use of the shorter Chionidae. The single genus includes two species, different in appearance but very similar in habits, with non-overlapping ranges. The Pale-faced Sheathbill (*Chionis alba*) breeds on the Antarctic Peninsula and subantarctic islands of the Scotia Arc, and many birds migrate to Patagonia, Tierra del Fuego and the Falkland Islands in winter. The Black-faced Sheathbill (*Chionis minor*) is a year round resident on four widely separated island groups close to the Antarctic Convergence in the southern Indian Ocean. These four populations are usually regarded as subspecies. They have probably been genetically isolated for about 10,000 years, since the last ice age ended and the pack ice "bridge" linking the islands retreated southwards.

Morphological Aspects

Sheathbills display several adaptations for the rigorous Antarctic and subantarctic environment. They are sturdily built, with stout legs and feet. They have dense, pure white plumage, with a thick grey layer of underdown. Lacking webbed feet and other adaptations for aquatic life, they are restricted to foraging on land, although the bulk of their food actually comes from the sea.

Both species have diagnostic bill sheaths and facial caruncles. The sheath is greenish and the caruncles pink in the Pale-faced Sheathbill, whereas the bill and facial features are all black in the Black-faced Sheathbill. Both species have thick, fleshy eye-rings. The sheath and facial features are smaller and less obvious in juveniles and one year old birds, and are useful for ageing birds. It has been suggested that the sheath is used as a hook to carry eggs, but modern studies do not support this idea. The sheath and facial features contrast with the all white plumage and probably evolved to enhance social signals, in which the head plays a prominent part. Social dominance in wintering flocks of Pale-faced Sheathbills was found to correlate with the size of the bill, and this is likely to apply in the other species too. Adults also develop blunt, black carpal spurs which are used to batter opponents in the rare and brief bouts of territorial fighting. The bill is conical and stout and is used for ripping flesh off carcasses, pecking open eggs, scooping up krill dropped by penguins, scraping algae off intertidal rocks, probing and uprooting boggy vegetation to search for terrestrial invertebrates, and picking up insects.

Sheathbills' flight is strong and direct, usually with a continuous succession of wingbeats, but with occasional gliding. Their flying capacity is clearly considerable, for the migration of Pale-faced Sheathbills takes them over hundreds of kilometres of open sea, which they evidently cover without alighting on the water. When foraging, they seldom fly unless commuting to and from roosts, or threatened by predatory skuas. On the ground, their gait is purposeful and chicken-like, and they can run rapidly. They use their feet to hold down bits of bone or skin while pecking at the flesh, but they do not scratch for food. They often tuck one leg into their dorsal feathers for long periods of time, and will even hop about on one leg while feeding. Sheathbills sometimes wade, but they avoid deep water, and do not voluntarily swim.

Sexes are alike but in both species the males average about 15% heavier than the females, and have larger bills and sheaths, although these weights and body dimensions overlap somewhat. Body masses vary through the year and tend to be lowest in immatures and those wintering adults which have no access to penguin colonies.

Moult occurs once a year and is relatively protracted, with the replacement of the primaries taking 70 days. Adults moult

after breeding, in late March, but immatures and non-breeding adults start earlier, in January.

It is not clear whether the white plumage is an adaptive coloration. It confers camouflage in the snow, but sheathbills ordinarily spend little time on clean snow, and their plumage makes them very conspicuous on the shoreline or in penguin colonies. One possibility is that it evolved to facilitate territorial advertisement in these colonies.

Habitat

Sheathbills inhabit coastal regions from the Antarctic Peninsula north to the subantarctic islands and southern South America. Their lives are strongly intertwined with those of penguins, and, to a much lesser extent, other colonial seabirds, notably cormorants and albatrosses, and seals. Breeding territories of both species of sheathbill almost always include parts of a penguin colony and the nest itself is often in a cavity surrounded by penguins. The sheathbills patrol among the penguins looking for food, and their breeding chronology is linked with that of the penguins. Cormorant colonies support a few breeding sheathbills in the same manner, while albatrosses and petrels are usually exploited opportunistically. An exception to this occurs in the Kerguelen Islands, where many Black-faced Sheathbills breed without access to seabirds; at this locality, the sheathbills have become true shorebirds, foraging all year round on extensive rocky intertidal areas.

Outside these colonies sheathbills forage along the shoreline on both sandy and rocky beaches and among the rotting piles of kelp wrack. On some islands many sheathbills forage extensively for invertebrates on the lowland bogs, meadows and tussock grass, sometimes wandering more than 1 km from the shore. They are common visitors to Antarctic and subantarctic research stations where they live off kitchen scraps and other refuse. In the past, many were attracted to shore-based whaling or sealing operations. The Pale-faced Sheathbill can also be found among the pack ice, particularly during the pupping season of the Weddell Seal (*Leptonychotes weddelli*).

General Habits

Sheathbills are the smallest members of the subantarctic predator-scavenger guild which also includes giant petrels (*Macronectes*), skuas and Kelp Gulls (*Larus dominicanus*). Their small size restricts their predatory capability to the smallest chicks of penguins or cormorants, but it also allows them to move more freely among the breeding penguins than the larger birds, without incurring the same antagonism shown to larger birds by the penguins. They are adept at stealing unguarded eggs and small chicks, and most breeding adults have perfected the art of robbing penguins and other seabirds while they are in the midst of regurgitating food to their chicks (see Food and Feeding).

In both species one finds a fascinating range of social behaviour. Breeding adults establish strongly defended territories, and, with a few exceptions, these foraging territories include parts of a penguin or cormorant colony. The nest is placed within the feeding territory if the terrain is suitable. The preferred hosts are Adelie (*Pygoscelis adeliae*) and Chinstrap (*Pygoscelis antarctica*) Penguins in the Pale-faced Sheathbill, and Rockhopper (*Eudyptes chrysocome*) and Macaroni (*Eudyptes chrysolophus*) Penguins in the Black-faced Sheathbill. The larger King Penguins (*Aptenodytes patagonicus*) are also exploited, particularly in winter, but very large colonies of these birds support few breeding sheathbills, probably because the flat terrain on which they occur provides few cavities for sheathbill nests. This limitation also applies to very dense colonies of Macaroni Penguins on flat ground.

Detailed studies at Marion Island and the Crozet Islands have revealed interesting variations and flexibility in the social and foraging behaviour of Black-faced Sheathbills, dependant on the

Sheathbills are distinct oddities in the world of the Antarctic and subantarctic to which they are restricted. In no way adapted to an aquatic lifestyle, they form the only terrestrial bird family in an environment teeming with seabirds. They are, nonetheless, built to withstand the rigours of a hostile climate: the body is plump and sturdy, the legs and feet strong, and the white plumage dense, with a thick layer of underdown. The Pale-faced Sheathbill, seen here, has a greenish bill sheath and pink facial caruncles. The bill is stout and conical, well suited for the bird's multifarious scavenging habits. Sheathbills seem averse to water and reluctant to fly; they are most often seen walking or scampering along the shore in much the same fashion as a domestic fowl.

[*Chionis alba*, Gosling Island, South Orkneys. Photo: Pete Oxford/ Planet Earth]

type of penguin being exploited. The crested penguins (Rockhopper and Macaroni) are the preferred hosts during the summer, but these penguins leave the islands after breeding and moulting, and little food is available to sheathbills at their colonies through the six months of winter. Most sheathbills breeding here abandon their territories in winter. Some forage nearby on the shore or on inland vegetated areas, solitarily or in flocks. Many move to nearby King Penguin colonies, where they may establish temporary winter territories, and even temporary pair-bonds with birds which were not their previous mates. These territories and pair-bonds are abandoned in spring when the sheathbills move back to their former breeding territories as the crested penguins return. In contrast, pairs with breeding territories within King Penguin colonies remain territorial and paired all year, and they allow their chicks to overwinter within their territories, thereby giving them access to more reliable, high-quality food. A preliminary study has shown that the non-breeding territoriality is achieved without elevated levels of testosterone, the male hormone which is usually associated with territoriality in many birds. It appears to be a behavioural response to the availability of high-quality, defendable food resources in the winter.

Wintering birds which feed on the shore or in inland vegetated areas tend to form flocks of 2-50 birds, and they also roost communally at night on shoreline platforms. A study at Marion Island showed that 83% of the sheathbills which foraged in inland areas occurred in flocks, and 98% roosted communally. By feeding and roosting in flocks, the wintering sheathbills were improving their chances of finding profitable foraging areas in bog and tussock vegetation. Compared to single birds, those in flocks had higher rates of food intake, spent more time eating and less time looking around or being alert, and were less vulnerable to predation from skuas.

Within the same populations, therefore, one can find a complete range of social behaviour, including solitary foraging, year round or seasonal territoriality, flocking and communal roosting. This fascinating flexibility of social and foraging behaviour is a key to the year round survival of Black-faced Sheathbills in very isolated, sometimes inhospitable islands. Pale-faced Sheathbills avoid the more severe winter conditions at their breeding grounds by migrating, but this option is not available to the Black-faced Sheathbills living on more remote islands.

Boundary disputes between neighbours are rare and involve ritualized movements and redirected aggression. The disputing neighbours crouch low with wings slightly opened and jab with their bills at the air, the ground or bits of debris; this is interspersed with bill-wiping. These encounters usually end peacefully, with the protagonists wandering off or performing the "Bowing Ceremony" (see Breeding) with their respective mates, but fights can erupt. Fights involve pecking and grabbing the opponent with the bill, while vigorously battering with the wings and carpal spurs. Between bouts, protagonists also face each other in "Upright" postures with the wings slightly open to expose the black carpal spurs. Fights usually last just a few seconds and result in bedraggled plumage but no injuries, and "Bowing Ceremonies" often follow fights. Fighting occasionally occurs outside territories in conflicts over carcasses.

Sheathbills spend most of the daylight hours foraging, but also spend an hour or two preening and resting. In general, they spend considerable time bathing and preening, which is essential for maintaining insulation in a muddy, wet and windy environment. Territorial adults preen and rest on a conspicuous perch within their territories and frequently have to threaten or chase off intruders. In contrast, non-territorial birds gather in flocks, sometimes numbering 300 birds or more, at the edges of seabird colonies or on the shoreline in order to preen and rest.

Nocturnal roosting behaviour varies through the year. Breeding adults roost within their nest cavities in summer, but non-breeders and all wintering birds roost communally on shoreline rock platforms, sometimes forming flocks of several hundred birds. These night roosts are usually close to foraging sites but the birds will fly several kilometres, sometimes crossing open water, to reach suitable roosts which offer favourable micro-climates near the sea. A few sheathbills roost in inland caves which offer the same protection. Communal night roosts might also act as information centres in winter for birds foraging in flocks on widely distributed patches of food: those birds lacking knowledge of profitable patches can follow the flocks to these patches at dawn.

Skuas are sheathbills' main predators, but predation rates are relatively low, and juveniles and weakened birds are the usual victims of skua attacks. Nevertheless, all sheathbills are wary of skuas, and will avoid open beaches or meadows if skuas are present. Birds foraging on inland bogs or meadows usually fly to the shore if a skua approaches, and at Marion Island sheathbills could be found further inland during the winter months, when skuas were absent, than in summer. Other predators include Peregrine Falcons (*Falco peregrinus*), which sometimes kill sheathbills wintering in the Falkland Islands. There is also a low level of intraspecific predation among sheathbills, mainly of eggs and chicks, but also occasionally of wintering juveniles.

Voice

Sheathbills utter harsh, high-pitched, strident calls, which are audible above the hubbub of penguin colonies. Most calls are associated with defence or advertising of territories, and non-territorial birds tend to be silent.

In the Black-faced Sheathbill "Forward" threat displays and "Bowing Ceremonies" are often accompanied by series of loud, staccato "kek, kek, kek, kek..." calls, which can be given by either sex. The alarm call is a single sharp call usually given in response to a skua overhead. Short series of calls and single clucks are heard when flocks take off or land. Chicks and newly-fledged juveniles solicit food with shrill cheeping calls. The calls of the Pale-faced Sheathbill are not well known, but consist of harsh, throaty caws and muttering.

There appears to be variation in voice between the different island populations of the Black-faced Sheathbill, and this might have significant taxonomic implications, but no detailed studies have yet been carried out.

Food and Feeding

Although sheathbills themselves are restricted to land, most of the food they eat comes from the ocean. They are omnivorous and extremely opportunistic, and will attempt to eat any form of animal matter and some types of algae. This generalist diet appears to be a key to their survival in harsh, seasonally variable environments where each food type is often available only for a short period. Penguins provide the bulk of the food for both species, and access to seabird colonies is usually essential for breeding success. Detailed studies of energetics and time budgets of the Black-faced Sheathbill on Marion Island support this idea: the rate of food intake from the shoreline or from terrestrial invertebrates is simply inadequate to sustain breeding on this island. In contrast, the exceptionally large intertidal areas in the Kerguelen Islands provide large amounts of low-quality food, which are sufficient to support breeding in this unusual population, albeit with lower reproductive success than elsewhere.

Eggs are an important, briefly available, food item, particularly for sheathbills nesting in association with Macaroni or Rockhopper Penguins, which do not guard their first-laid eggs very well. Predated eggs are often carried to the proximity of the nest cavity, which can be surrounded by a conspicuous cluster of white eggshells. Small chicks are snatched from beneath unwary penguins or cormorants and dragged away to be eaten. Eggs and chicks are also sometimes taken from petrel burrows. Carrion is an important source of food, and sheathbills will spend hours picking tiny scraps of blubber and flesh off the skin and skeletons of carcasses discarded by larger predatory or scavenging birds. Within penguin colonies, sheathbills also eat faeces, feather-shafts shed by moulting birds and any invertebrates living in the muddy ooze.

Sheathbills are extreme examples of opportunistic feeders, the real "dustbin" birds of the Antarctic. They leave nothing remotely edible untouched, which probably explains their success in a harsh environment where feeding opportunities on land tend to be rather fleeting. Penguins play a major role in the lives of sheathbills, for in one way or another they provide them with most of their food. Limited by their size as to the type of predation they can practise, sheathbills take penguin eggs and small chicks with impunity and feed on all kinds of carrion. Both species are adept kleptoparasites; they will steal food from penguins and other bird species, such as albatrosses and cormorants, when these are in the act of regurgitating food for their young. In a King Penguin (Aptenodytes patagonicus) *colony a Black-faced Sheathbill has located a chick on the point of receiving food from its parent; with beady eye, it calculates the exact moment when intervention will reap its reward. Given the powerful bill of the parent King Penguin, the success of such a daring operation depends on spot-on timing and a quick get-away!*

[Above: *Chionis minor crozettensis*, Crozet Islands. Photo: D. Parer & E. Parer-Cook/Auscape.

Below: *Chionis minor crozettensis*, Crozet Islands. Photo: R. Seitre/Bios]

Sheathbills of both species are highly successful kleptoparasites. They steal food from penguins, and sometimes from albatrosses and cormorants, by fluttering or leaping against these birds while they are in the act of regurgitating a bolus of food to their chicks. The sheathbills occasionally strike small penguins with sufficient force to knock them over. Any food spilled during this disruption is then scooped up by the sheathbill. Mated pairs sometimes work together to harass and rob a penguin in this manner. On Marion Island, 90% of the food delivered to sheathbill chicks within colonies of Rockhopper Penguins comprised marine crustaceans obtained by means of kleptoparasitism. Although it was essential to the sheathbills, the loss of food had little impact on the penguin hosts and amounted to only about 1% of the food coming into the colonies. The penguins threaten and lunge, but are unable to drive off the nimble sheathbills. Larger penguins, however, such as King Penguins, are less easily robbed. Such piracy involves careful timing, skill and daring and is almost never attempted by juveniles.

Sheathbills gather at rookeries and haul-outs of seals, particularly when the seals are pupping. Weddell Seals and Southern Elephant Seals (*Mirounga leonina*) are preferred by Pale-faced, and Elephant Seals by Black-faced Sheathbills. Here, too, the sheathbills will try eating almost anything available, including carrion, placentae, faeces, blood picked from scabs and wounds, and nasal mucous. Any seal with an open wound is relentlessly tormented by sheathbills. They will even take milk by inserting the bill between the pup's mouth and its mother's nipple.

Leafy algae, primarily *Porphyra*, scraped off intertidal rocks are the main food taken by sheathbills foraging along the shore. They also eat limpets, mussels, amphipods and other intertidal invertebrates. Piles of rotting kelp wrack provide profitable supplies of the larvae and adults of kelp flies, and plankton washed ashore on beaches is also eaten. Stormy seas and ice often restrict shoreline foraging in winter.

Terrestrial invertebrates are important food for Black-faced Sheathbills at some islands, particularly in winter. Any invertebrates larger than 1 mm long are eaten. Earthworms make up most of the intake, but larvae and adults of flightless moths, weevils, flightless flies and other insects, as well as spiders, snails and slugs are also eaten. These prey types are obtained by uprooting or flipping over moss and grass tussocks, or by probing the bill into soft substrates. Bogs and meadows that have been intensively foraged by flocks of sheathbills have a ploughed-over appearance. At Marion Island the terrestrial invertebrates supported one third of the 3500 sheathbills during winter, when preferred food from penguin and seal colonies was less abundant. These sheathbills showed acute habitat discrimination and foraged predominantly in those vegetation types in which invertebrates were most abundant and accessible. Snow cover greatly restricts inland foraging and prolonged periods of snow can lead to starvation, usually of immature birds.

Breeding

Detailed studies of Pale-faced Sheathbills at Signy Island, in the South Shetland Islands, and of Black-faced Sheathbills at Marion Island and also at Île de la Possession, in the Crozet group, show remarkable similarities in the breeding biology of the two species. The timing of breeding in sheathbills is closely tied with that of the penguins and other seabirds on which they depend. Sheathbills begin to occupy their territories in October, often before the host penguins have arrived. Ovogenesis occurs at the time that eggs are available from penguins, and by the time the sheathbill chicks hatch the penguins are already feeding small chicks. Laying occurs in middle to late December, and the chicks hatch in middle to late January, fledging at the end of March.

The age of first breeding is three to five years old, but most three year olds are unsuccessful. At all three study areas many adults were unable to gain access to territories, suggesting that there was an excess of potential breeders. At Île de la Possession, this floater population comprised 30-40% of all adults. Breeding territories contained 40-300 *Eudyptes* or *Pygoscelis* penguins or 200-400 King Penguins.

Sheathbills show strong fidelity to their territories, nest-sites and previous mates. Divorce is rare and usually follows breeding failure. The most common ritualized display in both species is the "Bowing Ceremony", also called a "Bob-call" display. In this display, both members of the pair bow their heads rapidly up and down, while uttering a series of staccato calls. The display is usually given within the territory and can be initiated by either sex. It is used as a greeting display or given in response to intruders or other disturbances. Both sexes defend the territory, but males tend to be more active and aggressive. Territorial intruders are warned off with loud calls and a "Forward" threat posture similar to that of gulls. If that fails, the intruder is evicted by chasing, which involves running, flying or a flapping run.

Nests are simple cups on top of untidy, smelly piles of tussock grass, moss, algae, feathers or old bones. They are hidden from view within crevices, behind rock overhangs, in small caves and occasionally in petrel burrows; sheathbills do not dig their own cavities. Protection from skuas and inclement weather are probably the critical factors in nest-site selection. Where possible, nesting among penguins appears to provide some additional protection against skuas.

Clutch size in both species is typically of two or three eggs, but ranges from one to four. Eggs are pyriform, or pear-shaped, and have a creamy white base colour, speckled with grey or brown. At Marion Island, eggs were laid at intervals averaging four days, with a range of three to six days apart. Incubation commences soon after the first egg has been laid, and is undertaken by both sexes. Incubation shifts in males are longer than those in females, with means of 172 and 90 minutes respectively. The off-duty bird forages within the territory or rests on a vantage point near the nest cavity. Incubation takes 28-32 days. Egg survival varies within and between populations, with a range of 60-84%. Egg failure can be due to infertility, predation by skuas and other sheathbills, flooding of nests, accidental breakage or eggs rolling out of nests.

Hatching is asynchronous. At Marion Island the first chick hatched one day before the second (range 0-7 days), and the second three days before the third (range 0-4 days). Asynchronous hatching facilitates brood reduction by rapid elimination of younger chicks, when food is limited, so that the older chicks have improved chances of survival. The first-hatched chicks are always heavier than their siblings and have higher survival rates. Chicks may die as a result of starvation, predation by skuas and possibly by other sheathbills, and trampling by penguins. Most pairs succeed in rearing one chick per season. Production averaged 1·6, 1·8 and 1·9 fledglings per pair in three studies of Pale-faced Sheathbills, and 1·1, 1·2 and 1·4 fledglings per pair in three studies of Black-faced Sheathbills. The type of penguin exploited does not appear to affect breeding success. At Kerguelen, pairs with no access to seabirds showed lower productivity (0·7 fledglings per pair) than those breeding in seabird colonies (1·1 fledglings per pair).

The chicks are semi-precocial and nidicolous. They hatch with dense brown down, which is replaced by mottled grey mesoptile down at 7-14 days. White contour plumage appears from day 12 and covers the chicks by day 50. Chicks are able to move about the nest within hours of hatching but are brooded by a parent, continuously for the first two weeks and thereafter progressively less. About 30 days after hatching the chicks begin to wander away from the nest, and by 55-60 days they forage independently, although they often still follow their parents and solicit food for up to six months. Chick growth is slower and fledging occurs later, at 65-70 days, in pairs that nest in the intertidal zone in the Kerguelens.

Parents deliver food by the billful to the chicks at the nest, but they do not regurgitate it. Males and females spend similar amounts of time and effort in brooding and feeding the chicks. Chicks receive the same food as adults, but crustaceans, particularly krill and pelagic amphipods, and other marine food stolen from penguins are generally more important than carrion or invertebrates as food for chicks.

Penguins are not alone in suffering the attentions of sheathbills; seals too are often the victims of their indelicate attacks. Sheathbills will gather at seal rookeries and haul-outs, especially around the time of pupping, when the spoils are greatest. There, they will attempt to eat anything available, including umbilical cords, placentae, faeces and carrion. Nothing is disdained and no conduct is too demeaning. They will torment seals with open wounds in order to feed on their blood, and they have even acquired the remarkable skill of drinking a seal's milk by interposing the bill between the pup's mouth and the mother's nipple.

Movements

Pale-faced Sheathbills are partial migrants. Some birds remain near nesting sites or at other subantarctic locations through the winter, but most migrate to the southern extremes of South America. The post-breeding northward movements occur from late March to July, with most birds gone from their breeding sites in late May. At Signy Island, breeding birds tend to return to nesting areas throughout October and early November.

Migratory routes are poorly charted, but birds have been reported flying over the sea 600-700 km from land. They probably cross the 800 km or so of the Drake Passage in a single flight, but in Antarctic waters migrants stop over on icebergs and pack ice where they forage opportunistically among seals or penguins. Ship-assisted passages have been documented on numerous occasions, and account for the appearance of this species in such unlikely places as Brazil, St Helena, South Africa and even England (after the Falklands war).

The behaviour, diets and movements of Pale-faced Sheathbills on their wintering grounds are very poorly known. Most birds appear to winter on the coasts of the Falkland Islands, Tierra del Fuego, and Patagonia, but vagrants have been reported further north on both the Pacific and Atlantic coasts. Some non-breeders remain on the Falkland Islands through the summer, instead of returning to the breeding grounds in the south.

Black-faced Sheathbills are resident all year round. There is, however, some intra- and inter-island movement within an archipelago, generally associated with birds moving to a King Penguin colony in winter. On the western islands of the Crozet group, hundreds of sheathbills cross 30 km from Île des Pingouins, or 15 km from Île des Apôtres, to winter in the large King Penguin colonies on Île aux Cochons. There are no similar movements among the eastern islands of the group, even those 20 km apart, because food is available on these islands all year. Similarly, movements between Marion and Prince Edward Islands, 22 km apart, are very rare.

Immatures and non-breeding adults wander more than breeders. On Marion Island, colour-ringed breeding adults were always within 1 km of their nesting sites, whereas almost half the subadults and a third of juveniles were seen 1 km or more from their ringing sites. Daily commuting flights between feeding grounds and night roosts may cover several kilometres, and at Heard Island include stretches of open water.

Relationship with Man

Most populations of sheathbills have been affected very little by humans, except through the alien mammals they have introduced (see Status and Conservation). Unless molested, sheathbills are unafraid of people, and they are intensely curious and bold. They will steal unguarded food and even pencils from field biologists, or peck at one's boots to test their edibility. They are attracted to weather stations and research camps, where they live on kitchen scraps and other waste, loitering around like flocks of small white chickens, and they will even occasionally wander indoors in search of food. The availability of this food has caused some Pale-faced Sheathbills to overwinter in places not normally used in winter, including Signy Island and South Georgia.

Sheathbills were hunted for food in the past. Norwegian whalers on South Georgia in the early twentieth century referred to them as "ptarmigan" and found them to be good eating, despite their unpleasant feeding habits. Intensive hunting was reported to have reduced this population by 1913, but hunting is no longer a problem at the breeding sites of either species. Interactions between humans and Pale-faced Sheathbills wintering in South America are less well documented, but there does not appear to be any significant hunting or other persecution. In the Falklands, many sheathbills aggregate in harbours and coastal settlements, where they presumably benefit from having extra sources of food.

Status and Conservation

The breeding population of Pale-faced Sheathbills is unlikely to exceed 10,000 pairs, scattered over about 400 sites on the Antarctic Peninsula and islands of the Scotia arc, and about half of

The breeding of sheathbills is intimately linked with that of penguins. In the first place, the timing coincides. Then the sheathbill's nest is often situated within or at least near a penguin colony. The Black-faced Sheathbill here has its nest under a boulder, hidden from sight to avoid predation from skuas. Normally, by the time the eggs hatch the penguins are already feeding their young, thereby providing the sheathbill parents with a reliable source of food on which to feed their chicks, in turn. Both parents bring food to the nest, but they do not regurgitate it. Although young sheathbills leave the nest after 30 days and are able to forage independently after two months, they are prone to solicit their parents for food for up to six months.

[*Chionis minor marionensis*, Marion Island. Photo: Alan E. Burger]

At rest, these Pale-faced Sheathbills conserve heat by standing with one leg tucked up into the plumage, out of sight, while the head rests along the back, in some cases with the bill too snugly concealed under the feathers. All sheathbills spend part of the day in comfort behaviour. Bathing and preening are of great importance since the plumage must be kept in trim constantly in the face of harsh climatic conditions. Birds holding territories do not leave them to indulge in these activities, but non-territorial birds will form flocks, sometimes quite large ones, in order to preen and rest communally near seabird colonies or on the shoreline.

[*Chionis alba*, Falkland Islands. Photo: Stan Osolinski/ Oxford Scientific Films]

these birds are to be found on the South Orkney Islands. The population of Black-faced Sheathbills is in the range of 6400-10,000 pairs, with more than half breeding in the Kerguelen Islands. There are insufficient data to determine population trends, and many island populations have never been adequately censused, notably Heard Island and Kerguelen. Most local populations of both species are relatively small, with less than 1000 pairs, and Black-faced Sheathbill populations are very isolated, making them vulnerable to introductions of mammals and viral or bacterial disease. The practice of keeping domestic chickens, which might carry diseases that affect sheathbills, at some of the French bases in the Crozet and Kerguelen groups should be discouraged for this reason.

Studies on Marion Island and Île de la Possession provide some basis for understanding the population dynamics of the Black-faced Sheathbill. Annual survival rates are high in breeding adults (88% on Marion, 85% on Possession), but lower in non-breeding adults (75% on Possession), subadults (49% on Marion, 63% on Possession) and juveniles (37% on Marion, 40% on Possession). Most mortality occurs in winter and can usually be attributed to the combined effects of starvation and inclement weather, and, to a lesser extent, predation by skuas. Most birds die during cold, snowy weather which inhibits foraging and raises thermal stress. Juveniles and subadults are most frequently found starved.

Both species of sheathbill have life history traits normally associated with stable, saturated populations, including: delayed breeding, at the age of three years or more; low annual reproductive output, with an average of less than two fledglings per pair; high adult survival, of 85-88%; territories centred on food resources; and high fidelity to territory, mate and nest-site. Research at Signy Island, Marion Island and Île de la Possession showed floating populations of adults unable to secure territories; on Possession, an increase in the population of penguins coincided with a similar increase in the numbers of sheathbill pairs breeding. Overall, these data suggest that populations of sheathbills are limited by the availability of breeding territories, and that their breeding numbers are thus strongly correlated with the populations of suitable penguin species that provide their food. Future changes in penguin populations, perhaps caused by human exploitation of krill, will likely also affect sheathbills.

Introduced mammals are the greatest threat to sheathbills. Pale-faced Sheathbills are apparently not affected at their breeding sites, but feral cats have effects on Black-faced Sheathbill populations, although their impact has differed in different islands. At Marion Island, prior to their extermination in 1990, feral cats appeared to have had little impact on sheathbills, as the cats preyed primarily on small petrels, with sheathbills comprising less than 1% of their prey. In an interesting twist, the eradication of cats might actually be detrimental to sheathbills, because an increasing population of introduced house mice appears to be reducing densities of terrestrial invertebrates, an important source of winter food for sheathbills.

At Île aux Cochons, in the Crozet Islands, feral cats have severely depleted the population of Black-faced Sheathbills. Sheathbills are rare here despite a huge King Penguin colony and thousands of Rockhopper Penguins; this is the only island in the Crozets that has cats. Likewise, cats appear to be having a negative impact on sheathbills on parts of the main island of Kerguelen where petrels are rare. Quantitative studies of the impact of cats on sheathbills are required in both the Crozet and Kerguelen groups.

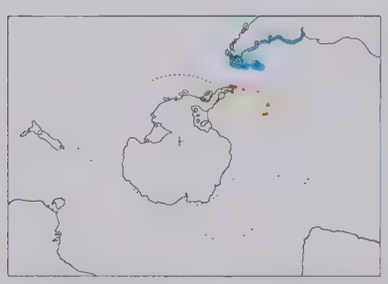
Genus *CHIONIS* J. R. Forster, 1788

1. Pale-faced Sheathbill

Chionis alba

French: Chionis blanc **Spanish**: Picovaina de Malvinas
German: Weißgesicht-Scheidenschnabel
Other common names: Wattled/Snowy/American/Greater Sheathbill, Snowy Paddy



Taxonomy. *Vaginalis alba* Gmelin, 1789, New Zealand; error = Falkland Islands.
Genus *Chionis* described by diagnosis, but no species included; thus, description of genus pre-dates those of both species. Monotypic.

Distribution. Breeds on Antarctic Peninsula, and along Scotia Arc on South Shetland Is, Elephant I, South Orkney Is and South Georgia; probably also South Sandwich Is, where breeding not confirmed. Non-breeding migrant to Falkland Is, Tierra del Fuego and Patagonia, with some birds wandering further N.

Descriptive notes. 34-41 cm; 460-780 g; wingspan 75-80 cm. No obvious seasonal variations in plumage or soft parts. Facial features more colourful and bill sheath less conspicuous than in *C. minor*. Female smaller than male, but similar in external appearance. Juvenile similar to adult, but sheath and facial wattles smaller; fledglings may have traces of grey down.

Habitat. Coastal, frequently occurring on islands. Typically found in seabird colonies, especially of penguins, but occasionally cormorants or albatrosses; also seal rookeries and haul-outs, and rocky and sandy shoreline. Sometimes near human settlements, e.g. in Falklands. Migrating birds sometimes stop off on icebergs.

Food and Feeding. Omnivorous. Krill, fish, squid and other marine prey stolen from penguins; also takes eggs and small chicks, mainly from penguins; carrion, faeces of birds and seals, intertidal algae and invertebrates, seal placentae and blood, and human refuse.

Breeding. Arrives at breeding sites Oct-Nov, lays Dec-Jan, chicks hatching Jan-Feb and fledging Mar. Monogamous, with high fidelity to territory, mate and nest-site; sexes have similar roles in all phases of breeding. Strongly territorial when breeding; territories invariably include colonies of penguins or, rarely, cormorants, which provide food. Nest is cup in pile of debris, within cavity, in or near feeding territory. Usually 2-3 eggs (1-4); incubation 28-32 days; chicks have dense brown down, followed shortly by coat of mottled grey down; fledging 50-60 days. Average success varies with sites, 1·5-1·9 fledglings per pair.

Movements. Most birds leave breeding sites late Apr to Jun, a few leaving later, in Jul, and some overwintering in breeding sites or other subantarctic locations if food is available; return Oct-Nov. Migratory routes poorly known. Main wintering grounds on shores of Falkland Is, Tierra del Fuego and S Patagonia. Some birds wander further N, e.g. to Uruguay. Ship-assisted vagrants in Brazil, South Africa, St Helena and even Europe.

Status and Conservation. Not globally threatened. Total population numbers c. 10,000 pairs widely distributed through breeding range: Antarctic Peninsula has 17+ sites, with 200 pairs; South Shetland Is 26 sites, 650 pairs; Elephant I 152 sites, c. 1450 pairs; South Orkney Is 6 sites, 5500 pairs; South Georgia c. 200 sites, c. 2000 pairs. Censuses incomplete. No serious threats from humans, and populations generally considered to be fairly healthy and stable. Poisoning from human chemical waste products may have caused some deaths in past, e.g. near Signy I.

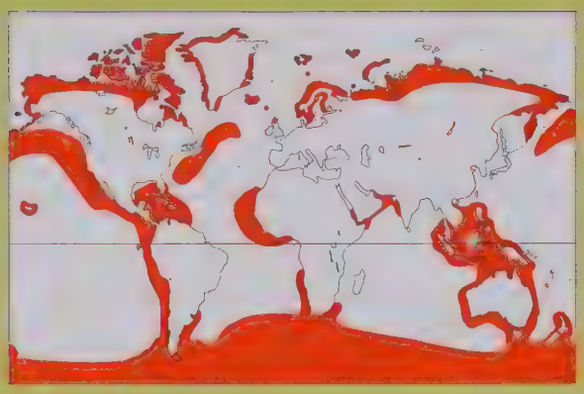
2. Black-faced Sheathbill

Chionis minor

French: Petit Chionis **Spanish**: Picovaina de las Kerguelen
German: Schwarzgesicht-Scheidenschnabel
Other common names: Lesser Sheathbill, Paddy

Taxonomy. *Chionis minor* Hartlaub, 1841, no locality = Kerguelen Islands.
There is no genetic mixing among subspecies, except in rare cases of ship-assisted vagrants. Four subspecies usually recognized.
Subspecies and Distribution.
C. m. marionensis Reichenow, 1908 - Marion and Prince Edward Is.
C. m. crozettensis (Sharpe, 1896) - Crozet Is.
C. m. minor Hartlaub, 1841 - Kerguelen Is.
C. m. nasicornis Reichenow, 1904 - Heard I and McDonald Is.
Descriptive notes. 38-41 cm; 450-760 g; wingspan 74-79 cm. Bill, bill sheath and facial caruncles all black, eye-ring pink; leg colour variable among and within populations, ranging from pink to purplish black. Small races are generally slightly smaller than most *C. alba*. Sexes alike, but male averages c. 15% larger than female. Bill sheath and eye-ring smaller in juvenile, a useful aging character; legs darker in immatures. Races form two groups, and differ slightly in overall size, in size of bill sheath, and, somewhat irregularly, in leg colour; race *nasicornis* very similar to nominate, with facial features and bill sheath perhaps slightly larger; races *marionensis* and *crozettensis* slightly smaller, with smaller bill sheath and more prominent and extensive caruncles.
Habitat. In summer, nearly all birds occur in colonies of penguins, particularly those of Rockhopper (*Eudyptes chrysocome*) and Macaroni (*Eudyptes chrysolophus*) Penguins; King Penguin (*Aptenodytes patagonicus*) colonies more important in winter. Also feeds among cormorants and albatrosses, at seal rookeries and haul-outs, in rocky and sandy intertidal zone, inland bogs, meadows and tussock grass within 1 km of shore, and around human settlements.
Food and Feeding. Omnivorous. Krill, fish, squid and other marine prey stolen from penguins; also eggs and small chicks, especially of penguins, carrion, faeces of birds and seals, intertidal algae and invertebrates, seal placentae and blood, and human refuse. Habits generally very similar to those of *C. alba*, but terrestrial invertebrates (e.g. earthworms, insects, spiders), taken from inland vegetated areas, are important as winter food.



Breeding. All pairs nest in association with penguins or other colonial seabirds, except in parts of Kerguelen (see page 547); some birds in King Penguin colonies remain in nesting territories all year; others reoccupy territories in Rockhopper or Macaroni Penguin colonies in Oct-Nov; eggs laid Dec-Jan, chicks hatching in Jan-Feb and fledging from late Mar to Apr. Normally 2-3 eggs (1-4); no replacement clutches; incubation averages 28 days (27-33); chicks have dense brown down, followed shortly by coat of mottled grey down; brooded continuously for first 14 days and less thereafter; fledging 55-60 days. Some chicks remain with parents through winter in King Penguin colonies. Fledging success varies with parents' age and quality of territory, average 1·1 fledglings per pair on Marion I, 1·4 in Crozets and 1·2 in Kerguelen. Age of first breeding 3-5 years. Successful breeders return to same territory and mate each season.
Movements. Sedentary. Some intra- and inter-island movement within an archipelago, in response to food availability. Adults usually stay within 1 km of breeding territory all year; non-breeders and immatures wander more widely, sometimes 10's of km from natal site.
Status and Conservation. Not globally threatened. Total population 6500-10,000 breeding pairs: 3000-6000 pairs in Kerguelen Is; 1400 on Marion and Prince Edward Is; c. 1000 on Crozet Is; size of population on Heard I not known, but probably numbers more than 1000 pairs. Feral cats reported to have depleted breeding population severely on Île aux Cochons, in Crozet Is, and causing declines in parts of Kerguelen. Rising numbers of house mice on Marion Î might affect sheathbills by depleting terrestrial invertebrates, an important winter food. Population of sheathbills on I de la Possession, in Crozets, increasing slightly, in response to rising penguin populations.

Class AVES

Order CHARADRIIFORMES

Suborder LARI

Family STERCORARIIDAE (SKUAS)

- Medium-sized to large gull-like piratical and predatory seabirds, with strong bill and plumage generally brown, or brown and white.
- 41-64 cm.

- Cosmopolitan in all oceans, but mainly at high latitudes.
- Predominantly marine, but also inhabits tundra.
- 2 genera, 7 species, 10 taxa.
- No species threatened; none extinct since 1600.

Systematics

The skuas (Stercorariidae) are thought to have diverged from their closest relatives, the gulls (Laridae), about 10 million years ago, towards the end of the Miocene. However, there are very few fossil skuas. One of these, named *Stercorarius shufeldti*, and looking like a rather small *Catharacta* skua, was found in Pleistocene deposits of Oregon, USA, consistent with the view that skuas, together with gulls and auks, originated in the Northern Hemisphere. However, while gulls and auks radiated into large numbers of species with most remaining in the north, skuas evolved into only seven species, with almost equal representation in the two hemispheres.

The three small skuas, the Pomarine Skua (*Stercorarius pomarinus*), the Arctic Skua (*Stercorarius parasiticus*) and the Long-tailed Skua (*Stercorarius longicaudus*), share many features of plumage, morphology, distribution and ecology, that separate them from the large skuas of the genus *Catharacta*, which lack the white-bellied morph found in small skuas, have only marginally elongated central tail feathers, and lack the distinctive barred plumage of juvenile small skuas. Thus it appears that there was an early split into the small skuas of the genus *Stercorarius* and the large skuas of the genus *Catharacta*, with the small skuas evolving in the Northern Hemisphere but the large skuas colonizing the Southern Hemisphere and more recently radiating there into three species. It has generally been supposed that the one Northern Hemisphere large skua, the Great Skua (*Catharacta skua*), recolonized the North Atlantic from the Southern Hemisphere, no ancestor of the large skuas having remained continuously in the Northern Hemisphere. This has led to much speculation as to the taxonomic affinities of the North Atlantic Great Skua with the various large skua taxa in the Antarctic and subantarctic.

Molecular data now provide some indications of the evolutionary relationships. In the mitochondrial cytochrome *b* gene of gulls and skuas there are about 70 differences in 1000 base pairs between present day gulls and skuas and the most likely reconstructed sequence of their common ancestor, whereas Arctic and Long-tailed Skuas and *Catharacta* taxa differ from their most likely common ancestral sequence by about 50 in 1000 base pairs. The molecular data would suggest that the split between the small and large skuas into two genera occurred closer to the date of separation of skuas from gulls than to the present day. The sequences of the Chilean (*Catharacta chilensis*), South Polar (*Catharacta maccormicki*) and Brown (*Catharacta antarctica*) Skuas differ from their putative ancestor by only 3 to 10 bases in 1000, indicating that these taxa are only very recently diverged, but the Southern Hemisphere taxa and Great Skuas differ from their ancestral sequence by about 6 to 12 bases in 1000, suggesting that the Great Skua diverged from the Southern Hemisphere skua before the separation of the southern stock into three species.

Most surprisingly, the molecular data show the mitochondrial sequences of Great Skuas and Pomarine Skuas to be extremely similar, differing from each other by only 8 bases in 1000. Since mitochondrial DNA is clonally maternally inherited, the most plausible explanation seems to be hybridization between female Great Skuas and male *Stercorarius*, resulting in Pomarine Skuas carrying the mitochondrial sequence from Great Skuas but nuclear genes from both Great Skuas and the *Stercorarius* parent. The molecular data seem to have uncovered a most unexpected event: hybridization between a female Great Skua and a male Arctic Skua or Long-tailed Skua, leading to the evolution of the Pomarine Skua; or possibly hybridization between Pomarine Skuas and female Great Skuas, leading to the replacement of the Pomarine Skua mitochondrial DNA by Great Skua mitochondrial DNA. While such events seem unlikely to a natural historian, no other molecular explanations for the sequence data have yet been forthcoming. However, although Pomarine Skuas are generally thought to belong in the genus *Stercorarius* because of their many similarities with Arctic and Long-tailed Skuas, there are aspects of their biology that suggest strong affinities with the Great Skua. The Pomarine is the only small skua to share the characteristic "Wing-raising Display" with the "Long Call" shown by all *Catharacta* (see Voice), and multivariate analysis of skeletal measurements and characters has shown the Pomarine Skua to be closer to the Great Skua than to the Arctic or the Long-tailed Skua. All this is consistent with the idea that Great Skua genes recently entered the Pomarine Skua population through hybridization.

With Chilean, South Polar and Brown Skuas differing only by a few bases per thousand in mitochondrial cytochrome *b* sequences, one might be tempted to view these taxa as subspecies rather than full species. However, the separation into three full species has been based on a careful and thorough analysis by P. Devillers. He emphasized their tendency not to hybridize extensively in areas of overlapping breeding range, and for there to be few hybrids in the population, suggesting both behavioural avoid-

ance of hybridization and reduced hybrid viability or fertility. The three species differ in behaviour as well as in plumage and measurements, according to Devillers more than Arctic and Pomarine Skuas differ from each other! For example, South Polar Skuas are transequatorial migrants, while Brown and Chilean Skuas winter close to their breeding areas. Even juvenile plumages of the three Southern Hemisphere species are clearly distinguishable.

Taxonomic views have varied over the years, and in the past all four *Catharacta* skuas were sometimes lumped in a single species; indeed, the genus *Catharacta* is still frequently merged into *Stercorarius*, by some authors. With the current widely agreed separation of the southern forms of *Catharacta* into three species, it would seem odd to lump the Great Skua with one of the southern species, as some authors have advocated, since it seems to have diverged more from the southern forms than they have from each other. Therefore, the Great Skua is probably best treated as a distinct, monotypic species; this treatment diverges from most previous versions, but seems the only logical arrangement given the new molecular data. Under the present arrangement, the Brown Skua is divided into three races, with nominate *antarctica* in the Falklands, *hamiltoni* on Tristan da Cunha and Gough, and *lonnbergi* on other subantarctic islands and the Antarctic Peninsula.

Amongst the small species, Arctic and Pomarine Skuas are monotypic, despite their wide breeding ranges, while the Long-tailed Skua is usually split into two subspecies, with nominate *longicaudus* breeding in Europe and western Siberia, and *pallescens* breeding in Greenland, North America and eastern Siberia.

Morphological Aspects

Although closely related to gulls, skuas show many differences from gulls that can be associated with their more piratical and predatory way of life and to breeding at high latitudes.

As in terrestrial birds of prey, females are larger than males. Though the difference in size between the sexes averages only about 3% for linear dimensions and 12% for weight, it is usually evident when looking at a breeding pair standing together. As with birds of prey, this reversed sexual size dimorphism is associated with differences in the behavioural roles of the sexes during breeding (see Breeding).

Although the sexes differ in size, they differ only very slightly in shape, the most consistent tendency being for males to have relatively longer tails and central tail streamers than females. Longer tails may allow males to perform better in the aerial display flights of the small skuas and may enhance their success in piracy, but the longer central tail streamers of males are probably a sexual signal rather than any aid to flight performance. Indeed, the Pomarine Skua may bite off its large and spoon-shaped, twisted central tail feather projections after breeding has begun, as they increase drag in flight and so have a significant energetic cost. The striking differences in central tail feather projections of the three small skuas probably aid in species recognition, but may also signal quality of the individual. Central tail feather projections become longer with age and it seems likely that birds with longer projections will gain a partner more readily, as has been shown with several other species with tail projections. The small skuas all moult the central tail feathers in spring as part of their limited pre-breeding moult, and this occurs just as the post-breeding moult has been completed, so the birds may have difficulty in finding the sulphur-containing amino acids and time needed to renew the central tail feathers between the end of the post-breeding moult and the start of breeding; these feathers take about 40 days to grow. In many immature small skuas the central tail feathers are not renewed, and other traces of immature plumage are retained into their first breeding season, strongly suggesting difficulty in carrying out this moult. Then birds with particularly long tail projections may be signalling particularly high quality.

Among the large skuas there is a complete moult of the flight-feathers each autumn/winter, but many body feathers and coverts are retained for more than a year. In particular, back feathers seem not to be renewed for many years, and, as a result, these wear and fade dramatically, even giving a good indication of the status of the individual as a young, middle-aged or old adult. Also, the older birds with more faded and worn feathers look conspicuously paler than young birds with fresh plumage. Whether these signals are intended to convey information to conspecifics is not clear, but it seems likely that they do, even if

Polymorphism occurs in four of the seven skua species. Intermediate colour morphs are sometimes found, rendering accurate identification at times extremely tricky and more dependent on structure than on plumage. This pair of Arctic Skuas presents a clear-cut case of a pale and a dark morph side by side. The distinction is not one of sex, despite the tendency among Arctic Skuas for the dark morph birds to be predominantly males. Interestingly, the incidence of dark morph birds decreases the farther north one goes until on the far northern Arctic tundra the majority of Arctic Skuas are pale birds.

[*Stercorarius parasiticus*, Foula, Shetland, Scotland. Photo: Günter Ziesler]

All four species of the genus Catharacta *show the same characteristic build; they are large, bulky birds that can appear heavy, even clumsy, on land, although all are capable of agile, speedy flight. Note the powerful hooked bill of this Chilean Skua, an admirable instrument for tearing food. The short, sturdy legs and feet end in long, sharp claws, a feature not found in any other web-footed birds.*

[*Catharacta chilensis*, Argentina. Photo: Conrad Greaves/ Aquila]

the reason for the pattern is to do with costs of feather renewal rather than status signalling.

Juvenile skuas are generally darker in tone than adults, and have shorter, more rounded wings and lack the elongations of the central tail feathers. Juvenile small skuas have heavily barred underparts and flanks, and well marked back feathers with pale edgings. Juveniles of the larger skuas lack barring, but have more uniformly coloured underparts than adults. The legs of juveniles are usually blue, but darken to black within a few weeks in large skuas, or over several years in small skuas. Immature birds pass through a series of plumages, slowly developing from the juvenile to the adult pattern.

In all skuas, flight is powerful and the ability to accelerate is well developed by comparison with gulls. Skuas not only have large pectoral muscles, but also have higher concentrations of mitochondria and of aerobic enzymes associated with energy metabolism, so that they are able to chase other seabirds more effectively than gulls can. The short wings of *Catharacta* allow a faster wingbeat than that of gulls, giving the birds enhanced ability to accelerate, while, compared with gulls, both *Catharacta* and *Stercorarius* skuas have relatively larger areas of the wing given to primaries and thus can generate greater forward thrust.

The powerful, hooked bill of skuas allows them to tear food more effectively than gulls can, and the long and sharp claws, unique among web-footed birds, and the heavily scuted and hard legs are probably also adaptations to a predatory way of life, though skuas are unable to hold prey with their feet in the manner of terrestrial birds of prey. This limits their ability to handle carrion and prey, and reduces their hunting success in some situations (see Food and Feeding), though they possess short and thick, heavily muscled necks that probably help to permit them to tear prey. Heavily armoured legs and feet also tend to limit heat loss, and this may be advantageous in the cold climates inhabited by most skuas, though they may reduce the ability of heat-stressed birds to dump excess heat too. The caeca of skuas are very much larger than those of gulls, though the reasons for this are unclear.

The generally dark coloration of skuas is thought to be an example of aggressive camouflage, allowing the skua to approach closer to a potential victim of kleptoparasitism than it could if it was light in colour. This idea is consistent with the fact that the populations of Arctic Skuas that most use kleptoparasitism when breeding are those at the southern end of the breeding range, and where the dark colour morph is most frequent. However, on the Arctic tundra, most Arctic Skuas are pale morph birds. Plumage polymorphism is best known in the Arctic Skua, which shows a clinal increase in pale morph birds with breeding latitude, but also exists in the Pomarine Skua, where about 5-20% of each population are dark morph, regardless of geographical location. In the Long-tailed Skua a dark morph occurs but only extremely rarely and only in the population in Greenland. The South Polar Skua also has pale and dark colour morphs, dark birds predominating in the Atlantic parts of Antarctica and pale morph birds predominating in the Pacific parts of Antarctica. In Arctic Skuas and South Polar Skuas there is a tendency for males to be darker than females, with the dark morph being more frequent among males, but the colour morphs are thought to be controlled by a single autosomal gene with two alleles. Although Brown and Great Skuas can not readily be classified into two distinct colour morphs, they show a great deal of individual variation in colour and tone. Great Skua fledglings in particular seem to fall into pale (cinnamon) and dark (brown) types, and this may be an expression of the colour morph gene, since Arctic Skua chicks can readily be classified into pale and dark morphs. In Shetland, dark morph male Arctic Skuas have been found to be preferred by females and so, when forming a new partnership, achieve slightly higher breeding success through breeding earlier in the season. However, pale morph males tend to start breeding on average at an earlier age than dark males. Observations of the success of chases by pale and dark morph Arctic Skuas in Shetland found no differences in success rates of the two morphs. This does not necessarily disprove the "aggressive camouflage" hypothesis, since pale morph birds are much less common than dark morph birds in Shetland, and it is possible that the pale morph birds gain a balancing advantage through their relative scarcity. Atlantic Puffins (*Fratercula arctica*), terns and other victims may recognize the common colour morph, the dark, as a threat but be less responsive to the rarer, but less cryptic, form.

In addition to having short and well insulated legs, all skuas also have particularly dense body and head plumage, giving them especially good insulation from cold. This undoubtedly helps where they sometimes have to incubate underneath a cover of fresh snow, through Antarctic blizzards or in Arctic sub-zero conditions. However, combined with a high metabolic rate due to their high density of mitochondria and enzyme activity, skuas maintain a particularly high core body temperature for non-passerine birds, and may have difficulties in shedding excess heat in sunny or warm conditions. It is possible that the lower latitude limits of their breeding distributions may be set by the maximum temperatures and rates of solar energy irradiation that they can tolerate while breeding. Certainly, skuas nesting in Scotland resort to rapid panting when incubating under (rather rare) warm and sunny conditions, and the numbers bathing in freshwater pools are considerably higher on warmer afternoons.

Habitat

Skuas use the full range of marine habitats: Long-tailed Skuas are the most pelagic, spending the winter far out to sea, whereas Great Skuas prefer to remain out of sight of land but over the continental shelf, and Arctic Skuas migrate and winter close to the coastline, often entering estuaries and bays to associate with local aggregations of gulls and terns. Chilean Skuas winter in the channels, straits and fjords of southern South America, even using the rocky shore and intertidal habitat. Skua winter habitats range from subantarctic ocean, for the Long-tailed and Brown Skuas, to tropical ocean, in the Pomarine Skua. While most species spend the winter at sea, some birds in populations of Brown Skua that breed on subantarctic oceanic islands, where there are huge populations of nocturnal burrow-nesting petrels, are able to remain on their island throughout the year without the need to exploit marine habitats and foods at all. This is made possible by the presence of certain winter-breeding seabirds and by the behaviour of prions (*Pachyptila*), a major prey of many Brown Skua populations. Although prions breed during the summer, they continue to visit their burrows throughout the year, and so provide a food supply for skuas on the island even in mid-winter. This means that, at least in principle, some Brown Skuas in the

Undoubtedly the most graceful of the skuas in both flight and silhouette, the Long-tailed Skua is also the smallest, its long, slender tail streamers accounting for almost half its total length. The flight action has a light, buoyant, effortless quality that is distinctly tern-like. The bird soars easily with great agility in order to hawk for insects. It hunts lemmings, its main source of food on the tundra, by hovering and then swooping down on its prey, a feat that neither of its heavier congeners is capable of performing. Outside the breeding season its diet is little known; it is reputed to be less piratical than other skuas, but will take fish and scavenge on carrion. Little observed once migration begins in the northern autumn, it is thought to be the most pelagic of the three Stercorarius *species, and to spend the winter entirely in the Southern Hemisphere.*

[*Stercorarius logicaudus pallescens*, Rowley Island, Northwest Territories, Canada. Photo: Jan van de Kam]

Chatham Islands and other colonies near New Zealand, and at Gough Island and Tristan da Cunha, are able to remain continuously on their respective islands without the need to feed at sea at all. In practice, it seems likely that these birds will at least use the marine habitat from time to time during winter, and probably all fledglings will disperse to sea. However, it is established that some skuas are present on these islands whenever visits have been made in winter.

During the breeding season skuas use a wider variety of habitats. The three small *Stercorarius* skuas breed predominantly on tundra. The Long-tailed Skua not only inhabits coastal Arctic tundra, preferring drier ground, but also nests on alpine tundra in the mountains of Sweden and Norway and far inland in Alaska, Canada and Russia. Pomarine Skuas inhabit mainly low-lying flat, wet tundra along the coast, while Arctic Skuas prefer drier conditions than the Pomarine, but extend less far inland than Long-tailed Skuas and remain at lower altitudes. Arctic Skuas also inhabit many moorland or grassland habitats close to major seabird colonies where they can feed by kleptoparasitism, rather than on the terrestrial prey they take in tundra habitats. When nesting in association with seabird colonies in temperate areas, Arctic Skuas prefer to nest on ground that is well drained and with relatively short vegetation. They avoid grass or heather more than 10 cm high, apparently because they need to have a good view of any approaching predators while incubating. Nesting habitat tends to be on islands and away from human disturbance where possible, although Arctic Skuas are less intolerant of humans than are Great Skuas.

Great, Brown and Chilean Skuas all tend to nest on islands in grassy habitat, avoiding tall grass or bracken, shrubby areas, steeply sloping ground and areas of human activity. The exception to this last is furnished by those pairs that have learned to nest close to scientific bases or weather stations where they receive food scraps; for example, on Gough Island the weather station kitchen is fiercely defended as a core area of the territory of a particularly aggressive pair of skuas. In Iceland, Great Skuas nest mainly on the *sandur*, huge areas of very flat ground created by the deposition of gravel from braided melt-water rivers that criss-cross the plain between the upland glaciers and the sea.

The South Polar Skua is well named in that it has been recorded closer to the South Pole than any other wild animal, and small numbers nest inland at relatively snow-free mountain sites where there are breeding Antarctic Petrels (*Thalassoica antarctica*) and Snow Petrels (*Pagodroma nivea*). However, most South Polar Skuas nest in the same habitat as is chosen by Adelie Penguins (*Pygoscelis adeliae*), namely relatively flat coastal areas of snow-free ground. These sites generally lack vegetation so that the birds nest on bare rock, on moss or lichen, or on scrapes in the gravel. It had been supposed that the skuas chose this nesting habitat in order to hold territories that included penguins, so that they could defend a food supply of penguin eggs and chicks. In fact, only a small proportion of South Polar Skuas exploit penguins as a food supply, and many skuas hold territories that include sections of penguin rookery but make no use of this potential feeding opportunity. The close association between South Polar Skua and Adelie Penguin nesting habitats seems to be primarily due to both species seeking a very limited nesting resource: flat coastal snow-free ground close to open ice-free sea.

General Habits

Skuas are not particularly social. At sea they usually travel and forage individually, though the larger species will join mixed-species flocks over shoals of fish or at fishing boats, and Pomarine Skuas do seem habitually to travel in small groups. Co-operative hunting will occasionally occur, but is unusual. Even when groups of skuas chase a single victim, this is generally a result of a shortage of potential victims resulting in scramble competition, rather

One of the skuas' most characteristic displays is the "Long Call", which can be used to proclaim ownership of a territory, to repel intruders, or to greet the mate. In the four Catharacta *species and also the Pomarine Skua* (Stercorarius pomarinus), *the call is typically accompanied by a "Wing-raising Display", in which the large white flashes around the bases of the primaries stand out most effectively. The Brown Skua is chiefly a coastal species, to be found on and around subantarctic islands that are heavily populated by penguins and burrow-nesting seabirds on which it relies heavily for its food. Where the environmental conditions are not too severe and prey is plentiful, it may not disperse out to sea at all, remaining resident on its breeding grounds throughout the year.*

[*Catharacta antarctica lonnbergi*, Antarctica. Photo: Philip Shaw/Aquila]

Skuas are infamous for their attacks on other seabirds but they do not always rely on such tactics for obtaining food. In Shetland, for example, even though there are huge numbers of seabirds available for exploitation, Great Skuas tend to feed mainly on sandeels (Ammodytes) *when shoals are present near the surface, and they also relish the discards of fishing boats. At such locations of temporary plenty, large numbers of skuas can gather together, often in the company of other seabird species. Squabbles may break out even on the water, birds displaying aggressively and lunging out at each other.*

[*Catharacta skua*, Foula, Shetland, Scotland. Photo: Günter Ziesler]

than collaboration for mutual benefit. Territorial defence by breeding skuas is very strong. While skuas often nest in colonies, they can also nest as isolated pairs, and colonial nesting seems to be a consequence of shortage of nesting habitat or highly aggregated distribution of food resources.

Many skua colonies have traditional freshwater bathing sites within or adjacent to the colony, and both breeding and non-breeding birds attend these frequently. The largest bathing pool on Foula, Shetland, can have up to 200 Great Skuas on it on a warm summer afternoon. Here the birds drink, bathe and interact vigorously with frequent displays and fights. While bathing, they exhibit a number of apparently highly ritualized exaggerated bathing postures. After bathing, the birds rest in groups beside the pools, preening thoroughly or just sleeping. The functions of this communal bathing are unclear. Drinking fresh water will reduce energy costs of salt excretion, and drinking and bathing may reduce energy costs of keeping cool on warm sunny days; certainly the numbers bathing are higher on days when it is warmer. Perhaps the communal activity allows dominance relationships to be maintained or information transfer. Since absence from the territory does increase the risk of chicks being killed by neighbouring skuas, there would seem to be some good reason for birds joining bathing flocks, as breeders apparently do almost daily.

On the territory, skuas tend to have a traditional spot where they sit or stand when thet are not otherwise occupied. As a consequence of the trampling, but more especially the manuring, these patches develop distinct vegetation; in Shetland, Great Skua patches are clearly visible as bright green swards of short grass looking like tiny golf greens within a matrix of longer coarse grass or heather. Similar, but much larger, patches, fully the size of a real golf green, are created by non-breeding skuas loafing on their traditional "club" sites. These nutrient enriched areas of sweet grass are very attractive to sheep, and so tend to be closely grazed, despite the aggression of breeding skuas towards sheep that approach their nest or chicks.

Male and female skuas differ in breeding role to a variable extent among species. Female Great Skuas at Shetland tend to remain in the territory guarding the eggs or chicks, and are provisioned by the male. Arctic Skuas in Shetland show much less pronounced division of duties though again the larger females spend longer guarding, and less time foraging, than the males do. On the tundra, differences in behaviour between the sexes seem less evident. Given the larger size of female skuas, the female is probably better able to defend the eggs and chicks from potential predators, so such a division of duties is not unexpected.

Voice

Unlike the gulls, skuas tend not to be particularly vocal birds, and they are normally silent at sea. Indeed, even when they are on their breeding grounds their vocalizations are fairly limited.

Although registering a clamorous protest, the otherwise defenceless Gentoo Penguin (Pygoscelis papua) *parent can do little more than stand and watch as its hapless chick is snatched away by a Brown Skua. This skua species is heavily predatory on penguins, regularly plundering their eggs and young, and scavenging the corpses of adults too.*

[*Catharacta antarctica antarctica*, Falkland Islands. Photo: Francisco J. Erize/ Bruce Coleman]

All *Catharacta* and the Pomarine Skua have a "Long Call", a series of 4-12 "laughs" lasting 0·2 seconds each, which they give to indicate territory ownership to intruders or to greet the mate. This call is usually accompanied by the "Wing-raising Display", which shows off the white flashes in the proximal parts of the primaries. Long-tailed and Arctic Skuas have similar "Long Calls", given with the head lifted and neck stretched, but without the "Wing-raising Display".

Long-tailed and Arctic Skuas both perform noisy display flights, often with adults from elsewhere joining in over the territory. The cries of Arctic Skuas are often described as "cat-like". Sharper and less melodic cries are made when birds are chasing intruding skuas. Female skuas give a characteristic soft panting call when soliciting food or copulation. Chicks, in turn, have a shrill food-begging call.

Great Skuas, when nervous, give a repeated soft "quack", so human visitors to Great Skua colonies are continuously accompanied by this call; I have never heard this call given by Brown Skuas or South Polar Skuas, and these species mostly give a harsh cry as they swoop at a human intruder to their territory. This harsh cry is given by only a very small percentage of Great Skuas, those few most aggressive individuals in breeding colonies that regularly strike human intruders. The voice of the Chilean Skua is said to be much higher-pitched and more nasal than that of the Brown Skua. The South Polar Skua also has a much harsher and higher-pitched voice than the Brown Skua, with the Great Skua being least raucous.

Food and Feeding

Skuas use a wide range of feeding behaviour, though they are notorious as pirates and predators. Piracy, or kleptoparasitism, is carried out by threatening other birds with physical attack or injury, in order to cause them to drop or regurgitate food that the skua can recover and swallow. Arctic Skuas often attack terns, puffins and small gulls, while Great Skuas tend to attack larger seabirds, such as Common Murres (*Uria aalge*), gulls and Northern Gannets (*Sula bassana*). Attacks can involve stooping from great height like a Peregrine Falcon (*Falco peregrinus*), in order to startle an auk to drop a fish, or may involve prolonged chases of slower-flying and less manoeuvrable seabirds. Terns often drop fish when chased by Arctic Skuas apparently to avoid physical attack, but gannets chased by Great Skuas can be repeatedly caught by the wingtip and tipped into the sea. Although Great Skuas appear to be intimidated by the gannet's powerful bill and do not attack birds they have pulled down onto the sea, the gannet may often regurgitate food, apparently to allow it to get away from the skua's attentions.

Tundra-nesting skuas feed on small mammals, but also on insects, berries, small birds, eggs and carrion. The three *Stercorarius* species differ in their abilities to exploit these different foods, owing to the greater flight agility of the Long-tailed Skua, but greater muscular digging and tearing power of the Pomarine Skua. Long-tailed Skuas pounce on lemmings (*Lemmus*) from above, whereas Pomarine Skuas lack the agility to do this and tend to dig the lemmings out from within their tunnels. In winter, Arctic Skuas feed largely by kleptoparasitism, but Long-tailed Skuas do not, and probably catch food for themselves, while Pomarine Skuas appear to be the most predatory, killing phalaropes and other small seabirds at sea.

Catharacta skuas are great opportunists, learning new feeding opportunities quickly. They will feed as predators but can often obtain food more easily, or with less risk of injury, by other means. South Polar Skuas generally fish for themselves at sea, catching Antarctic silverfish (*Pleuragramma antarcticum*), but they will take Adelie Penguin eggs or small chicks, especially if feeding conditions at sea are poor. Brown Skuas are much more predatory, and, where sympatric with South Polar Skuas, the larger Brown Skuas feed predominantly on penguins and rarely on fish. Great Skuas on St Kilda, off north-west Scotland, feed mainly on seabirds during breeding, especially on Black-legged Kittiwakes (*Rissa tridactyla*), Atlantic Puffins and storm-petrels. Some of these they find dead at the colony or at sea, simply because there are such large numbers of seabirds at these colonies, but some they kill by catching hold of them in mid-air, and dragging them to the sea surface and then drowning them. By contrast, Great Skuas breeding in Shetland kill or scavenge very few seabirds, though plenty are available; in Shetland they prefer to catch sandeels (*Ammodytes*), when shoals are available at the sea surface, and to scavenge on small whiting (*Merlangius merlangus*) and haddock (*Melanogrammus aeglefinus*) discarded from fishing boats. They catch sandeels by joining mixed species flocks of Northern Gannets, gulls and Northern Fulmars (*Fulmarus glacialis*) above dense shoals of sandeels and splash-diving onto the masses of fish. Discards are taken from behind fishing boats in direct competition with gannets, fulmars and large gulls, sometimes by stealing fish from these other species, but more often by simply picking discarded fish directly from the sea. Neither of these options is normally available at St Kilda.

Breeding skuas of most species are diurnally active and sleep during the night. Great Skuas in Shetland are essentially inactive from 22:00 to 04:00 hours, despite it being moderately light through the night in mid-summer. However, Brown Skuas nesting on islands with burrow-nesting petrels are essentially inactive throughout the day, and forage entirely at night by walking around until they find a petrel, then jumping on it and killing it.

Some skuas, certainly including several or all of the *Catharacta* taxa, have a very poor sense of taste. This may be adaptive for birds that often feed on carrion, but it is striking to see the large skuas happily eat meat laced with hot chilli sauce or with bitter tasting alphachloralose narcotic. Experiments presenting meat buried in snow to South Polar Skuas also showed that they have little or no sense of smell; unlike the petrels, skuas' brains have only small olfactory bulbs and they are unable to locate prey by scent.

Within skua colonies individual birds will learn particular feeding specialities. A few Great Skuas at Foula specialize on stealing eggs from Northern Fulmars without being spat on and covered in oil. One bird specialized in killing Black Guillemots (*Cepphus grylle*) by sitting on a boulder above the guillemot nest and pouncing on the emerging adult; this behaviour led to the desertion of an entire Black Guillemot colony. One bird learned to walk into the Arctic Tern (*Sterna paradisaea*) colony to pick up chicks, rather than fly in causing terns to attack in force. A few birds learn to scavenge on sheep afterbirth, and some go on from this to learn to attack lambing ewes and newborn lambs. At Hermaness, Shetland, a few Great Skuas take many Black-legged Kittiwake chicks from nests, whereas at Foula they never do, but they do kill many kittiwake fledglings. Several years of shortage of sandeels in Shetland led to the development of widespread cannibalism, Great Skuas eating chicks from other territories. Although sandeel stocks have since recovered, many Great Skua chicks are still being killed each year, apparently because this habit has been retained.

Breeding

Skuas are generally monogamous and pair for life, showing strong territory site fidelity. There are two major exceptions to this generalization. One is the Pomarine Skua, which shows an element of nomadism, and forms new partnerships as a result. This behaviour is in response to the fluctuations in lemming abundance which cause this specialist predator to seek areas of high lemming numbers before settling to breed. The other exception is the bizarre habit of Brown Skuas at some colonies to nest in communal groups, which always consist of a single adult female and two or more males; such polyandry is unusual among birds, although it has now been recorded in a number of families. It could arise if one male was unable to provision a mate and chick, in which case a second male could permit higher breeding success to be achieved. In the Chatham Islands this is clearly not the case as the breeding success of pairs, trios and larger groups is uniformly very high. In fact, groups have marginally lower breeding success because the confusion among adults leads to a slight loss of egg viability through irregular incubation. Nor can kin selection be invoked as an explanation,

The Brown Skua is probably the most piratical of all the Stercorariidae. In these photos, two skuas collaborate to force a Southern Giant Petrel (Macronectes giganteus) *off its nest, while another has already successfully got hold of a Gentoo Penguin* (Pygoscelis papua) *egg. Some Brown Skuas never leave the islands on which they breed, as the presence of large seabird colonies assures them of an easy living all year round.*

[Above: *Catharacta antarctica lonnbergi*, Macquarie Island. Photo: G. Robertson/ Auscape.

Below: *Catharacta antarctica antarctica*, Falkland Islands. Photo: Wayne Lynch/DRK]

On their territories skuas are notoriously aggressive towards all intruders, birds and mammals alike, including humans. Their usual method of attack, and a most effective one, is a blow to the head, delivered with either bill or feet. This sheep and its lamb have strayed too close to an Arctic Skua's nest-site and are receiving a timely warning.

[*Stercorarius parasiticus*. Photo: Tim Loseby]

since the males in groups are normally not closely related. On the few small uninhabited islands in the Chathams where skuas nest, much of the island is covered with dense scrubby woodland, bracken, flax and tree ferns, excluding skuas from holding territories. Most territories are on the edge of the island, often on rocky areas on the edge of the sea. This limited nesting habitat may encourage group formation, allowing males to hold a territory that they might lose to another male if they tried to defend it alone. The habit of winter residency seems to correlate with formation of groups, and it may be that low levels of territorial defence in winter permit the establishment of groups that carry on into breeding seasons. Whatever the reason, groups are remarkably stable: some trios and groups of up to seven birds on territories on Rangatira Island, in the Chathams, have remained intact for seven or more consecutive breeding seasons. DNA fingerprinting has shown that chicks in group territories may be fathered by any male in the group, but that extra-group copulations either do not occur or do not fertilize eggs. Bonds within groups appear every bit as strong as within pairs.

Established breeding pairs of skuas usually re-establish the pair-bond by meeting on the territory used in the previous year. Limited courtship ceremony is needed and, with high adult survival rates, most neighbouring territories are likely to contain the same adults as in the previous year too, so territorial boundaries are already established. Birds that have lost a partner soon accept a new mate; experimental removal of one bird early in the season often leads to a replacement partner entering the territory within 48 hours. Occasionally birds will force their way in to replace an existing adult. This can sometimes be achieved by dive-bombing the bird on the territory or by physical attack and fighting; broken wings or other serious injuries are not uncommon when these conflicts escalate, though usually the owner is successful in retaining its status. New pairs of inexperienced birds often form on club sites and sometimes attempt to breed on a small territory on the fringe of the club. This is usually unsuccessful due to disturbance from other club birds, and the eggs are usually lost, but some such pairs later manage to expand their territory into the colony proper.

Formation of the nest scrape is usually carried out by both adults together, following circular parading displays and much squeaking. Often several scrapes are made before one is selected for the eggs. Most clutches are of two eggs, but about 5-10% may consist of only one. Clutches of more than two eggs are very unusual, though a few females lay three eggs consistently, year after year. These larger than normal clutches usually fail to hatch because all eggs at some times fail to receive adequate warming. Skuas have only two brood patches to warm the eggs, and incubate with one egg on each foot to insulate them from the ground since nests have little or no lining material. The webs provide good insulation but have very little blood flow through them so do not transfer significant heat to the eggs. The habit presumably allows skuas to avoid making a conspicuous nest, so that predators such as Arctic foxes (*Alopex lagopus*), or indeed other skuas, will be less likely to notice a skua clutch on the tundra. The lack of material to raise eggs off the ground can lead to loss of large numbers of eggs through chilling if heavy rainstorms occur during the incubation period.

Eggs are laid at intervals usually of 48 hours, but sometimes of 24 or 72 hours. Incubation begins with the laying of the first egg, so that hatching is asynchronous, though usually with a gap smaller than that between the laying of the two eggs, since the second egg is slightly smaller and so develops faster, and incubation temperature is usually rather lower over the first day or two than for the rest of the incubation period. When food is short, the larger and older chick will attack the younger one, preventing it from getting much of the meal regurgitated by the parent. In the South Polar Skua this almost invariably leads to the death of the second chick, but in other skuas the second chick has a good chance of surviving, except in unusually poor seasons. In view of the hostile behaviour between siblings, it is not surprising that skua chicks have a habit of wandering, leaving the nest a day or two after hatching, but often returning for periods of brooding until too big to fit under the adult. However, even in skua populations where sibling conflict is not induced by food shortage, and in single-chick broods, chicks wander some distance from the nest but seem to learn the limits of the territory. Approaching danger leads to chicks crouching motionless, often behind a stone or clump of vegetation, until danger has passed. Surprisingly, chick wandering can lead to adoption by an adjacent pair. On Foula, while sandeels were scarce and Great Skua breeding success was very low because chicks were starving or being eaten by neighbouring adults when parents were away foraging, several starving chicks tried to beg from adults returning to a nearby territory to feed their own chicks, and at least some of these were accepted into the new family. Perhaps attempting to be adopted by a more successful adult, with its attendant risk of being killed, is a viable alternative to staying at home and starving to death.

Breeding success is high in most skuas. If eggs are lost during incubation a replacement clutch may be laid about 10 days after the loss. Though clutches lost towards the end of incubation are rarely replaced, egg loss is most frequent early in incubation. Only the South Polar Skua normally has low breeding success, apparently due to difficulties in catching enough fish to keep chicks alive, as well as added losses caused by sporadic harsh weather conditions. In Long-tailed Skuas, breeding success varies considerably with variations in food supply. This is true also of other skuas, but food supply is not so variable for Arctic Skuas, and is uniformly high for most Brown

Skuas, giving them consistently the highest chick production among skua taxa.

Hybridization among skuas tends to be of a predictable nature. Where pairs of species breed side by side, assortative mating is strong, with hybridization rare. The few hybrids that do arise on the Antarctic Peninsula are of male South Polar Skuas with female Brown Skuas, because the Brown Skua returns to establish territories and pairs first. When male South Polar Skuas return there are already some unpaired female Brown Skuas with which they can pair, whereas female South Polar Skuas have not yet arrived. A female Brown Skua accepted by a male South Polar Skua is likely to be able to repel any female South Polar Skua trying to enter the territory because Brown Skuas are so much larger. However, although there are suggestions that hybridization between these two species may have increased with recent range expansion, few hybrids can be identified in the adult population, suggesting that the viability of hybrids may be low.

Skuas are long-lived, and the larger species especially so. The oldest recorded ringed bird is a 34 year old Great Skua trapped on its nest on Foula. Colour ringing indicates a survival rate of breeding adults of 89% per annum at present on Foula, where food has been in short supply in recent years, while the survival rate at Handa, north-west Scotland, where food supply seems to be better, is 94% per annum. Brown Skuas in the Chatham Islands have an average adult survival rate of over 94% per annum.

Movements

The family includes species that are transequatorial migrants through to species in which some populations are predominantly resident or show only local winter dispersal. The South Polar Skua holds the record amongst all birds for the longest movement recorded by ringing: a bird ringed as a chick on the Antarctic Peninsula shot north of the Arctic Circle in Greenland six months later.

Young skuas tend to migrate further than adults, and are more likely to be driven off course by bad weather. "Wrecks" of skuas may occur in Europe in autumn when there are strong onshore storms that carry inexperienced birds over land. Such conditions have led to recoveries of Great Skuas, ringed a few months earlier as chicks in Scotland, on motorways, lakes and farmyards in Austria, Switzerland, Poland and southern Germany.

Transequatorially migrating skuas pass rapidly through the tropics, but movements within temperate regions tend to be slow, the birds taking advantage of feeding opportunities that arise. In general, autumn migrations tend to be more leisurely than those in spring, and the concentrated spring migration can lead to spectacular numbers of skuas passing within view of Irish and Scottish coastal seawatching sites, if onshore winds deflect the birds from their preferred paths further offshore.

The extent to which skuas deliberately migrate over land is unclear. It seems likely that some Arctic and Pomarine Skuas nesting on the tundra of north Russia or Canada migrate over land rather than taking the much longer northern coastal route to the Atlantic or Pacific, but the highly pelagic Long-tailed Skua is rarely encountered inland and perhaps avoids these overland routes.

Many juvenile and some immature skuas remain in the wintering area through the following summer, rather than returning to the breeding range, while some immature birds migrate beyond the breeding area to explore. Subadult Great Skuas ringed as chicks in Scotland have been recovered from as far beyond their natal area as west Greenland, Svalbard and north Russia while others from the same cohort summer off Brazil or the Cape Verde Islands.

Relationship with Man

Because of their tendency to breed at high latitudes, skuas were little known to ornithologists before the nineteenth century. During the seventeenth and eighteenth centuries, the leading European ornithologists obtained some specimens of skuas shot during migration through Europe, and expeditions to the Faeroes, northern Scandinavia, Greenland and Spitsbergen returned with some skuas collected at their breeding areas. This limited material resulted in enormous confusion, compounded by the variety of colour morphs and juvenile and subadult plumages. As a result, by 1876, the review by H. Saunders, the leading expert on skuas in the nineteenth century, contained no mention of the South Polar Skua, but listed, for example, 18 different post-Linnaean scientific

Less colonially inclined than most other skuas but strongly territorial, the Pomarine Skua breeds in widely dispersed pairs on marshy tundra at high northern latitudes. Choice of the general breeding area is heavily dependent on the presence of rodents, especially lemmings, which are important food for its young. It prefers low mossy tundra and will often site the nest in hummocky grass alongside a bog or a freshwater pool. In a bad lemming year it may not breed at all, instead migrating early, but in a good year even birds in immature plumage have been known to breed.

[*Stercorarius pomarinus*, Canada. Photo: Brian Hawkes/ Aquila]

As a general rule, skuas tend to be rather successful breeders, the only notable exception being the South Polar Skua. Fish supplies sometimes prove too scanty for the second chick to stand any chance of survival, and sudden severe storms can also cause mortality among the young. Note the chick's sturdy legs and pale soft, woolly down with erect silky spikes; the egg tooth is still present on the already robust bill.

[*Catharacta maccormicki*, Ross Island, Antarctica. Photo: Rich Kirchner/ NHPA]

names for the Long-tailed Skua, and 23 for the Arctic Skua. He pointed out that the name Linnaeus gave to a small skua, *Larus parasiticus*, from which we now derive the scientific name of the Arctic Skua, was given to a bird which the description of Linnaeus shows clearly to have been a Long-tailed Skua! Similarly, the name *Catharacta*, now used for the genus of large skuas, was a name originally given by Aristotle to a bird mistakenly thought to be a great skua by eighteenth century ornithologists, but clearly from Aristotle's description a juvenile Northern Gannet!

Though ornithologists did not know skuas well, local peoples in certain remote areas did. In Iceland, the Faeroes and Shetland, skua eggs and chicks were a valuable food resource, easily collected from the ground nesting areas. In the Faeroes, in particular, skua chicks were tethered to prevent them from wandering, and harvested as food shortly before their due fledging date. However, the Faeroese Great Skuas were considered a mixed blessing, as they attacked cliff-nesting seabirds that were also harvested, and so skuas were on the list of "vermin" for the heads of which a bounty was paid. In Shetland, the Great Skua was a highly prized, but very rare, bird during the eighteenth century, owing to its habit of chasing away White-tailed Sea-eagles (*Haliaeetus albicilla*), and so preventing the eagles from attacking sheep and lambs. However, with the increase in numbers of Great Skuas in Shetland during the early nineteenth century, and the decrease in eagle numbers, the balance of favour shifted towards harvesting skuas as food. Especially at Foula, Great Skua eggs were harvested around mid-May, causing the birds to lay a replacement clutch about ten days later. The replacement clutch was also harvested, then the smaller number of pairs producing another replacement clutch were usually allowed to breed unmolested.

Harvesting probably had rather little effect on skua numbers, but during the late nineteenth century many "sportsmen" and taxidermists visited skua colonies to shoot adults for museums and private collectors. Many colonies were exterminated, and Great Skua numbers were reduced to only about four pairs in the Faeroes and a couple of dozen pairs in Shetland around 1890-1900. Then strict protection, including wardening of colonies in Shetland, resulted in a sustained population increase, continued in Scotland until very recently, with considerable colonization of new areas on the southern fringe of the breeding range and dramatic northward expansion of the range into Svalbard, Norway and Russia. Population growth in the Faeroes was less dramatic, partly due to greater illegal persecution there, but also because Faeroese populations did not receive the benefits of increased food supply that were provided in Scotland. In particular, Scottish Great Skuas have taken advantage of the huge quantities of undersized haddock, whiting and other fish discarded from fishing boats, and this has formed a large part of their breeding season diet, and has undoubtedly contributed to their high breeding success and population growth. Association with fishing boats is not entirely beneficial though, as a few birds swallow baited hooks and are killed as a result, and some become entangled and drown in fishing nets, especially in the wintering areas.

Although Great Skuas are often denounced for attacking sheep, it is not clear that they are, on balance, damaging to the interests of crofters and their sheep. Sheep tend to congregate on the "club" sites used by non-breeding skuas, and this is probably because the skuas' droppings add large amounts of nitrogen and phosphorus to the vegetation and so stimulate the growth of nutrient rich grass. These areas frequented by skuas are thus the best areas for sheep to graze. This improvement to the grazing by skuas has not been generally recognized by crofters, but it may well more than counterbalance the amount of damage that skuas do by very occasionally killing lambs and by chasing sheep away from their nests or chicks.

Status and Conservation

Several skua taxa have small populations, notably the South Polar Skua with 5000-8000 pairs, the Brown Skua with 13,000-14,000 pairs, the Great Skua with 13,600 pairs, and the Chilean Skua with unknown but probably similar numbers. However, none of the species is threatened or declining significantly in range or numbers.

Indeed, generally skuas can be considered a considerable conservation success story. Great Skuas in Scotland and the Faeroes were rescued from the verge of local extinction (see Relationship with Man), despite a prevailing view in 1870-1900 that their loss from the British and Faeroese avifaunas was almost inevitable. Although there were hundreds of Brown Skuas on

The Arctic Skua breeds colonially at seabird sites where its food supply is assured, yet it is also found nesting widely dispersed over moorland and tundra. The chicks, normally two in number, are able to leave the nest, a simple depression in the ground, 1-2 days after hatching and they usually separate to hide in vegetation nearby, the cryptic dark brown down affording them a certain measure of protection against predators.

[*Stercorarius parasiticus*, Spitzbergen, Svalbard. Photo: Michel Gunther/ Bios]

Amsterdam Island, in the southern Indian Ocean, in the 1870's, the population was reduced to only a single breeding pair after humans introduced agriculture, feral cattle, pigs, rats, goats, dogs and cats. However, with the help of several recent conservation measures, skua numbers have increased again to 19 pairs.

Nevertheless, as these same successes illustrate, the past history of skuas confirms that populations are potentially vulnerable to persecution. Increases to the normally low adult mortality rate can lead to rapid decreases in numbers and whole colonies can easily be driven to extinction through persecution of adults, so current and recent cases of persecution require vigilance. Great and Arctic Skuas in Scotland have suffered from some illegal persecution, which has kept numbers down in a few particular areas. Brown Skuas in the Falklands have probably also suffered from some persecution by sheep farmers, though in that case the skuas gain some support for their habit of attacking the local sheldgeese (*Chloephaga*), which farmers consider to be a greater threat through their competition for grazing. Brown Skua numbers have been reduced where they nest near farms, as on Tristan da Cunha and in the Chatham Islands. Again, numbers near Antarctic bases have changed as a result of human activities, some increasing as a result of new feeding opportunities and some decreasing as a result of increased disturbance.

As top predators in several ecosystems, skuas tend to accumulate high levels of pollutants that are amplified through the food chain. These include all lipid-soluble pollutants, such as organochlorine pesticides, PCB's and organic mercury. Skuas that feed on prey which concentrate pollutants that are not lipid-soluble into particular tissues can also acquire high concentrations. For example, Brown Skuas eating prion and petrel livers and kidneys accumulate high levels of cadmium. Despite the high concentrations produced, there is little evidence of any toxic effects, but individuals with particular predatory specializations may be at risk.

Oil and chemical pollution threats to skuas seem to be relatively minor, but changes to fishery practices might have profound effects on Great Skua numbers if discarding were to cease. Locally, Arctic Skua numbers may be adversely affected by increases in Great Skua colonies and consequent predation and competition for territories, but such effects seem to be minor and result in movement, rather than extermination, of Arctic Skua colonies.

Perhaps the most important conservation issue is in the impact of skua predation on other seabird populations. Some petrel populations have been severely reduced in size by introduced alien mammals or habitat change, and the remnants of these may be vulnerable to skuas. Fortunately, the extremely rare Magenta Petrel (*Pterodroma magentae*), endemic to the Chatham Islands, nests well away from skua colonies, but on Rangatira Island, also in the Chathams, skuas nest over the burrows of the Chatham Petrel (*Pterodroma axillaris*), a Vulnerable species now reduced to only about 300 individuals. Though apparently they do not eat it, the skuas kill a high proportion of the similar and sympatric Black-winged Petrel (*Pterodroma nigripennis*), and killed the only Juan Fernandez Petrels (*Pterodroma externa*) occupying burrows in New Zealand and may have prevented a new colonization by that species! On Gough Island, the endemic Atlantic Petrel (*Pterodroma incerta*) is eaten by skuas, but currently it is still a relatively abundant bird, and the skuas also have plentiful supplies of prions, Soft-plumaged Petrels (*Pterodroma mollis*) and storm-petrels, so their impact on the Atlantic Petrel population is slight.

Since the numbers of Great Skuas seem now to be artificially high as a result of the provision of discards from fishing boats, any sudden reduction in the supply of discarded fish in northern Scotland could result in Great Skuas switching to predation in order to meet their food requirements, and this could have a major effect on populations of smaller seabirds, especially storm-petrels, Black-legged Kittiwakes and Atlantic Puffins, and perhaps Red-throated Divers (*Gavia stellata*), Arctic Skuas, Eurasian Oystercatchers (*Haematopus ostralegus*) and Common Eiders (*Somateria mollissima*). That situation requires monitoring in view of the current concern to abolish discarding within the European Union Common Fisheries Policy.

dark morph
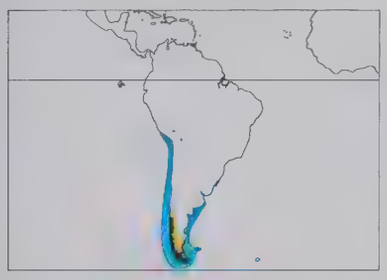
ssp pallescens
pale morph

Genus *CATHARACTA* Brünnich, 1764



1. Chilean Skua

Catharacta chilensis

French: Labbe du Chili **German**: Chileskua **Spanish**: Págalo Chileno

Taxonomy. *Stercorarius antarcticus* b. *chilensis* Bonaparte, 1857, Chile.
Sometimes considered conspecific with all three congeners, and all four probably form superspecies; genus frequently merged into *Stercorarius*. Occasional hybridization with *C. a. antarctica* reported. Monotypic.

Distribution. Coasts of S South America, from SC Chile (Concepción) and S Argentina (Deseado) to S Tierra del Fuego. Apparently winters mainly along coasts of Chile and Argentina, extending N to S Peru and possibly E to W Falkland Is.

Descriptive notes. 53-58 cm; 1100-1700 g; wingspan 130-138 cm. Brown dorsal plumage with bright cinnamon underparts in many but not all individuals; lesser and median underwing-coverts usually bright cinnamon. All ages have a dark brown or blackish cap ending just below the eye; in adults, this contrasts strongly with a straw-coloured streaked collar and ear-coverts. Unlike other *Catharacta* species, which have black bills, in this species bill is pale blue with dark tip. Cinnamon underparts are most pronounced in juvenile birds, apparently becoming duller in immatures; in juveniles the straw streaking is not evident; unique among skuas in having gull-like strongly edged or barred feathers on the backs of juveniles.

Habitat. Marine, apparently predominantly coastal, and occurring especially in channels and straits. Breeds on islands and remote mainland coastal areas of Chile and Argentina.

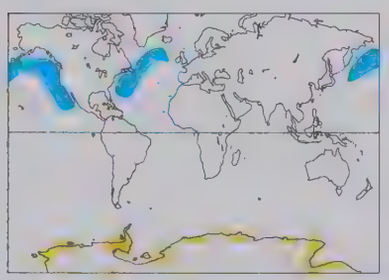
Food and Feeding. Largely unknown. Dense gull-like colonial nesting suggests feeding may be more gull-like than skua-like. Species will visit bird colonies, presumably as a predator on eggs and young, and will scavenge on Patagonian rubbish dumps; may feed intertidally alongside Kelp Gull (*Larus dominicanus*).

Breeding. Starts Nov. Colonial, sometimes at high nesting density similar to large gulls and unlike all other skuas. Nest scrape usually lined with dead grass. Usually 2 eggs, but occasionally only 1; incubation 28-32 days; chick has uniformly coloured light pink-grey-brown down. Unlike other *Catharacta*, adults generally do not attack humans entering their territory.

Movements. Little known, but apparently disperses northwards along the coasts of Argentina and Chile to S Peru in Apr, returning to breeding areas in Oct.

Status and Conservation. Not globally threatened. Total population unknown but probably numbers several thousands of pairs. No information available on population trends or changes in extent of breeding range. Census data are required for this rather poorly known species. Threats unknown but it is likely that eggs and chicks are harvested for food.

Bibliography. Blake (1977), Clark (1986), Devillers (1977c, 1978b), Humphrey *et al.* (1970), Jehl (1973b), Johnson (1965b), Koepcke (1970), Meyer de Schauensee (1982), Moynihan (1962), Murphy (1936), de la Peña (1992), Pinto (1964), Sick (1985c, 1993), Wetmore (1926, 1965), Woods (1988).



2. South Polar Skua

Catharacta maccormicki

French: Labbe de MacCormick **German**: Antarktikskua **Spanish**: Págalo Polar
Other common names: MacCormick's/Antarctic Skua

Taxonomy. *Stercorarius maccormicki* Saunders, 1893, Victoria Land, Antarctica.
Sometimes considered conspecific with all three congeners, and all four probably form superspecies; genus frequently merged into *Stercorarius*. Occasional hybridization with *C. antarctica lonnbergi* reported. Monotypic.

Distribution. Antarctic Continent and Peninsula, especially in Ross Sea area. Winters as far N as Alaska and Greenland, though distribution in North Atlantic confused by presence of *C. skua*, and difficulties of field identification.

Descriptive notes. 50-55 cm; 900-1600 g; wingspan 130-140 cm. Two colour morphs: pale birds show strong contrast between pale golden brown to smoke grey body plumage and dark brown wings, back and tail; dark morph birds have dark brownish olive body, head and neck, and very similar sepia wings and back, so appear less "two-tone" and can be more easily confused with *C. skua* or *C. antarctica*. Buffy-yellow hackles on the neck are larger on pale morph birds. Birds become paler with age, and amongst adults plumage fades to a lighter tone through the breeding season. Pale morph birds predominate in Ross Sea area, while dark morph birds predominate on Antarctic Peninsula; in all regions, males in breeding pairs are almost invariably darker in colour than their larger mates. Compared with other *Catharacta*, present species has slighter body, thinner bill, smaller head and narrower wings, and lacks the capped and rufous appearance of juvenile *C. skua*. As a long distance migrant, primary moult is more intense than in congeners, several primaries often being renewed at the same time in May-Aug.

Habitat. Marine, apparently being pelagic in winter and feeding predominantly at sea while breeding. Breeds on relatively snow-free areas in Antarctica; sometimes associated with penguin rookeries or inland petrel colonies, though perhaps due to shared need for snow-free nesting habitat more than to a custom of exploiting other seabirds for food. Predominantly coastal, but forms small colonies inland in snow-free mountain areas.

Food and Feeding. Mostly feeds on fish, especially Antarctic silverfish (*Pleuragramma antarcticum*), caught at sea some distance from the breeding colony. Predation on eggs and chicks of penguins is of variable importance to particular pairs or at particular colonies, but is generally secondary to catching fish. Winter diet not known, but probably made up of fish actively caught, complemented by some scavenging.

Breeding. Starts Nov. Loosely colonial, highly territorial. Nest scrape usually unlined. Usually 2 eggs but only 1 laid by some inexperienced birds; incubation 28-31 days; chick has uniformly coloured pale grey-brown down; leaves nest 1-2 days after hatching; fledging 36-45 days. Older chick usually kills younger one, and breeding success characteristically low. Sexual maturity at 6+ years; adult survival 90-95 %.

Movements. Transequatorial migrant, departing from breeding grounds in Mar and returning Oct-Nov. Many Northern Hemisphere specimens are of immature birds, as far north as Greenland, Japan and British Columbia. Wintering areas thought to be throughout North Pacific and North Atlantic, perhaps with clockwise loop migrations. Commonest *Catharacta* in May-Aug on Grand Banks of Newfoundland. Records from E North Atlantic few, and confused by presence of *C. skua*.

Status and Conservation. Not globally threatened. Total population 5000-8000 pairs; 2000-6000 pairs in Ross Sea area, c. 800 pairs in Wilkes Land, 650 pairs on Antarctic Peninsula, 80 pairs in Adelie Land, 10 pairs in South Shetlands, 10 pairs in South Orkneys. Breeding success is almost invariably low, but is further reduced by harsh weather affecting chick survival or adult foraging. Hazards to adults at sea on passage or in winter unknown, but any species with low reproductive output and high adult survival is necessarily vulnerable to factors increasing adult mortality. Population trends unclear and more data needed.

Bibliography. 3. Brown Skua

Catharacta antarctica

French: Labbe antarctique **German**: Subantarktikskua **Spanish**: Págalo Subantártico
Other common names: Southern (Great)/Subantarctic/Falkland Skua; Lönnberg's Skua (*lonnbergi*)

Taxonomy. *Lestris antarcticus* Lesson, 1831, Falkland Islands.
Sometimes considered conspecific with all three congeners, and all four probably form superspecies; genus frequently merged into *Stercorarius*. Often considered conspecific with *C. skua*, but differs more from *C. skua* than from *C. maccormicki* and *C. chilensis* (see page 557). Occasional hybridization reported with *C. maccormicki* and with *C. chilensis*, but hybrids very rare. Race *hamiltoni* differs only slightly from nominate *antarctica*. Race *lonnbergi* has been considered a separate species. Proposed races *clarkei* and *intercedens* invalid, and nowadays included in *lonnbergi*. Name *lonnbergi* sometimes erroneously spelt *loennbergi*, but removal of Scandinavian umlaut does not justify addition of "e". Three subspecies currently recognized.

Subspecies and Distribution.
C. a. antarctica (Lesson, 1831) - Falkland Is and SE Argentina; winters off SE South America.
C. a. hamiltoni (Hagen, 1952) - Tristan da Cunha and Gough I; winters near breeding areas.
C. a. lonnbergi Mathews, 1912 - Antarctic Peninsula, subantarctic islands of Atlantic, Indian and Pacific Oceans; winters near or slightly dispersed from breeding areas.

Descriptive notes. 52-64 cm; 1200-2100 g; wingspan 126-160 cm. Brown plumage, but highly variable from uniformly dark brown to light brown with pale flecking; relatively large bill, and bulky body. Lacks distinct capped appearance of *C. skua* and *C. chilensis*; has dark lesser and median underwing-coverts. In all races, juveniles darker and more uniform in colour with more chestnut in body plumage and with less distinct white wing flashes than in adults. Race *hamiltoni* has less white or golden flecking, and little rufous on body, so appears uniformly dark with few markings on head and little contrast between head and collar; larger than nominate race in all linear measurements. Race *lonnbergi* much larger than either of the other subspecies, especially around New Zealand, showing less pale flecking than nominate race but more than *hamiltoni*.

Habitat. Marine, or on and around subantarctic islands populated by burrow-nesting seabirds or penguins. Nests mainly on islands free from human disturbance, though can be attracted to scientific bases that provide scavenging opportunities. May use territory just for breeding, or for breeding and all feeding needs, or may hold separate feeding territories. Breeding territories may be on grass, gravel or bare rock.

Food and Feeding. Highly predatory, feeding mainly on burrow-nesting prions, gadfly-petrels, storm-petrels, shearwaters and penguins, and scavenging on penguin eggs, chicks and adults, afterbirth and carcasses of seals. Will also scavenge around fishing boats and ships, and feed at sea, but some populations are essentially resident with seabird prey available all year round, and so rarely venture to sea. Burrow-nesting seabirds are mainly caught at night on the ground as they seek burrows, and remains are often put onto a "midden", a characteristic prey storage site within the territory.

Breeding. Starts Oct-Nov. Loosely colonial, highly territorial. May breed in trios or larger groups, with several males but only one female per territory; communal breeding associated with all year round residency, and may occur in more than 30% of territories at some New Zealand colonies. Nest scrape unlined or scantily lined with dead grass. Usually 2 eggs, but only 1 laid by some inexperienced

On following pages: 4. Great Skua (*Catharacta skua*); 5. Pomarine Skua (*Stercorarius pomarinus*); 6. Arctic Skua (*Stercorarius parasiticus*); 7. Long-tailed Skua (*Stercorarius longicaudus*).

birds: incubation 28-32 days; chick has uniformly coloured light pinkish brown down; leaves nest 1-2 days after hatching; fledging 40-50 days. Breeding success usually high. Sexual maturity at 6+ years; adult survival 90-96 %.

Movements Some birds at colonies in New Zealand, Tristan da Cunha and Gough I remain resident throughout year, with others dispersing to sea locally. In harsher environments all birds leave colony during winter and disperse at sea. Probably does not normally reach Northern Hemisphere, and several earlier northern records now reassigned to *C. maccormicki*. Usually breeds close to birthplace, facilitating racial divergences.

Status and Conservation. Not globally threatened. Total population c. 13,000-14,000 pairs: 3000-5000 pairs of nominate race, in Falklands and Argentina; 2500 pairs of *hamiltoni*, predominantly on Gough I with c. 200 pairs on Tristan da Cunha; and c. 7000 pairs of *lonnbergi*, with 1000-2000 pairs in Kerguelen Is, 1000 pairs on South Georgia, 550 pairs on Macquarie I, 460 pairs on Marion and Prince Edward Is, 400-1000 pairs in Crozet Is, 420 pairs in South Shetlands, 300 pairs in South Orkneys, 190 pairs on Elephant I, 100's of pairs at South Sandwich Is and Heard I, 150 pairs on Antarctic Peninsula, 105 pairs in Chatham Is, 100 pairs on Auckland I, c. 50 pairs each on Snares, Campbell and Antipodes Is, and a few pairs on Stewart I, Bouvetøya and Amsterdam I. Numbers have been greatly reduced by human persecution in Chathams and Tristan da Cunha, and possibly in parts of Falklands, but increases and range expansion on Antarctic Peninsula may be partly due to provision of increased feeding opportunities at Antarctic research bases, with skuas benefiting from refuse and disturbed seabird colonies. Many populations would be adversely affected by declines in numbers of prions, gadfly-petrels and storm-petrels breeding on islands, but populations of those long-lived birds are normally very stable.

4. **Great Skua**

Catharacta skua

French: Grand Labbe **German**: Skua **Spanish**: Págalo Grande
Other common names: Bonxie, Northern Skua

Taxonomy. *Catharacta Skua* Brünnich, 1764, Faeroes.
Sometimes considered conspecific with all three congeners, and all four probably form superspecies; genus frequently merged into *Stercorarius*. Has often been grouped in single species with *C. antarctica*, but range, mitochondrial DNA, plumage and biometrics all indicate specific status for both forms. Monotypic.

Distribution. Iceland, Faeroes, N Scotland, and recently a few sites in Svalbard, Bear I, Norway, Jan Mayen and Veshnjak I, Kola Peninsula (NW Russia). Winters predominantly off Iberia, with young birds moving as far S as Cape Verde Is and Brazil; small numbers winter on Grand Banks of Newfoundland.

Descriptive notes. 53-58 cm; 1100-1700 g; wingspan 132-140 cm. Generally brown plumage but with much white, yellow, ginger and black flecking, individually very variable; birds tend to become paler with age, partly due to retention of back feathers for many years and these fading with wear and exposure, but also due to increased white feathers especially on head. Brown plumage reminiscent of dark juvenile *Larus* gulls, but distinguished by white wing panels towards bases of primaries; flight much more powerful than that of gulls, with more rapid and stiffer wingbeats; wings shorter and broader than gulls and tail relatively short. Compared to Southern Hemisphere *Catharacta*, present species has distinctly dark cap, conspicuous straw yellow hackles, and much rufous streaking, but little contrast between body and wing coloration or tone. Juvenile has much darker and more uniformly coloured plumage, but with general body colour varying from chestnut to brown; white wing flashes, or panels, less evident in juveniles.

Habitat. Marine. Avoids land during migration and winter, so can often be found in unexpectedly large numbers a few km offshore from coastal seawatching sites where it is only rarely seen. Aggregates in winter in areas where it can scavenge from fisheries, e.g. Bay of Biscay and W Mediterranean. Breeds on islands, usually avoiding areas frequented by humans, preferring flat ground with some vegetation cover, but less than 20 cm tall. Often breeds near other seabird colonies which provide opportunities for kleptoparasitism and scavenging or predation.

Food and Feeding. A highly opportunistic feeder, but also frequently showing individual specializations in diet and feeding, with some colony-specific learning. In Shetland, feeds chicks mainly on sandeels (*Ammodytes*) caught by surface-plunging, or on small whiting (*Merlangius merlangus*), haddock (*Melanogrammus aeglefinus*) and pout (*Trisopterus esmarkii*) discarded from trawlers. Will scavenge on goose-barnacles or dead seabirds, rob Northern Gannets (*Sula bassana*) and auks of fish, or kill birds, especially Black-legged Kittiwakes (*Rissa tridactyla*) and Atlantic Puffins (*Fratercula arctica*). In Iceland and NW Scotland, diet is more varied including some squid and more seabirds. Winter diet includes waste from fishing boats, scavenging, and fish caught or stolen.

Breeding. Starts May. Loosely colonial, highly territorial. Nest scrape usually lined with dead grass. Usually 2 eggs, but only 1 laid by some inexperienced birds; incubation 28-32 days; chick has uniformly coloured light pink-grey-brown down; leaves nest 1-2 days after hatching; fledging 40-50 days. Sexual maturity on average at 8 years (5-12); adult survival 90 % (Shetland).

Movements. Migrates, wintering mainly off Iberia; younger birds travel further, some reaching Cape Verde Is and Brazil. Leaves breeding areas in Aug-Sept and moves slowly S. Young birds often driven inland by autumn storms, but otherwise species avoids coasts and can be more numerous offshore than coastal records indicate. Northward migration in Mar-Apr; immatures may stay south or visit high latitudes in summer. Few cross to W Atlantic and these are probably birds from Iceland, as UK ring recoveries in W Atlantic are very rare. Most birds breed within 1 km of birthplace, but ringed birds from Shetland founded colonies in Norway, Svalbard and Russia.

Status and Conservation. Not globally threatened. Total breeding population is only 13,600 pairs: 7900 pairs in Scotland; 5400 pairs in Iceland; 250 pairs in Faeroes; 60 pairs on Svalbard; and less than 10 pairs each in Norway, Jan Mayen and Russia. Numbers have increased enormously since 1900 when Scottish and Faeroese populations were close to extinction (see page 566). Recent range expansion to Svalbard, Norway, Jan Mayen and Russia is continuing, and numbers are likely to increase there. Recent reductions in sandeel stocks at Shetland have led to declines in breeding success and decreases in numbers at the largest colonies, but increases continue further south in Scotland; however, discards from fisheries provide more than half the summer diet at Shetland, so that changes in fishing practices could drastically affect numbers. Some colonies have been limited in size by human persecution (often illegal). As a top predator, pollutant burdens can be high but there is little evidence of toxic effects. Some birds drowned in fishing nests or caught on hooks, especially in wintering areas. Harvesting for food has now almost ceased.

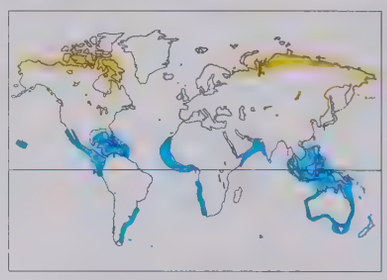
Genus *STERCORARIUS* Brisson, 1760



5. **Pomarine Skua**

Stercorarius pomarinus

French: Labbe pomarin **German**: Spatelraubmöwe **Spanish**: Págalo Pomarino
Other common names: Pomarine/Pomatarhine Jaeger

Taxonomy. *Lestris pomarinus* Temminck, 1815, Arctic regions of Europe.
May actually be more closely related to *Catharacta skua*, than to either of congeners (see page 556). Monotypic.

Distribution. Tundra of N Russia, N Alaska and N Canada. Winters at sea close to coasts, mainly between Tropic of Cancer and equator, and around Australia.

Descriptive notes. 46-51 cm (including central tail streamers of up to 11 cm); 550-850 g; wingspan 125-138 cm. Striking white wing panels more like *Catharacta* than smaller skuas. Adults occur in pale and dark morphs, as in *S. parasiticus*, but dark morph occurs at frequency of c. 5-20% in all populations. Moult leads to heavy barring appearance of underparts from late autumn, but vent area and flanks often barred even in summer plumage, similar to subadult *S. parasiticus*. Tail streamers often lost during summer. Compared to *S. parasiticus*, has heavy bill, large head, large, stout body and broad wings. Juvenile and immature rather variable in plumage but distinguished from smaller *S. parasiticus* by heavier and more powerful flight, broader wings, heavier body, stouter bill, conspicuous white wing panels and more strikingly barred plumage with paler rump.

Habitat. Marine outside breeding season, remaining somewhat coastal, especially in upwelling regions of the tropics and subtropics. Breeds on Arctic tundra, only in areas where lemming (*Lemmus*) numbers are high; prefers low-lying moss tundra with pools, and hummocky areas in moist bogs.

Food and Feeding. While breeding, species is a specialist lemming predator, catching rodents mainly from the ground, and often digging open their burrows. Lemmings frequently constitute over 90% of diet in breeding season. Will also take birds' eggs, young waders and gamebirds, some carrion and fish. In winter, feeds on fish, sometimes by kleptoparasitism; also kills small seabirds, including phalaropes (*Phalaropus*), and scavenges on carrion.

Breeding. Starts Jun. Widely scattered over tundra, highly territorial. Nest scrape unlined and inconspicuous. Usually 2 eggs; incubation 25-27 days; chick has dark grey-brown down; leaves nest 2-4 days after hatching, but wanders less than other skua chicks; fledging 31-35 days. Sexual maturity at 3+ years; in good lemming years may breed in immature plumage.

Movements. Migrates to winter in low latitude seas, chiefly N of equator, apparently including extensive migration over land. Departs from breeding areas mainly in Sept, with peak migration through temperate North Atlantic in Oct, rather later than other congeners. Return migration in May, usually in small flocks. Immatures remain in temperate regions through summer.

Status and Conservation. Not globally threatened. Total population is unknown, but probably several 10,000's of pairs in Russia, Alaska and Canada. There is no evidence of changes in range or numbers but data are very poor. Breeding success depends on lemming abundance. Some eggs and chicks are lost to Arctic foxes (*Alopex lagopus*) and Snowy Owls (*Nyctea scandiaca*), but relatively few as this skua is large enough to drive off nest predators. Hazards to adults in winter are unknown.

6. **Arctic Skua**

Stercorarius parasiticus

French: Labbe parasite **German**: Schmarotzerraubmöwe **Spanish**: Págalo Parásito
Other common names: Parasitic Jaeger

Taxonomy. *Larus parasiticus* Linnaeus, 1758, Sweden.
Monotypic.

Distribution. Circumpolar in coastal tundra, mainly within the band 57°-80° N. Winters in oceans of Southern Hemisphere, especially close to coasts of South America, S Africa, S Australia and New Zealand.

Descriptive notes. 41-46 cm; 330-610 g; wingspan 110-125 cm. Two colour morphs strikingly different: dark morph, common at S end of breeding range, uniformly sooty brown; heterozygotes, often called intermediates, are almost identical to dark morph, but with paler cheeks and often slightly paler belly; pale morph, commoner further N and almost 100% of population above 75° N, has cream underparts and hindneck, with straw yellow ear-coverts and side of neck, and may have a pale brown pectoral band. Pale morph is very variable and can be quite dusky: such birds are often called "intermediates", but are in fact still homozygous for the light morph allele. Adult plumage becomes barred through feather wear and when birds moult in autumn. Pale panels evident on underwing, but not very distinct on upperwing, at proximal parts of primaries, whereas in *S. longicaudus* both surfaces are uniform, and in *S. pomarinus* pale panels are obvious on both surfaces. Juveniles can be assigned to colour morph fairly accurately, dark birds having dark brown, brown and grey barred plumage, while pale morph juveniles have brown, golden brown and cream barring. Legs blue in juveniles, but darken to black by adult plumage, at three years old or more; central tail feather projection increases to adult age. Immature and juvenile differ from *S. pomarinus* in lighter build, smaller bill, less obvious barring, darker rump and less powerful flight.

Habitat. Marine, and predominantly coastal, in winter often aggregating at coastal sites such as estuaries frequented by large numbers of terns or small gulls. Not uncommonly migrates over land. Breeds on tundra or moorland or grassland, either in association with coastal seabird colonies where it can rob other species of food, or at low nesting densities on tundra where it can obtain food from the terrestrial ecosystem.

Food and Feeding. When nesting close to other seabird colonies, will obtain most or all of food by kleptoparasitism, especially stealing fish from Arctic Terns (*Sterna paradisaea*), Black-legged Kittiwakes (*Rissa tridactyla*), Atlantic Puffins (*Fratercula arctica*) and Black Guillemots (*Cepphus grylle*). In tundra habitats, microtine rodents are often not a major prey item, in contrast with *S. pomarinus* and *S. longicaudus*; adult and fledgling passerines, wader chicks, bird's eggs, insects and berries are all exploited. Present species appears to be less able to catch insects or to pounce onto lemmings (*Lemmus*) than *S. longicaudus*, and less able to dig out lemmings than *S. pomarinus*. In winter and on migration, present species often associates with aggregations of terns or small gulls, and feeds mainly by kleptoparasitism.

Breeding. Starts May or Jun, later in N than in S. Colonial at seabird sites or widely scattered over tundra; territorial. Nest scrape unlined and inconspicuous. Usually 2 eggs, but only 1 laid by some inexperienced birds; incubation 26-27 days; chick has dark brown down; leaves nest 1-2 days after hatching; fledging 26-30 days. Sexual maturity at 3+ years; adult survival 84 % (Shetland).

Movements. Mainly transequatorial migrant, with very small numbers wintering in Northern Hemisphere. Leaves breeding areas in Aug, and moves slowly S down coasts associating with small gulls and terns during passage. Some migration over land. Winters coastally, especially in Coral and Tasman Seas, and around Humboldt and Benguela Currents. Rapid northward migration in Apr-May. Some immatures remain in south.

Status and Conservation. Not globally threatened. The most numerous skua, with total population in 100,000's of pairs: 8000 pairs in Norway; 4000 pairs in Iceland; 1000-10,000 pairs in Greenland and Svalbard; 3350 pairs in Scotland; 1300 pairs in Faeroes; 10,000-100,000 pairs each in Alaska and Canada; and perhaps 100,000 pairs in Russia. These last three, the largest populations, are not censused, and estimates are very approximate. No evidence of significant changes in numbers or distribution, though clearly has increased in Scotland in the last 30 years. Human persecution is a very local problem in Scotland, Faeroes, Iceland and Scandinavia. Increasing numbers of *Catharacta skua* have displaced some colonies in Scotland. Arctic fox (*Alopex lagopus*) is major predator of eggs and chicks at higher latitudes, and Snowy Owls (*Nyctea scandiaca*) can also take many chicks.

7. Long-tailed Skua

Stercorarius longicaudus

French: Labbe à longue queue **German**: Falkenraubmöwe **Spanish**: Págalo Rabero
Other common names: Long-tailed Jaeger

Taxonomy. *Stercorarius longicaudus* Vieillot, 1819, northern Europe.
Individuals with plumage characteristics of *pallescens* occasionally occur in nominate race. Two subspecies recognized.

Subspecies and Distribution.
S. l. longicaudus Vieillot, 1819 - Arctic and subarctic uplands of Scandinavia and Russia E to delta of R Lena; winters in subantarctic and offshore S South America and S Africa.
S. l. pallescens Løppenthin, 1932 - Arctic Greenland, North America and Siberia E of delta of R Lena; winters in subantarctic and offshore S South America and S Africa.

Descriptive notes. 48-53 cm (including central tail streamers of up to 22 cm); 230-350 g; wingspan 105-117 cm. Smallest, most buoyant and graceful skua; extremely long tail, uniform dark underwing with only bases of innermost two primaries white at base, and greyish tinge to upperparts also distinctive. Wholly sooty grey dark morph, known only from Greenland, is extremely rare. Moult and wear create barring pattern to underparts and tail-coverts, and form a dark pectoral band so that winter plumage of adults (3 years or more) is much more similar to that of *S. parasiticus* than is breeding plumage, though most confusion occurs in identification of juveniles and immatures; key features of subadult *S. longicaudus* are agile flight, small bill and head, narrow wings and long tail, pale barred rump, and grey rather than brown coloration. Race *pallescens* has whiter underparts than nominate.

Habitat. Marine and highly pelagic, seldom occurring within sight of land except when breeding. Nests on Arctic and subarctic or montane tundra, up to 1300 m in Scandinavia. Prefers dry ground, often occurring further inland than *S. parasiticus*.

Food and Feeding. Mainly lemmings (*Lemmus*) during summer, caught by pouncing on them on the tundra surface, after hovering 10-20 m above ground. When microtine rodents are scarce, will take shrews, many insects, berries and small birds, including adult and fledgling passerines and shorebird chicks. Winter diet is largely unknown, but probably includes marine insects and fish, some scavenging and kleptoparasitism. Usually solitary feeder, though will share tearing up prey with mate.

Breeding. Starts Jun. Widely scattered over tundra, highly territorial. Nest scrape unlined and inconspicuous. Usually 2 eggs, but only 1 laid by some inexperienced birds, or when food in short supply; incubation 24 days; chick has light grey-brown down; leaves nest 1-2 days after hatching; fledging 24-27 days. Sexual maturity at 4+ years.

Movements. Transequatorial migrant, but highly pelagic so routes and winter distribution poorly known. Rare vagrant inland. Moves S in Aug-Oct, returning to Northern Hemisphere in Apr-May. Rarely seen during coastal seawatches except with strong onshore winds.

Status and Conservation. Not globally threatened. Total population probably many 10,000's or several 100,000's of pairs. At least 13,000 pairs in Europe; 10,000 in Sweden, several thousand in Greenland and Norway, 1000 in Finland; at least several 10,000's of pairs each in Russia, Alaska and Canada. No evidence of any changes in numbers or distribution, but more information on populations required. Arctic fox (*Alopex lagopus*) is a major predator of eggs and young. Breeding success is closely linked with lemming abundance.

Class AVES

Order CHARADRIIFORMES

Suborder LARI

Family LARIDAE (GULLS)

- Fairly small to large, heavy-bodied, long-winged seabirds, with stout bill, webbed feet and generally rounded tail; most species white below with pale grey to black back and wings, some with dark hood when breeding.
- 25-79 cm.

- Cosmopolitan.
- Mainly coastal, but also inland in wide variety of habitats, typically near water.
- 7 genera, 51 species, 78 taxa.
- 5 species threatened; none extinct since 1600.

Systematics

The gulls (Laridae) form a worldwide family of about 50 species, with greatest diversity in temperate latitudes of both the north and the south. Herein, the gulls and the terns (Sternidae) are considered to form distinct families, as are the skuas (Stercorariidae) and the skimmers (Rynchopidae). The division of all these taxa into four separate families was suggested by J. Dwight in 1925, but since then many authorities have preferred to combine gulls and terns as subfamilies (Larinae, Sterninae) of the Laridae, or even as tribes (Larini, Sternini) of a much expanded family that also includes the skuas and the skimmers, even though such treatments tend to obscure the obviously close relationships between species within each of the four taxa. Nevertheless, all authors agree that there are four distinct groups, and these differing treatments simply reflect individual perceptions of the degrees of differentiation that may warrant familial status, or a rigorous attempt to match the taxonomic hierarchy to evolved differences in DNA. Although gulls and terns are similar in many respects, they also exhibit significant morphological and ecological differences which probably warrant their treatment as separate families; the skuas and the skimmers are generally agreed to be more distinct.

In most parts of the world, the fossil record of gulls is meagre. Gulls are believed to have diverged from other charadriiform groups as early as the Paleocene, but the earliest gull-like fossils found so far date to the Oligocene. *Halcyornis toliapicus* of the Upper Paleocene, although long thought to have been a gull, is no longer considered so. The fossil species *Rupelornis definitus* of the Middle Oligocene, about 30 million years ago, was described on the basis of a tibiotarsus from the Repelian Sands of Belgium. While it may indeed be a gull, the first true gulls come from the Lower Miocene, with both *Larus elegans* and *Larus totanoides* very common in the Aquitanian Formation in France. The most interesting species from this period is the unique *Gaviota niobrara* from Nebraska, USA. The Pliocene gravel of Florida yielded a right humerus of a species that was named *Larus elmorei*.

Several paleospecies and modern species are known from the Pleistocene, less than 2 million years ago, including a rich representation from the Fossil Lake Formation of Oregon, USA. Both the Mew Gull (*Larus canus*) and the Herring Gull (*Larus argentatus*) are known from the Pleistocene, only in Europe, and appear in recent deposits and middens in the Western Hemisphere, perhaps indicating a spread eastwards from Asia through Alaska. At least nine neospecies are known from the Pleistocene and 13 from the post-Pleistocene, especially from Alaska. The dearth of fossils from eastern North America, Australia and New Zealand may reflect the overall poor fossil fauna, rather than a relatively recent invasion by gulls.

Various researchers have used different criteria, such as behavioural, anatomical and biochemical characteristics, to examine relationships between gulls and the closely related families Sternidae, Rynchopidae and Stercorariidae. J. Dwight recognized several natural subgroups among the gulls, most species of which he assigned either to the large white-headed tribe or the small dark-hooded tribe. He classified the gulls in nine genera, whereas M. Moynihan, on behavioural grounds and emphasizing the commonality of display patterns, placed all gulls in the genus *Larus*. Others have recognized from five to 12 genera.

Apart from the unique Swallow-tailed Gull (*Creagrus furcatus*) of the Galapagos, the other species usually placed in separate genera are the high Arctic Ross's Gull (*Rhodostethia rosea*), Ivory Gull (*Pagophila eburnea*) and Sabine's Gull (*Xema sabini*), plus the two kittiwakes (*Rissa*). Less often separated are the south temperate Pacific Gull (*Larus pacificus*) and Dolphin Gull (*Leucophaeus scoresbii*), both of which have sometimes been placed in *Gabianus*; on a combination of behavioural and plumage characteristics, it seems appropriate to retain monotypic *Leucophaeus*, but not *Gabianus* which is distinguished essentially by its stout bill. Of all, the Swallow-tailed and Ivory Gulls show the greatest divergence in behaviour, plumage and soft part colours, and the most marked breeding adaptations.

Among the "hooded gulls", three primarily Central Asian species are of uncertain relationships. The Mediterranean Gull (*Larus melanocephalus*) has unique variations of display, the Relict Gull (*Larus relictus*) has display patterns similar to those of some primitive "white-headed gulls", and the Great Black-headed Gull (*Larus ichthyaetus*) differs from the rest in size and bill colour.

Among the "white-headed gulls", excluding Audouin's (*Larus audouinii*) and the Slender-billed (*Larus genei*), there is a remarkable uniformity in behaviour and in bill colour, the latter being yellow with a red gonydeal spot. The Herring Gull complex includes its close relatives the Lesser Black-backed (*Larus fuscus*), Slaty-backed (*Larus schistisagus*), Armenian (*Larus armenicus*) and Yellow-legged Gulls (*Larus cachinnans*), as well as nine others; the Mew or Common Gull and the Ring-billed

Gull (*Larus delawarensis*) are more distantly related. Probably no group of birds has done more to challenge the biological species concept than the Herring Gull and its relatives. For more than 70 years, systematists have applied different approaches to understanding relationships, mainly among the Herring, Lesser Black-backed and Yellow-legged Gulls, but inevitably extending to include Iceland (*Larus glaucoides*), Thayer's (*Larus thayeri*), Glaucous-winged Gulls (*Larus glaucescens*), and virtually all of the large white-headed species. One study shows that Herring and Yellow-legged Gulls do not interbreed in France, but do so comfortably in other parts of Europe, while another reveals that their genetic distance is equivalent to that between most gull species, and indeed that Yellow-legged is closer to Lesser Black-backed than to Herring. There is no entirely satisfactory and definitive relationship that can describe their mosaic evolution.

While species limits among many species pairs in the Herring Gull complex are controversial, two taxa have been particularly troublesome. The Asiatic form *heuglini* has variously been assigned to the Herring Gull or the Lesser Black-backed Gull; it is here treated as a race of the latter, but additional studies may reveal that it deserves elevation to species status. The high Arctic *thayeri* has likewise been assigned to either the Herring or the Iceland Gull, but has recently been treated as a full species. Several authors have recommended that it again be treated as a subspecies of the Iceland Gull, based on mixed pairs of *thayeri* x *L. g. kumlieni* observed at one site, and considerable plumage variation; very few intermediate or "hybrid" birds were found at the site, however, and one could equally argue that this shows post-mating isolation. Hybridization between Thayer's Gull and this race, known as Kumlien's Gull, is probably no greater than that between Herring and Glaucous Gulls (*Larus hyperboreus*) in Alaska or between Western (*Larus occidentalis*) and Glaucous-winged Gulls in the north-west USA. It, therefore, seems best to retain Thayer's Gull as a full species, pending further study in this contact zone.

Several radiations in the evolution of gulls can be identified. An early radiation may have arisen in Central Asia, where certain primitive species still occur. More recent radiations have involved the Herring Gull types which have diversified separately and relatively recently at temperate latitudes and in the Arctic, and an American radiation of hooded gulls producing Laughing (*Larus atricilla*) and Franklin's Gulls (*Larus pipixcan*). In the Southern Hemisphere, speciation has been slower. The Kelp Gull (*Larus dominicanus*), present on all southern continents, has differentiated so little that many authors consider it monotypic. The Australian Silver Gull (*Larus novaehollandiae*) is represented in New Zealand by the Red-billed Gull (*Larus scopulinus*) and in southern Africa by Hartlaub's Gull (*Larus hartlaubii*), and many authors still treat these three as a single species. Similarly, the Grey-headed Gull (*Larus cirrocephalus*) occurs in both South America and Africa, where it has differentiated only at the subspecies level.

In general, the genus *Larus* comprises two main groups: the large, white-headed gulls and the small, dark-hooded gulls, the latter including the so-called "masked" gulls. They differ not only in appearance, but also in behaviour. Nevertheless, the Sooty (*Larus hemprichii*) and White-eyed Gulls (*Larus leucophthalmus*) of the northern Indian Ocean and Middle East show behaviour like that of the white-headed gulls, despite their dark heads. Conversely, the Slender-billed, Hartlaub's, Silver, Red-billed and Black-billed Gulls (*Larus bulleri*) are, in terms of behaviour, "hooded" gulls without hoods.

Both M. Moynihan and N. Tinbergen provided classifications of the gulls based on behaviour, arguing that displays, being less directly adaptive to the external environment, are not so likely to show evolutionary convergence as are morphological features. Moynihan assigned all but the Ivory Gull to either the hooded or the white-headed groups, with the former group further divided into several subgroups. Primitive hooded gulls are mostly moderate-sized, with the bill either light or heavy and usually reddish, and they have a black or brown hood; these birds

The taxonomy of the large gulls has long been the focus of much debate, never more so than in recent decades. The Herring Gull (Larus argentatus) *complex has been the cause of heated argument among taxonomists, some of whom still maintain that the Armenian Gull is no more than a subspecies of the Herring Gull. The more popular view nowadays is that it is in fact a distinct species, but research may yet modify this approach when more is known about other gulls in this complex of forms.*

[*Larus armenicus*, Israel. Photo: Roger Tidman/ NHPA]

have elaborate hostile and courtship repertoires. Some have quite restricted and possibly relict ranges in the tropics.

Morphological Aspects

Gulls are rather uniform in shape, with heavy bodies, long wings, medium-length necks, moderately long tarsi, and fully webbed feet. They have 11 primaries, the outermost vestigial, and 12 rectrices. The tail is slightly rounded in all but Sabine's and the Swallow-tailed Gulls, in which it is forked, and Ross's Gull, which has a strongly wedge-shaped tail.

The bill is generally stout and slightly hooked, but there are variations. The larger-bodied gulls have a larger, thicker bill with a marked gonydeal angle, and they use this stout, hooked instrument to pry open shells. The smaller species have a thinner, more delicate and more pointed bill, with a less pronounced gonydeal angle, the smaller bill reflecting their smaller food items. Bill colour is an important variable among gulls. Most of the white-headed gulls, such as the Herring Gull, have a yellow bill, often with a bright red dot on the mandible that is used by young chicks as a stimulus to initiate feeding. Many of the hooded gulls have the bill bright red, dark red or black.

The wings are long, moderately broad, and slightly rounded. Again, there are differences among species, but in general the larger gulls have more rounded wings, while the smaller species have proportionately longer wings, producing a lighter flight with much more manoeuvrability. The legs are longer than those of terns, and the feet are webbed.

In most aspects gulls are generalists. Among seabirds they are the least specialized with regard to foraging method, food type, or nesting habitat, and are adapted to occupy a variety of habitats from the high Arctic and Antarctica to sea coasts and interior deserts. They are also more agile on land than most other seabirds. Their generalized body shape makes them equally adept at flying, walking and swimming. Most species walk with a slight side-to-side movement, which is often exaggerated for display purposes. Gulls can hover over objects, or duck under them. The smaller gulls are more manoeuvrable on the ground, and are able to avoid moving objects more readily than the larger gulls; at rubbish dumps, they are able to walk much closer to moving bulldozers while obtaining food, whereas the less agile larger species can sometimes be buried by moving refuse. All species can perch on objects, the size of the perch depending on the size and weight of the gull: smaller species, such as Franklin's and Little Gulls (*Larus minutus*), will perch on wires and thin vegetation, while the larger species perch more on posts, tree branches and boats. All gulls swim well, bathe frequently, and alight on the water without hesitation. They can land in small patches of open water, and require only a little space in which to take off.

Gulls range in weight from as little as 100 g in the case of the Little Gull to over 2000 g in the Great Black-backed Gull (*Larus marinus*). They exhibit no sexual dimorphism in plumage patterns, but females are slightly smaller than males, which in some species show a heavier, thicker neck and bill. Males are presumably larger because they defend the territories and engage in high levels of aggression. In general, within any of the major groups of gulls, the larger species live in the colder zones and the smaller ones in more temperate and tropical regions.

Gulls are generally white-bodied, with a darker mantle varying from pale silvery grey to black; the sole exception is the all-white Ivory Gull. During the breeding season they have either a dark hood, which can be rather obscure in some species, or an all-white head. In non-breeding plumage, the hood is lost or replaced by a variable dark ear-spot, while many white-headed species then have a streaked head. The wingtips of almost all species are black, offering resistance to wear, but they have a complex pattern of white "windows" and "mirrors" on the black

A distinctive feature of several gulls in breeding plumage is the dark hood, often with prominent white eye-crescents and a red bill. It is not unusual for some species to breed while still not fully adult. This second-summer Mediterranean Gull, identical to an adult apart from the black on its wings, is displaying to a first-summer bird, which has only a few dark markings on its head and some patches of greyish brown on its wing-coverts.

[*Larus melanocephalus*, near Tuz Gölü, Turkey. Photo: Alfred Limbrunner]

primaries which may differ among closely related species, and are of diagnostic importance.

Among the hooded gulls, some, for example the White-eyed, Sooty, Laughing, Franklin's, Lava (*Larus fuliginosus*), Great Black-headed and Mediterranean Gulls, have a complete dark hood which extends down the nape, with white crescents above and below the eyes. On others, such as Bonaparte's (*Larus philadelphia*), Common Black-headed (*Larus ridibundus*), Grey-headed, Andean (*Larus serranus*), Brown-headed (*Larus brunnicephalus*) and Brown-hooded (*Larus maculipennis*), the black, grey or brown covers the face and the top of the head, but not the back of the head or neck. Swallow-tailed and Sabine's Gulls have a complete hood, but without white "eyebrows". Heermann's Gull (*Larus heermanni*) and the Grey Gull (*Larus modestus*) have a white hood in nuptial plumage, contrasting with the dark neck and body. The Black-billed Gull has only the hint of a mask remaining.

Juvenile plumage is generally brown, with buff or black speckles produced by pale or dark tips to most contour feathers, and with the flight-feathers brownish black. After 2-4 months, the young birds moult into a first-winter plumage. This may resemble the juvenile or the adult plumage; in the latter case it is usually mottled with brown, and includes unmarked, brownish black primaries and a black tail band.

Gulls vary in their plumage cycles. The smaller hooded gulls reach adult plumage in two years, while the larger species have 3-4 distinct plumage classes and may not acquire full adult plumage until their fifth year.

Adults have one complete moult annually, starting immediately after the breeding season in most species and after migration in a few. Sabine's Gull, however, moults completely before breeding; at this time most species have only a partial moult, involving the head and some of the body. Franklin's Gull is the exception, with two complete moults each year. This may be because it migrates farther than any other gull, from the northern prairie regions of North America to southern South America, although Sabine's Gull migrates nearly as far.

Albinism and leucism are reported frequently among gulls. These conditions, however, are not only difficult to detect in birds that are largely white, but also pose problems in identification: white Herring Gulls could easily be confused with Glaucous Gulls, while leucistic individuals of any of the small gulls might be confused with the Ivory Gull at a distance. The proportion of leucistic birds is certainly very small, much less than 0·001%, but, owing to the abundance of gulls in many places, such birds are reported occasionally. On the other hand, melanism is inexplicably rare, with only one published record, involving a Bonaparte's Gull.

Overall, adult gulls exhibit the general pattern of seabirds that feed on underwater prey from above the surface. The white ventral coloration presumably functions as camouflage against the pale sky. Moreover, white adult gulls gathering over food are more visible to distant conspecifics, and this is believed to function in social attraction to favourable feeding areas. Like terns, gulls also have a relatively high percentage of orange and red oil droplets in their eyes, which allows them to see long distances through the atmospheric haze that often occurs over estuaries and over the ocean. They can therefore see the white of active gulls from a long way off, and can join foraging groups following ships or feeding over schools of fish. In many species, the dark-plumaged juveniles and immatures are generally less adept at diving, and employ this feeding strategy less often than adult gulls.

Gulls have functioning salt glands which enable them to live in marine habitats. Those of young birds are activated by exposure to salt loading. In Franklin's Gulls nesting in interior prairie regions, however, the salt gland is small during their months on their freshwater breeding grounds, but enlarges and begins to

All gulls are heavy-bodied and long-winged, and have fully webbed feet. The larger-bodied species have a particularly strong bill with the gonydeal angle usually well marked. The colour and pattern of the bill are often important as a distinction between species, but they change seasonally to a variable degree. Many gulls have black or blackish wingtips with a characteristic and diagnostic pattern of white marks towards the tips of the primaries. The Sooty Gull, however, has all-dark wings, but for a white trailing edge.

[*Larus hemprichii*, Shinzi Island, Oman. Photo: Hanne & Jens Eriksen/Aquila]

Gulls need to adapt quickly to changing conditions of temperature and precipitation. For some, such as Western Gulls breeding on the southern Californian coast, thermoregulation in extremely hot weather is a constant problem. One of the ways of cooling off involves opening the mouth wide so that the heat escapes through evaporation. In some Western Gull colonies, nests are arranged linearly along the water's edge, so that all colony members can easily visit the water. As well as cooling themselves, they also wet their breast feathers in order to cool their eggs. The wide open gape of some birds with brightly coloured mouths, notably some seabirds, may be used as a threat signal.

[*Larus occidentalis wymani*, California. Photo: A. & E. Morris/ Birds As Art]

function in early October, before they have reached salt water on their migration to the Pacific. Thus, the salt glands are turned on by external factors, perhaps decreasing light or hormone levels, rather than a change in salt loading.

Gulls living on salt-lakes, such as Mono Lake, where the salt concentration is 2½ times that of sea water, require special behavioural adaptations to handle the salt load. California Gulls (*Larus californicus*), for example, take in very little lake water with their invertebrate food; they visit freshwater sources along the shore, and feed on prey with dilute body fluids and high body-water content.

Habitat

Gulls occur throughout the world, and breed on all continents, including the margins of Antarctica, where the Kelp Gull nests, and the very high Arctic, the breeding grounds of the Ivory Gull. Most species typically occur around sea-level, but the Andean Gull is regularly found above 4000 m in the high Andes, where it ranges up to about 5300 m.

Habitat preferences vary widely, during both the breeding and non-breeding seasons. Gull colonies can be found in coastal or inland habitats, the birds showing a strong preference for islands. A few species, such as the Brown-hooded and Franklin's, nest mainly on inland lakes or marshes, whereas Lava and Swallow-tailed Gulls nest on remote oceanic islands. On migration, gulls usually travel directly to coastal and estuarine habitats, although they may do so in leisurely fashion, and regularly travel overland. During winter, they generally remain along coasts or at larger inland lakes, but some species can be found as far out as the edge of the continental shelf and others regularly feed on inland fields far from water.

Nesting gulls occupy a greater variety of habitats than most other colonial species. They utilize sandy or rocky islets or beaches, with or without vegetation, sandbars on rivers or lakes, wind-swept sand dunes and steep cliffs, coastal and inland marshes, trees, and even built-up areas. One species, the Grey Gull, breeds in the interior montane deserts of Chile, far from water. More than 40 species sometimes or always nest on the ground. Although most colonies are generally located in places secure from mammalian predators, some are in terrestrial habitats exposed to predation. Roof-nesting is now regularly reported for a number of species, including Herring, Yellow-legged, Great Black-backed and Mew Gulls and Black-legged Kittiwakes (*Rissa tridactyla*), and, less often, in Hartlaub's and Kelp Gulls.

Some gulls are specialists, nesting only in one habitat. These include Franklin's and Brown-hooded Gulls, which nest almost exclusively in marshes, the other regular marsh-nesters being Grey-headed, Common Black-headed, Mediterranean, Laughing and Little Gulls. Kittiwakes nest only on cliff ledges, although increasing numbers are now turning to ledges of buildings, while Bonaparte's Gulls normally nest in trees. Other species are generalists, using nearly all the possible habitat types. Herring Gulls nest on the ground on sand or gravel, or among rocks, but they also nest on cliffs, in trees, and even on buildings; during their expansion southwards into New Jersey, USA, in the early 1950's, they adapted to nesting on the higher areas of salt-marsh rather than on rocky or sandy islands. Mew Gulls nest in a variety of different marsh and dryland colonies, and Kelp Gulls in southern Africa nest on sandy cliffs, sand dunes, rocky or grassy islands, and rock ledges. In general, the large species are more habitat generalists than the small ones.

N. Tinbergen proposed that the ancestral gull was a ground-nesting species, and that all other nesting habits evolved from this generalized larid form. In terms of displays and vocalizations, however, the most primitive gulls are the small hooded gulls, and several of these are primarily marsh-nesting.

The distribution of gulls during the non-breeding season is controlled largely by food availability, and, since gulls eat a wide variety of foods, they can be found in nearly all aquatic habitats at virtually all ice-free latitudes. Even some high latitude species, including the Ivory and Ross's Gulls, move only far enough to find open water, although Sabine's Gull is a transequatorial migrant, like the prairie-nesting Franklin's Gull. Open fields in lowland areas are regularly used for feeding by, among others, the Common Black-headed Gull, which is one of several species, such as the Silver Gull, that commonly frequent urban areas. A large number of species, in particular the Herring Gull and its close relatives, also visit rubbish dumps.

General Habits

Gulls are highly gregarious birds that breed, roost, feed and migrate in groups, often of thousands. Generally, they are diurnal, performing most of their breeding and foraging activities during the day. The only species that are primarily nocturnal during the breeding season are the Swallow-tailed and Grey Gulls. Both members of a Swallow-tailed Gull pair spend the daytime at the nest-site, sleeping or preening, courting or sharing in incubation; they leave at night to feed at sea, returning to feed the chick before or shortly after dawn. They have large, specially adapted eyes to facilitate nocturnal feeding.

Although gulls are mostly diurnal, several species are known to fly and feed on moonlit nights or under artificial light. This behaviour has seldom been studied, but gulls seem to be more active at night during the breeding season, when the constraints of incubation impose additional feeding pressures, than during the non-breeding season. Except on bright moonlit nights, however, gull colonies are remarkably quiet after dark.

Many colony sites have been in use for many years, or even centuries. Once individual gulls have started to breed, they will return to the same colony, and even to the same nesting territory, for many seasons; many will do so throughout life, unless social or environmental conditions change, or they are unsuccessful because of predation, weather, flooding or human disturbance. The Common Black-headed Gull colony at Ravenglass, England, has been occupied since the 1600's, and some Black-legged Kittiwake colonies for more than a century. Records for these colonies are available only because their eggs have been har-

Their great adaptability has enabled the gulls to conquer virtually all of the world's varied habitats. They frequently nest beside water, but also far from it, and even in dry deserts. Some have adapted to built-up areas, while others breed in places remote from human civilization. The Glaucous Gull is one of a number of species with populations breeding mainly or solely in the high Arctic, far removed from the dangers of man, though it often seeks out human settlements, or colonies of geese or other gulls. With its varied diet, so typical of the Laridae, it has no problem in raising its young in these inhospitable parts of the Northern Hemisphere. Many gulls remain in this bitterly cold climate throughout the winter, but others move varying distances southwards. The extremes in habitat preferences within the gull family, between the species inhabiting the polar regions and those nesting in hot, dry steppe or montane desert, are quite extraordinary.

[*Larus hyperboreus hyperboreus*, Monaco Glacier, Liefdefjord, Spitsbergen, Svalbard. Photo: Tui De Roy/ Auscape]

During the day, gulls often sit around in large or small groups, preening, resting or just watching the scenery, waiting for the tide to turn before they resume feeding, or simply conserving their energy. Gulls living in high latitudes, such as Red-legged Kittiwakes, cope with the cold partly by reducing the levels of their activity, and hence minimizing their energy expenditure. During the non-breeding season, most gull species form flocks, the size of which depends on the species and the activity.

[*Rissa brevirostris*, St George, Pribilof Islands, Alaska. Photo: Richard Coomber/ Planet Earth]

vested by humans over this period, and it was important for local inhabitants to track the timing of egg-laying, population levels and productivity.

Since most gulls breed in temperate or Arctic regions, where conditions may shift quickly from hot and sunny to cold and rainy, parental care and chick behaviour must be adapted to these extremes. For some, however, such as Grey Gulls breeding in Chile or Western Gulls on the southern Californian coast, thermoregulation in extreme heat is the main problem. Some Western Gulls even nest in linear colonies along the water's edge, allowing all colony members access to water, which they visit periodically to cool themselves, and to wet their breast feathers so as to be able to cool their eggs. Further observations of some little studied Asian species may show similar patterns.

Grey Gulls experience the most extreme thermal conditions of any gull. They nest in deserts where there is no rain for many years, and hence no fresh water. This imposes severe constraints, for they must travel 30-100 km to reach the coast. The gulls maintain temporary courting territories on the coast in order to avoid extensive courtship activities at their inland territories. Grey Gulls are partly nocturnal, at least in the early stages of the breeding cycle, when they can perform functions such as courtship, copulation and territorial aggression at night. Once incubation begins, they shade their eggs during the hottest part of the day, and they exchange incubation duties only once every 24 hours, usually at night. Most chick feeding also occurs at night, when the off-duty adult arrives from the coast. The dark pigmentation of the feathers may be an adaptation to avoid excessive heat loading from solar radiation, by allowing the outer surface to absorb heat, and then to lose it by convection during the winds of the late afternoon.

Extreme cold stress is faced by Kelp Gulls breeding in Antarctica and by Ivory Gulls at the other end of the globe. They cope with the cold partly by remaining relatively inactive on their territories during most of the breeding cycle. Presumably, their time budget allows the gulls to reduce energy expenditure, while providing protection for the eggs and chicks.

During the non-breeding season, gulls tend to rest, forage and roost in groups, the size of which depends on the species and the activity. Franklin's Gull migrates and overwinters in flocks of up to a million birds, as recorded during migration through the central and southern USA, and in the boreal winter along the Peruvian coasts. In general, the smaller species form larger and denser passage and wintering flocks than the larger species.

Voice

Most gulls are noisy during most of their activities, including breeding, feeding and migration. Only when alone, in small groups, or flying determinedly, are they silent. A few species such as the Andean Gull are quite silent when breeding, presumably to avoid attracting predators. Being highly social birds, gulls have well developed systems of communication, involving both visual and vocal displays. There are notable differences in voice at both the interspecific and intraspecific levels, yet there are many homologous vocalizations among those species that have been studied. In general, gulls have a remarkable diversity of threat displays and vocalizations, with a relatively low number of calls and displays used in non-aggressive situations.

Most calls are variations of harsh croaking and screaming notes. The majority of species utter a variant of "kek-kek" when alarmed at the colony, and a harsh, loud scream when threatening an intruder at the colony or on the feeding grounds. Long calls and mewing notes are characteristic of many species.

Gulls have a number of generalized calls. Contact calls, often a variant of "kek-kek", are used between separated individu-

als. Food calls are given when a new food source is discovered. Alarm calls warn off conspecifics or perhaps threaten intruders. Long calls are used in a variety of aggressive, courtship and other family interactions. In addition, various other calls are uttered primarily during courtship or at the breeding colonies. Some species, such as the Black-billed Gull, will give a contact call when they leave the colony, the function in this case being to attract other gulls to follow them; this is believed to allow unsuccessful foragers to find food by accompanying successful individuals (see Food and Feeding).

During courtship and pair-bond maintenance, and while nesting, gulls give a number of calls that usually accompany ritualized visual displays. Long calls are used in a variety of situations, such as soliciting a mate, calling the mate or chicks, soliciting courtship feeding, and defending the territory. The most familiar of gull calls, in some species it is termed a "Laughing Call" and originally gave rise to the vernacular name Laughing Gull, and the scientific names *ridibundus* and *cachinnans*. It begins with a short "kah" note, followed by a series of high-pitched and then descending long "keaaaah" notes, and then by a series of shorter "Head-toss Calls", usually as the bird raises its head and points its bill skywards or even backwards over its shoulder. For some species, the long call does not end with head-toss notes.

The "Landing Call" resembles the long call, but has a shorter series of notes. It is given when a gull lands at its nest or at a temporary territory, such as a pier or rock used for courting. When an approaching bird gives a landing call, the mate sometimes responds with a long call, a head-toss call or a "Mew Call". This last call is one of several vocalizations used during the breeding season. The mew call, or "Crooning", is given in courtship, during chick feeding, or at nest-relief. "Choking" is a call given to mates during courtship or when showing a potential nest-site, and the copulation call is a series of short "ka-ka-ka-ka" notes that accompanies copulation and "Wing-flagging". Some species give a "Charge-call" during rapid "Swoop-and-soar" aerial displays, aimed at driving off intruders.

Although not all calls given to mates are individually recognizable, many are, including the long call, mew call and landing call. Individual distinctiveness, which can be demonstrated by sound spectrographs, allows mates and neighbours, and parents and chicks, to recognize each other. Gulls learn the calls of their neighbours at the breeding colony, reducing the need for overt territorial defence. Chicks also learn to recognize the calls of their parents, usually from the time they begin to wander from the nest.

Food and Feeding

More than any other group of seabirds, gulls exploit a wide variety of food types, and have evolved highly diversified foraging methods and habitats. This is demonstrated both in the family as a whole and within each species, and at all times of the year. There is no gull species that is specialized to feed on just one food source, using only one method, in only one habitat, although the little known Olrog's Gull (*Larus atlanticus*) does specialize on crabs in the intertidal zone. At any one locality, however, a single food type may dominate the diet in most years, or for a period of weeks: for example, euphausiid shrimps in the case of breeding Red-billed and wintering Bonaparte's Gulls, and mole crabs (*Eremita analoga*) for Grey Gulls.

Gulls are thus adaptable, opportunistic and omnivorous. They take living, moribund or dead fish and invertebrates from the water, intertidal zone or shoreline, and arthropods, rodents, eggs and chicks of birds, amphibians and reptiles on land. They also scavenge for offal, carrion and refuse, as well as feeding on sewage items and marine mammal prey, placentae and dung, and they can be aggressive predators and pirates. Great Black-backed Gulls will even kill and eat adult seabirds, such as Manx Shearwaters (*Puffinus puffinus*) and Atlantic Puffins (*Fratercula arctica*). Not only does their diet cover a wide variety of animal organisms, such as insects, squid, crustaceans, molluscs, earthworms, small mammals, fish and so on, but it also includes seeds and fruits. Indigestible material is regurgitated as pellets.

More seeds, fruits, insects, earthworms and small mammals are consumed during the breeding season than at other times of

Almost all gulls are essentially diurnal, but there are two major exceptions. The Grey Gull is one of these. Its breeding habitat is in the arid, rainless Chilean desert, devoid of any freshwater sources, and subjecting it to the most intense thermal conditions of any gull. It must therefore travel up to 100 km to reach the coast, where individuals maintain temporary courting territories. In this way it avoids energy-sapping courtship activities in the harsh climate of its inland nesting territories, although some courtship takes place at the breeding site at night, when temperatures are much cooler.

[*Larus modestus*, near La Serena, Chile. Photo: Günter Ziesler]

the year. Seeds and fruit are not preferred food items, but are usually eaten when superabundant or when other foods are scarce. Franklin's Gulls will eat sunflower seeds and other grain when they arrive at the snow-covered breeding grounds in early spring, before insects become active; Ring-billed Gulls will feed on dates and other fruits; and Herring Gulls will eat grain, grasses and berries. Being highly opportunistic, gulls will make extensive use of food that suddenly becomes available, such as the multitudes of pelagic red crabs (*Pleuroncodes planipes*) that are sometimes stranded on Pacific coast beaches during occurrences of El Niño (see Volume 1, page 341).

In the non-breeding season, gulls spend more time on large bodies of water, along coasts or on the open ocean, resulting in an increase in the presence of fish and marine invertebrates in their diet. Some species also increase their use of human refuse dramatically during this season, feeding almost exclusively on refuse from landfills or offal from fishing vessels. Landfills provide a dependable, though less nutritious, food source at all times of the year.

Gulls forage in a wide range of natural habitats, including the open ocean, the surf zone, intertidal mudflats, rocks and jetties, estuaries, bays, harbours, lakes, reservoirs and rivers, wet meadows and farm fields. They are an integral part of coastal and estuarine habitats, and many species are particularly characteristic of the intertidal zone.

For many people, however, the most familiar feeding habitats are man-influenced sites, such as landfills and rubbish dumps, sewage outfalls, city parks, picnic sites and fish-processing plants, and also behind boats and ploughs. In populated areas, many species become habituated to human beings and approach them for "hand-outs". In general, the habitat used for foraging by any species of gull depends on what is available, and most species use a variety of habitats opportunistically throughout the year.

Gulls feed by a variety of methods, on items obtained from the air, water and land, as well as by piracy. They capture insects in the air by flying in circles at sites where there are recent insect emergences, often over water or wet fields. The hooded gulls that nest in marshes or over inland lakes and rivers specialize in aerial hawking for insects. In the early spring, when the first large emergences of midges (Chironomidae) occur, big flocks of Franklin's and Brown-hooded Gulls fly gracefully above the water through dense swarms of insects, or glide along the surface, snatching them as they emerge; they thus gather enough food to courtship-feed mates or to provision young chicks. When winged ants emerge on sultry days in summer, Common Black-headed Gulls regularly soar high up among these insects, snatching them from the air. The intermediate-sized gulls, such as the Ring-billed, will also hawk for insects, but the larger species seldom do so.

From an aerial position, gulls also pluck food items from the surface of water or land, or plunge-dive. They will also swim on the water to pick up items, or dip into the water to snare them. Surface-seizing involves grasping individual prey while on the water. Some species even foot-paddle to stir up invertebrates just below the surface, or swim in tight circles, almost like phalaropes (*Phalaropus*), to pick up swimming arthropods or small fish. When dipping, gulls pick up prey from just above or just below the surface while in flight. The smaller gulls, more buoyant in flight and considerably more manoeuvrable than the larger species, frequently hover-dip over schools of small fish. In high winds, feeding over water becomes impossible.

The small and intermediate-sized gulls engage in foot-paddling when feeding in shallow water. This behaviour is particularly common among Franklin's, Bonaparte's and Laughing Gulls. Franklin's Gulls food-paddle in shallow water to "scare up" small aquatic insects; Bonaparte's in shallow bays, estuaries and the edges of the Great Lakes to draw up small fish; and Laughing Gulls in estuaries and bays when feeding on small insects, small fish, or the eggs of horseshoe crabs (*Limulus polyphemus*). Mew and Herring Gulls, and no doubt some other species, occasionally foot-paddle on inland fields, presumably to bring earthworms to the surface.

Gulls also walk on the ground, picking up live food items or scavenging along the shore. They sometimes obtain food by digging in the sand or mud, or among rubbish. Along the Peruvian shore, Grey Gulls probe the wet sand behind retreating waves for mole crabs. In total, over half of the foraging done by gulls

Despite their general adaptability, gulls are nevertheless also creatures of habit. Many return to traditional colony locations year after year, some colonies having been in existence for hundreds of years. Each spring, at the start of the breeding season, most of the world population of Heermann's Gull arrives at the same island in the northern Gulf of California; this pair is indulging in a somewhat frenzied bout of courtship feeding. Following breeding, this species loses the striking white plumage of its head, which then becomes more uniform in colour with the rest of its body plumage.

[*Larus heermanni*, Baja California, Mexico. Photo: Ramón Torres Valdivia]

At its breeding sites, the remarkable Swallow-tailed Gull is almost entirely nocturnal in behaviour. Both pair members remain at the nest-site during the day, sharing incubation duties. At night the non-incubating adult flies out to sea to forage for the abundant squid that are one of its preferred foods; since the bird does not return until around dawn, the single chick has a long wait before it receives a feed. The species' abnormally large eyes betray its nocturnal habits. Apart from its behaviour and breeding adaptations, this gull is also unique in several other aspects, including its plumage and bare-part features. Once fledged, the young do not return to their natal colony to breed.

[*Creagrus furcatus*, Galapagos. Photo: Hans Reinhard/ Bruce Coleman]

takes place on the ground. The smaller species, however, tend to be more aerial in their foraging methods than the larger gulls, both during and outside the breeding season.

One foraging method almost unique to gulls is the dropping of hard-shelled items onto hard surfaces to break them open. Even with their strong bills, gulls can not open certain prey such as clams and mussels. They solve this problem by rising vertically in the air to 10 m or more, and then dropping the shell on to a surface such as rocks, a road or car park, a jetty, driftwood, an abandoned boat, or a beach-house roof. Gulls which indulge in this habit include Kelp, Mew, Herring, Glaucous-winged and Western Gulls. Age-related differences exist, and young gulls must learn which food items to drop, where to drop them, and from what height.

Some species of gulls frequently engage in piracy from their own or other species, and this can be an important foraging method, particularly during the breeding season. At breeding colonies, piracy can be the end result of an aerial chase, or involve the stealing of food from other adults that are feeding chicks, or from chicks that are trying to swallow large food items. Large chicks will even try to pirate food from smaller neighbouring chicks, making it particularly important for parents to feed their chicks items that they can swallow quickly and easily. For some species, such as Audouin's Gull, kleptoparasitic attacks, in this case by adult Yellow-legged Gulls, are the most frequent kind of disturbance at colonies. Several species, including Laughing and Common Black-headed Gulls, sometimes engage in piracy at terneries. Both the Laughing Gull in the Caribbean and Heermann's Gull on the Pacific coast specialize in piracy on Brown Pelicans (*Pelecanus occidentalis*): they land on or near a pelican surfacing after a dive, and wait to snatch escaping food items as the pelican empties water from its bill.

Piracy also occurs in the non-breeding season: over schools of fish, behind boats, at garbage dumps, and at other sites where there are dense flocks of gulls and abundant food. This foraging method is often more prevalent among adults than among young, perhaps because it requires skill in selecting victims and in pursuing them. Most studies also show that adults are victimized less often than young, and that success rates of piracy attempts directed at adults are lower than for those directed at immatures.

In mixed-species flocks, the larger gulls are the pirates more often, and the victims less often, than are the smaller species. For example, at a garbage dump in New Jersey, USA, Great Black-backed Gulls were seldom victims, while Ring-billed and Laughing Gulls were more often victims than the larger species. Up to 32% of the fish obtained by gulls when following fishing boats can be lost to pirates, but the larger species such as the Great Black-backed lose far less in this way.

Gulls follow boats to obtain food items, both offal that is thrown overboard during processing operations and fish brought to the surface by the churning action of the boat itself. Dense throngs of noisy gulls accompany fishing boats in to port while the fishermen clean their catch and throw the waste overboard. The white plumage of the swirling, diving gulls over the open ocean acts as a signal to other birds, resulting in multi-species foraging aggregations.

Although Herring Gulls often plunge-dive in the surf, where edible matter is exposed by the turbulence, gulls have only a limited ability to dive for fish and to pursue them underwater. To exploit fish below the surface, some species frequently associate with diving seabirds, with marine mammals, or with

Gulls are typically noisy creatures, especially during breeding and feeding activities. Their communication systems are highly developed, and embrace a large number of vocalization types, often accompanied by visual displays, many of which are used in aggressive contexts. One of the most familiar and characteristic calls is the long call, sometimes termed the "laughing call", which is generally given with the neck fully stretched and is used mostly during courtship and breeding. Calls differ among species, but also, less markedly, among individuals within species. The Lava Gull has one of the most distinctive plumages within the gull family.

[*Larus fuliginosus*, Santa Cruz, Galapagos. Photo: Tui De Roy/ Auscape]

predatory fish that drive other fish to the surface. Bonaparte's Gulls will feed with Hooded Mergansers (*Mergus cucullatus*), which "churn up" fish. Kelp Gulls exploit food items exposed by right whales (*Eubalaena glacialis*) off the Argentine coast in winter, and Black-legged Kittiwakes and Herring Gulls in the North Atlantic forage with humpback whales (*Megaptera novaeangliae*) or pilot whales (*Globicephala melaena*). Sea lions (*Zalophus*, *Eumetopias*) off California are often accompanied by flocks of gulls, including Bonaparte's, Heermann's, Glaucous-winged and Western Gulls and Black-legged Kittiwakes; interestingly, Western Gulls that forage in assemblages with sea lions have higher feeding success than those which feed only with other seabirds. Similar associations involving different species of gulls and mammals have been observed from Alaska to Peru.

At coastal or inland localities, some gulls take advantage of food stirred up by the movements of other species. One example is that of Slender-billed Gulls in the French Camargue and elsewhere: the gulls frequently accompany Greater Flamingos (*Phoenicopterus ruber*) and feed on brine-shrimps (*Artemia*) disturbed by the larger birds.

The exploitation of rubbish dumps has played a major role in the dramatic increases of many gull populations during the twentieth century. In less than one hour at a dump, gulls can usually obtain enough food to sustain their daily needs. Rubbish dumps can provide food for juveniles in the critical months immediately after fledging. The previously high mortality during this period has been drastically reduced by the availability of superabundant refuse; thus, many more gulls survive their first year of life, contributing to the population increases experienced by several species that have become pests. Conversely, with the increased practice in the 1980's of covering and even closing over landfills, a number of gull populations have stabilized, and some, such as the Herring Gull in eastern North America, are even declining.

Even at rubbish dumps, immatures are less able to compete for the best foraging sites. Immature Herring Gulls in Britain are often forced to the secondary dumping sites, rather than being able to feed on the primary dumping face. Direct competition with adults influences the extent to which juveniles can feed on the high-quality patches of food. The amount of food varies temporally and spatially at dumps, and the numbers of gulls and the timing of their arrival at dumps vary in relation to the amount of available food. Gulls have learned that most dumps do not operate on Sundays, and they seek alternative food sources every seventh day; but they are confused by public holidays, and wait for hours in vain!

There is disagreement over the proportion of refuse used as a source of food for growing chicks. In some cases, parents appear to feed chicks a large amount of such food, while other species avoid feeding it to their chicks, even though they themselves may eat refuse during the breeding season. Silver Gulls use landfills all year, but less so during the breeding season. Western Gulls feed heavily on refuse in the early part of the season, but switch to small fish when the chicks hatch; the very act of hatching appears to trigger this change for each individual pair.

Diversity in food items, foraging habitats and foraging methods does not increase with the age of the individual gull, nor with the age of maturity for individual species. Young gulls feed on as many different food items, in as many different habitats, and using as many different methods, as do adults. The time given to each habitat and each method, and the success in gaining food, do change, however, as a function of age. Younger birds generally acquire less food per unit of time than do adults.

Age-related differences in foraging success have been found in nearly every species of gull examined, and for nearly every method. Young birds are less efficient and must spend more time searching for and manipulating prey. They make fewer capture attempts, have a lower capture rate, and are more likely to attempt to eat inappropriate prey, including inedible items. Young birds must therefore devote more time to foraging than adults. Differences among age-classes are less marked where food is more readily available, as at refuse tips and when feeding on offal. Proportionately more young feed at the sites where their foraging success rates most closely approach those of adults; immatures can thus partially compensate for their generally lower feeding success by selecting their foraging sites.

Foraging efficiency generally increases with age. This fact has been suggested as a possible cause of delayed maturation in some species of gulls. If sub-optimal foraging efficiency is a cause of delayed breeding, then species that wait the longest before

The foraging methods of gulls are highly diverse, reflecting their omnivorous diet and unmatched opportunism. Many are inveterate scavengers, exploiting almost any habitat, from coastal waters, intertidal shingle and mudflats to inland fields and rubbish dumps, and grabbing any food that happens to be available. Some species conform more to the popular idea of a gull, and forage almost exclusively along the coast or at sea. Audouin's Gull, for instance, forages mainly over the sea, where it often joins other seabirds to exploit shoals of fish swimming near the surface. Its normal hunting method, used frequently, is a specialized form of contact-dipping: it quarters back and forth just offshore, flying very slowly and very close above the water; on sighting a fish just below the surface, it gives a quick downward and sideways turn of its head and bill, snatches the prey from the water, and then continues its flight with hardly a pause. Like many other gulls, it also readily exploits fish offal thrown overboard by fishing boats, and this has recently been found to be a particularly important source of food for this very localized Mediterranean species. If its normal food sources diminish for any reason, it may resort to feeding at non-marine sites such as rice fields and even occasionally rubbish dumps.

[*Larus audouinii*, Ebro Delta, Spain. Photos: Jacob González-Solís]

In their role as predators, gulls take large numbers of chicks and eggs of other birds. In North America, American White Pelicans (Pelecanus erythrorhynchos), *despite their far greater size, are a frequent target of several gull species, which exploit them in a number of ways. Some pelicans, as here, lose their eggs and newly hatched young to California Gulls. There are populations of this large gull that specialize on bird eggs, while others take substantial quantities of grain; in parts of its breeding range the species appears to subsist largely on refuse. The California Gull's diet also includes crabs, rodents and a variety of insects, as well as fruit and carrion; it is best known, however, for consuming vast numbers of crickets and grasshoppers.*

nesting for the first time should exhibit the greatest difference between juveniles and adults in foraging success rate. This is indeed the case: the disparity between age-classes, as shown by success rates and inter-food intervals, is less for species such as the Laughing Gull, which reach sexual maturity at 2-3 years of age, than it is for those such as the Herring Gull, which are sexually mature at 4-5 years of age.

This difference between species could arise because the foraging methods of gulls that do not breed until 4-5 years are more difficult than those of gulls breeding at 2-3 years; or because young of the former have more difficulty learning the foraging methods; or because their food supply is either more ephemeral or more patchily distributed. It may equally be due to a combination of all of these factors. A final possibility is that the young of the smaller gulls maintain closer contact with their parents after the breeding season, permitting easier location of the feeding grounds and a higher potential for imitative learning. These aspects remain to be studied for most species.

The degree to which colonies serve as information centres for food finding by gulls has been widely debated. One suggestion is that unsuccessful foragers would follow successful individuals from the colony. This requires that they watch within the colony for gulls which, on returning, immediately begin to feed chicks, and that they then follow these successful individuals when they leave on another foraging trip. Although this information centre hypothesis is attractive, there are few quantitative data to support it. Common Black-headed Gulls that nest in dense colonies might be expected to have information transfer within the colony, but no evidence has been found.

Laughing Gulls may sometimes follow others from the colony, as probably happened in New Jersey, USA, when a group of 13 neighbours in one area of a 5000-pair colony fed on the eggs of estuarine turtles. Obtaining turtle eggs is a difficult task: the gull has to locate a female turtle that is excavating a nest, wait for her to begin laying, peck at her shell until she departs, and then pull out the exposed eggs. It is highly likely, therefore, that these neighbouring birds had left the colony together and were seeking food in a flock when the turtle was encountered. The Black-billed Gull and some other species will make a contact call when leaving the colony, the purpose in this context apparently being to encourage others to follow, thus allowing foraging groups to form. Presumably, for some species, there are reciprocal advantages to foraging in groups, in terms of food finding and making use of food resources.

Breeding

In all gull species, pair-bonds are overwhelmingly heterosexual and monogamous, with a relatively high degree of mate fidelity from year to year. The mating systems of gulls have received considerable attention because of the relatively recent recognition of female-female pairs or trios in Ring-billed, Herring, Western, Red-billed and California Gulls. Female-female pairs constitute at least 10% of the total in some Western Gull colonies, and 6% of Red-billed Gull pairs. They can be identified initially from the occurrence of supernormal clutches of five or six eggs, sometimes with two distinct colour patterns. Other species for which such clutches have been reported in the literature or located in museum collections, and which might indicate female-female pairing, include Laughing, Common Black-headed, Mew, Glaucous-winged, Glaucous and Great Black-backed Gulls. Clutches of four eggs have been reported for Black-billed and Silver Gulls and for Black-legged Kittiwakes, species that normally lay two-egg clutches.

Female-female pairs apparently result from a shortage of breeding males, which may be a consequence of differential survival rates. In an experimental study of Ring-billed and California Gulls, removal of males resulted in an increase in female-female pairings compared with control colonies. In addition, a DDT-induced feminization of male embryos, associated with inability to breed as adults, may explain the highly skewed sex ratios and reduced number of male gulls in some populations (see Status and Conservation). Mature females faced with a shortage of males may nest with subadult males. Alternatively, some gulls form polygynous trios.

One or both members of a female-female pair may mate and produce fertile eggs, but, although some young are raised, reproductive success rates are generally far lower than in male-female pairs. For example, research indicated that the hatching rate of Ring-billed Gulls nesting in Quebec averaged nearly 70% for heterosexual pairs, whereas it was only 38% in female-female pairs and 33% in trios; in Michigan, it averaged 61-77% for male-female pairs and 30-34% for female-female pairs. The lower hatching success is due to a higher infertility rate of eggs in female-female pairs. Nonetheless, female-female pairing is a strategy whereby surplus females can produce some young themselves.

Some promiscuity occurs among gulls, both sexes copulating with birds other than their mates. For example, male Western Gulls on Santa Barbara Island participate in considerable promiscuous activity with unmated females.

Pairing for life is characteristic of gulls that have been studied, so long as both members return to the colony. Divorce occurs, however, when pairs are unable to work out incubation and brooding activities, or when they are unsuccessful at raising offspring. Individuals that remain together lay earlier, and raise more young, than those that have found new mates. Moreover, the effect of divorce persists for more than one year. Long-term studies indicate that there is strong selection pressure for monogamy in gulls.

Hybridization between gull species is not rare. Western Gulls interbreed with Glaucous-winged Gulls regularly where their ranges overlap in Washington and Oregon. Herring Gulls interbreed with Glaucous, and Thayer's with Iceland. Common Black-headed Gulls interbreed with Brown-headed Gulls in Asia and with Mediterranean Gulls in Europe, and within this group of hooded gulls interbreeding has also been reported for Black-billed x Red-billed and Hartlaub's x Grey-headed.

Gulls nest almost exclusively in colonies. One advantage of this is that it facilitates early warning and anti-predator behaviour. Most gull colonies are noisy, and at the first sign of a predator alarm calls are given; active defence, including communal mobbing and attacks, is generally pronounced. The Andean Gull, however, is an exception: when predators or humans approach, the gulls silently leave their nests and disappear from the vicinity, making it difficult to locate the colony in the vast, barren landscape of the Altiplano. This may be the Andean Gull's only defence in a habitat that has been heavily occupied by people for many centuries. Gulls in general have no nocturnal anti-predator defences, and will desert their nests for hours at a time; repeated nocturnal intrusions, as by owls or foxes, may cause them to desert the colony, even abandoning eggs or chicks.

Most gulls breed in colonies of a few to several hundred pairs, although some, such as Bonaparte's and Herring Gulls, will occasionally breed solitarily, while single pairs of Band-tailed Gulls (*Larus belcheri*) will nest beside other seabirds. Conversely, certain species, such as the Black-legged Kittiwake, form colonies of tens of thousands of pairs, and Franklin's Gulls breed in dense colonies of up to 150,000 pairs in freshwater marshes. The degree of coloniality increases with foraging range and unpredictability of food sources, in accordance with the information centre hypothesis (see Food and Feeding).

Differences in coloniality and nesting density also relate to body size: larger species have an easier time with defending their territory, eggs and young, making it possible to nest in small colonies or solitarily. Spacing of nests may be influenced by the risk of chicks being killed by aggressive conspecifics. Some of the smaller gulls, including Relict and Heermann's, can nest very densely as an anti-predator strategy, since adults seldom attack chicks of neighbouring pairs. Bonaparte's Gull is unique in that it never nests in large or dense colonies, but instead in very small groups of well dispersed pairs: 5-20 pairs may nest in a loose colony that extends over a square kilometre or two, each pair in the top of a spruce tree, in visual contact with colony members only when they are in the air mobbing a predator.

Although some species breed in monospecific colonies, many nest in mixed colonies with other gulls, or with other species such as terns, grebes, gannets, cormorants, herons, ducks, skuas, auks and even penguins. Sometimes the gulls are intermingled with other species, as in most Herring and Lesser Black-backed Gull colonies, or when Laughing Gulls nest with Common Terns (*Sterna hirundo*), but often they form discrete, monospecific clumps within the matrix of other nesting species, as Brown-hooded Gulls do within heron and ibis colonies in reedbeds in Argentina. They may also form discrete subcolonies adjacent to colonies of another species, as with the Black-billed Gull and Kelp Gulls on shingle islands in braided rivers of New Zealand. In some cases, the different species begin nesting at the same time. In others, the gulls act as a magnet, drawing the other species to their colonies. Ducks, grebes and some herons nest preferentially in gull colonies, apparently because they derive anti-predator advantages. Large species such as herons and egrets can defend their young from the gulls, and can enjoy increased reproductive success by nesting in gull colonies. Grebes often nest with those gull species that do not prey on their young, and they, too, have higher breeding success than they do when nesting without gulls.

Of special note is the relationship between gulls and ducks that nest within gull colonies. By nesting close to a gull nest,

Dead fish represent an important food source for many species, including the Pacific Gull. Such food, when it is not immediately obvious to the scavenger's eye, is often found by walking along beaches searching the intertidal area. Pacific Gulls are also among those species which habitually drop hard-shelled items such as gastropods onto hard surfaces in order to break them open and get at the contents. This species has the deepest, heaviest bill of any gull, and a distinctive tail and underwing pattern. Its numbers have decreased in eastern parts of its range, where it suffers from competition with the recently established Kelp Gull (Larus dominicanus).

Marine fish and invertebrates form a considerable part of the diet of many gull species. Very few marine animals are considered unsuitable, whether they be small insects or larger items such as starfish. For species which live all their lives in coastal areas, such as the Western Gull, the tide-line is an important feeding habitat; predation on other seabirds is also common, and these gulls often associate with marine mammals and eat seal placenta.

the duck derives the advantages of early warning of and protection against predators, but at the risk of the gull preying upon the ducklings once they hatch. In some cases the ducks have been found to benefit, but in others their reproductive success in gull colonies approaches zero. This has been labelled an "ecological trap".

All gulls are territorial, the size of territory depending on the size of the species, the number of pairs in the colony, and the structure and availability of nesting habitat. Herring Gulls may exclude neighbours from encroaching within a 5 m radius of the nest, while kittiwakes may defend only a narrow cliff ledge.

The small gulls generally nest in denser colonies than the larger gulls, with nests in some cases as close together as 50 cm. Intermediate-sized gulls, such as the Ring-billed, and larger species, such as Olrog's, may also nest in very dense colonies with small inter-nest distances. The large gulls, however, usually nest in more open colonies, with larger territories. This pattern results partly from the degree of aggression or cannibalism exhibited towards neighbouring chicks by each species. Cannibalism is common among the large gulls and, when territories are not sufficiently large, the wandering young are regularly killed or eaten by neighbours. Territory size, therefore, often increases during the fledging period. With Great Black-backed Gulls, over half of the territories may be increased in size after hatching; in densely occupied nesting sites of this species, where territories can not be enlarged, cannibalism is a significant cause of mortality, and reproductive success is lower than in less dense areas. In some gulls, such as the Slaty-backed, males feed more chicks of their own species to their brood than do females. Cannibalism is far rarer among the smaller gulls, and has not been reported for well studied species such as Franklin's, Laughing and Brown-hooded Gulls.

Most gulls have a twelve-month annual cycle, with a predictable nesting period that usually lasts from three months for the smaller species to five months for the larger ones. The exception is the Swallow-tailed Gull of the Galapagos, which breeds in all months of the year; even within a colony there is asynchrony among pairs, and timing varies from island to island. Individual Swallow-tailed Gulls have a breeding cycle of 9-10 months' duration. With no clear environmental cues to initiate breeding, individual gulls are absent from the colony for up to ten months between the end of one breeding cycle and the start of the next. Even so, there are peaks in this species' breeding activities in May-June and in February.

The age of first breeding varies, from two years for some smaller species to five years of age for some large ones. Even within a species, however, there is some variation. For example,

The Grey-headed Gull is one of several species that hawk flying insects, but it obtains most of its food by scavenging; it also preys on eggs of colonial-nesting birds, and pirates food from cormorants. Like many gulls, it may drink fairly regularly. This species has a curious distribution, with two disjunct populations: one in Africa, where it is locally common along coasts and at larger inland lakes, and another in South America, where its habits are less well known.

in exceptional circumstances Herring Gulls may breed at three years of age, although most breed at four or five, and some delay breeding until they are six years old. Factors that influence age of breeding within a species include availability of mates, of nesting sites and of nesting materials, body condition, weather conditions, and food availability. In newly established colonies, there is often a preponderance of young birds breeding that have not yet attained full adult plumage. Once they reach breeding age, most gulls breed every year.

In a normal breeding season, the sequence of events is as follows: arrival in the colony vicinity a few weeks before occupation; colony occupation for a few weeks, before the start of nest building and egg-laying; territorial defence and courtship; a copulation period of a few days to two weeks; an egg-laying period of 1-3 weeks; an incubation period of 24-30 days, resulting in incubation activities in the colony over about 6-8 weeks; and a pre-fledging phase of 4-6 weeks. These time periods are slightly shorter for the small gulls, and slightly longer for the large gulls.

Environmental constraints such as low food supply or poor weather impose synchrony on the breeding cycle. For example, species that breed at high latitudes spend less time on the breeding grounds prior to egg-laying, and the laying period may be highly synchronized. Franklin's Gulls usually arrive on their prairie marshes when snow is still on the ground and the marshes frozen; they do not occupy the colony until conditions moderate, and this can result in highly synchronous nesting. Unusually bad conditions can result in no breeding in a given year: for example, in 1986, Black-legged Kittiwakes occupied their colony on Bylot Island, off the north coast of Baffin Island, north-east Canada, but did not breed because of the slow snow-melt, harsh weather, and poor food supply. Even for species nesting in temperate climates, low food supply or excessive storms can delay the onset of colony occupation or egg-laying, resulting in synchrony of egg-laying in that year.

Breeding synchrony is often imposed on a population by environmental factors and migration constraints, but it can also be caused by social factors. In 1938, F. Fraser Darling suggested, on the basis of his studies of Herring and Lesser Black-backed Gulls, that the social facilitation that results from the displays of colony members leads to increased synchrony within colonies. Larger colonies, with more birds, and more frequent and intense displays, have greater synchrony. That is, a higher proportion of the birds initiate egg-laying in a shorter period of time, and the egg-laying period is generally shorter than in less synchronous aggregations. He proposed that this was one advantage of colonial nesting. Higher breeding synchrony leads

Kleptoparasitism is commonly used by a number of gull species as a method of obtaining food. In America, the Brown Pelican (Pelecanus occidentalis) *appears to be a particularly favoured target for such attacks. As the pelican surfaces from a dive, the gull alights on its back, or on the water nearby, and waits its chance to snatch any food items which escape as the pelican releases water from its massive bill and pouch. The Laughing Gull in the Caribbean and Heermann's Gull* (Larus heermanni) *on the Pacific coast are two species which have come to specialize in this form of food piracy.*
